La connaissance des diverses vibrations actives en Raman (tableau 1) et du domaine d'absorption des vibrations actives en infrarouge[5] permet de proposer une attribution quasi directe du spectre Raman de PbP_2O_7 (ainsi, ν_{as} PO_3 est la fréquence la plus élevée observée dans le spectre infrarouge, tandis que ν'_{as} PO_3 est la plus élevée du spectre Raman ; de même, la fréquence d'absorption de la vibration ν'_s PO_3 dans le spectre infrarouge sera assez proche de celle de ν_s PO_3 dans le spectre Raman). Le résultat de ces attributions est repris dans le tableau 2.

Ces attributions attirent cependant deux remarques très importantes :

1) La vibration ν_{as} du pont central $P-O-P$ active en infrarouge devrait normalement être inactive en Raman : cependant, cette vibration, de faible intensité dans le spectre infrarouge, apparaît dans le spectre Raman avec une intensité encore beaucoup plus faible : nous reviendrons sur ce point.

2) Il est tentant d'attribuer la raie de faible intensité observée à 522 cm^{-1} dans le spectre Raman à la vibration δ'_{as} PO_3 (puisque la vibration δ_{as} PO_3 se marque à 536 cm^{-1} dans le spectre infrarouge) ; cependant, une autre attribution peut être proposée : à partir de la fréquence de la vibration ν_{as} $P-O-P$ (à 732 cm^{-1} dans le spectre infrarouge), on peut

ν_{as} P—O—P	732f	736ff
δ_{as} PO_3	536m	
δ'_{as} PO_3		522f[a]
δ'_s PO_3	376f	
δ_s PO_3		336ff
ν_{as} PbO_6	224m	
ν_s PbO_6		192f
		95ff[b]

a) Plus vraisemblablement, cette fréquence sera attribuée à ν_s P—O—P (tableau 4).

b) Intensités : FF très forte, m moyenne, f faible, ff très faible.

estimer la fréquence de la vibration ν_s P—O—P entre 500 et 525 cm^{-1} en utilisant les formules simplifiées suivantes [9] :

$$\nu_{sym} \simeq \frac{1}{2\pi C}\sqrt{k\left(\frac{1}{m_P} + \frac{1 + \cos\alpha}{m_0}\right)}$$

$$\nu_{asym} \simeq \frac{1}{2\pi C}\sqrt{k\left(\frac{1}{m_P} + \frac{1 - \cos\alpha}{m_0}\right)}$$

avec α désignant l'angle $\widehat{P-O-P}$ (180° dans ce cas) et $k = 6{,}4 . 10^5$ dyn/cm.[8]

Dès lors, il apparaît plus logique d'attribuer la raie 522 cm^{-1} à la vibration ν_s P—O—P ; nous reviendrons également sur cette question.

INTERPRÉTATION DES SPECTRES INFRAROUGE ET RAMAN DE PbP_2O_7

(en considérant le groupe P_2O_7 comme une entité au point de vue vibrationnel)

Renoncer à l'approximation de Bues et Gehrke devrait, en principe, permettre une attribution plus rigoureuse des vibrations observées dans les spectres : dans le tableau 3, les fréquences observées dans le spectre infrarouge sont comparées aux fréquences calculées par Mooney et coll. : en découlent des attributions qui sont comparées aux attributions proposées dans le cadre de l'approximation de Bues et Gehrke. Cette comparaison entre fréquences calculées et observées provoque certaines ambiguïtés :

$\nu_{13}\ (E_u)$	δ (OPO*)	384 ↗		
$\nu_{14}\ (E_u)$	τ (OPPO)	19		

a) Voir à ce sujet la discussion dans le texte.

— Alors que la liaison centrale P—O * (nous désignerons par O* l'oxygène central du groupe P_2O_7 : $O_3P-O^*-PO_3$) est fortement affaiblie par rapport aux liaisons latérales P—O, il apparaît assez étonnant que le calcul de Mooney et coll. conduise à une valeur plus élevée ($1260\ cm^{-1}$) pour $\nu_6(A_{2u})$ [νPO*] que pour $\nu_5\ (A_{2u})$ ($1012\ cm^{-1}$) et $\nu_{11}\ (E_u)$ (à $1138\ cm^{-1}$), alors que ces dernières sont des vibrations [νPO]. En fait, nous avions attribué une fréquence beaucoup plus basse à $\nu_6(A_{2u})$: $732\ cm^{-1}$, ce qui paraît plus logique.

— Deux vibrations $\delta(O-P-O^*)$: $\nu_7(A_{2u})$ à $510\ cm^{-1}$ et $\nu_{13}\ (E_u)$ à $384\ cm^{-1}$ sont calculées, alors qu'une seule est observée dans le spectre infrarouge à $376\ cm^{-1}$: on est tenté de l'attribuer à $\nu_{13}\ (E_u)$, calculée à une fréquence très proche et constater ainsi l'absence de $\nu_7\ (A_{2u})$ dans le spectre. Cependant, il n'en demeure pas moins une incertitude renforcée par les arguments suivants :

— à plusieurs reprises, des divergences importantes apparaissent entre fréquences calculées et observées.

Tableau 4

a) Vibration normalement inactive Raman.

— Dans le cadre de l'approximation de Bues et Gehrke, une seule vibration de ce type apparaît parmi les vibrations actives en infrarouge : δ'_s PO_3 (A_{2u}).

Dans le cas des autres vibrations, on peut observer une meilleure concordance entre fréquences calculées et observées ; il subsiste cependant des écarts de 20 à 40 cm^{-1}, ce qui est peu étant données les approximations réalisées lors du calcul des fréquences. Une autre cause d'écarts, réside dans le fait que les fréquences ont été calculées pour un groupe P_2O_7 « isolé », sans tenir compte des influences de la nature du cation sur les différentes vibrations ; nous avons pu montrer [5] que ces influences étaient particulièrement importantes.

Le tableau 4 reprend les fréquences observées dans le spectre Raman, comparées aux valeurs calculées et mises en parallèle avec les attributions réalisées en utilisant l'approximation de Bues et Gehrke. Sauf dans le cas de deux fréquences que nous discuterons ci-dessous, les fréquences calculées correspondent assez bien aux fréquences observées, avec parfois des écarts de 30 à 80 cm^{-1}, comme dans le cas du spectre infrarouge. Nous ferons cependant les remarques suivantes à propos des raies observées à 522 et 736 cm^{-1} :

— La bande observée à 732 cm^{-1} dans le spectre infrarouge a été attribuée à la vibration antisymétrique ν_6 (A_{2u}) [ν_{as} P—O—P] ; la fréquence calculée pour la vibration symétrique correspondante, ν_2(A_{1g})[ν_s P—O—P], est beaucoup trop élevée (nous l'estimions entre 500 et 525 cm^{-1}, voir plus haut). Dès lors, dans ce cas, on a observé un décalage trop important entre fréquence calculée et fréquence observée.

— Le problème de l'apparition dans le spectre Raman de la vibration ν_6 (A_{2u}) [ν_{as} P—O—P] provoque également une difficulté d'interprétation. Cependant, que l'on utilise ou non l'approximation de Bues et Gehrke, on ne peut expliquer la présence de cette vibration dans le spectre Raman sans envisager une déformation du groupe P_2O_7 : cette observation montre en effet qu'il y a rupture des règles de sélection valables pour les « molécules » centrosymétriques et indique que l'angle P—O—P s'écarte légèrement de 180°, supprimant ainsi le centre de symétrie caractéristique de la configuration D_{3d}.

Les calculs de Mooney et coll. amènent ces auteurs à attribuer la bande 747 cm^{-1} du spectre infrarouge de ZrP_2O_7 à la vibration ν_2 (A_{1g}) normalement active en Raman et inactive en infrarouge : considérant la faible intensité de cette bande dans le spectre infrarouge (dont elle devrait être absente d'après leurs calculs) et son absence dans le spectre Raman (où ils l'attendaient), ils envisagent que la déformation est si faible qu'il serait encore possible de considérer une symétrie D_{3d} pour le groupe P_2O_7 de ce composé !

CONCLUSIONS

Les calculs de Mooney et coll., s'ils confirment dans les grandes lignes les attributions proposées dans le cadre de l'approximation de Bues et

Gehrke, n'apportent pas de solution plus satisfaisante aux difficultés rencontrées lors de l'utilisation de cette approximation (par exemple, la présence de ν_{as} P—O—P dans le spectre Raman) ; en outre, certaines ambiguïtés sont apportées aux attributions (par exemple, dans le cas de la bande observée à 376 cm^{-1} dans le spectre infrarouge).

Ces éléments, ajoutés au fait qu'il n'est possible d'utiliser que des fréquences calculées de manière très approximative, ne correspondant que d'assez loin aux fréquences observées, montrent qu'il est justifié de continuer à utiliser l'approximation de Bues et Gehrke qui présente l'avantage de caractériser beaucoup plus concrètement les différentes vibrations et permet un dépouillement plus aisé des spectres vibrationnels des composés de ce type.

THE GALVANOSTATIC STUDY OF THE ELECTROCHEMICAL ADSORPTION PROCESS ON THE CHLORINE-ACTIVE CARBON ELECTRODE IN MOLTEN SALTS. III[1]

ANODIC POLARIZATION (CHARGING) EQUATION

S. STERNBERG, S. PETRESCU and VALERIA PETRESCU

Polytechnic Institute, Str. Polizu 1, Bucharest, Romania

Received July 4, 1973

An equation is given which correlates the active carbon potential φ with the anodic polarization time, *t*, of a process of anodic polarization in a molten salt system. The obtained equation was verified and found to agree with the experimental data for the AgCl – KCl system within a temperature range of 400° – 600°.

In this paper we intend to find an equation which correlates the active carbon potential φ with the anodic polarization time *t*, of an anodic polarization process, in a molten salt system. We have started with the following equation (fig. 1):

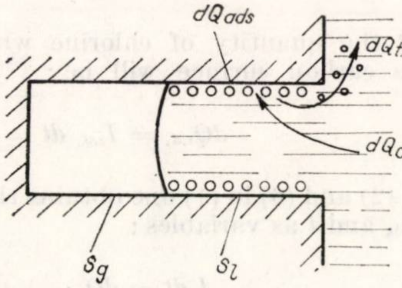

Fig. 1. — Model of the charging (anodic polarization) process.

$$dQ_c = dQ_{\text{ads}} + dQ_{t.d.} \tag{1}$$

in which:

dQ_c – quantity of chlorine deposited on the active carbon surface during the elementary charging time *dt*, with the current intensity I_c

$$dQ_c = I_c \, dt \tag{2}$$

---

[1] Part II: S. Petrescu, S. Sternberg and V. Petrescu, *Rev. Roumaine Chim.*, **18**, 1715 (1973).

dQ_{ads} – quantity of chlorine adsorbed on the active carbon electrode which remained on it in dt

$dQ_{t.d.}$ – quantity of chlorine which is "lost" from the active carbon electrode by thermal desorption, in dt.

1. THE HYPOTHESIS OF QUASIEQUILIBRIUM CHARGING (SMALL I_c)

The hypothesis is advanced that the thermal desorption "losses" in time unit (the thermal desorption current $I_{t.d.}$) increase with increasing surface concentration of chlorine adsorbed on electrode, c_s :

$$I_{t.d.} = K\, c_s \tag{3}$$

If the anodic polarization (charging) process takes place sufficiently slowly (low I_c), the surface concentration c_s can be expressed in terms of the amount of adsorbed chlorine, Q_{ads} (at the instant t) and the active surface, S, of the carbon electrode ; assuming the system is in equilibrium (uniform distribution of chlorine on active carbon surface outside as well as inside the carbon electrode) one obtains :

$$c_s = Q_{\mathrm{ads}}/S \tag{4}$$

Consequently :

$$I_{t.d.} = K\, Q_{\mathrm{ads}}/S \tag{5}$$

During dt the quantity of chlorine which is thermally desorbed from the active carbon surface will be :

$$dQ_{t.d.} = I_{t.d.}\, dt = (K/S)\, Q_{\mathrm{ads}}\, dt \tag{6}$$

Replacing (2) and (6) in (1) one obtains the following differential equation, having Q_{ads} and t as variables :

$$I_c dt = dQ_{\mathrm{ads}} + (K/S)\, Q_{\mathrm{ads}}\, dt \tag{7}$$

Separating the variables it results :

$$dt = dQ_{\mathrm{ads}}/(I_c - K\, Q_{\mathrm{ads}}/S) \tag{8}$$

By integrating this equation, it is obtained :

$$t = -\,(S/K) \ln{(I_c - KQ_{\mathrm{ads}}/S)} + \mathrm{const} \tag{9}$$

To determine the integration constant we impose the following condition :

$$t = 0 \rightarrow Q_{\mathrm{ads}} = 0 \tag{10}$$

Thus, with this condition, it results from (9):

$$\text{const} = (S/K)\ln I_c \tag{11}$$

Replacing (11) in (9):

$$t = (S/K)\ln I_c/(I_c - KQ_{\text{ads}}/S) \tag{12}$$

or in an exponential form:

$$I_c/(I_c - K\,Q_{\text{ads}}/S) = \text{Exp}\,(K\,t/S) \tag{13}$$

It results for Q_{ads} the following equation:

$$Q_{\text{ads}} = (I_c S/K)\,(1 - e^{-Kt/S}) \tag{14}$$

This equation perfectly satisfies from the qualitative point of view. Thus it was expected to obtain Q_{ads} proportional to the active carbon surface S and to the charging current I_c. Also, one can observe that as t increases, Q_{ads} increases, reaching a plateau as t tends to infinity (fig. 2). At the plateau the thermal discharge "losses" become equal to charging current $I_c = I_{t.d.}$. In this case Q_{ads} becomes limiting Q_{ads}:

$$Q_{\text{ads. limit}} = I_c\,S/K \tag{15}$$

From this relation we can find constant K:

$$K = I_c\,S/Q_{\text{ads. limit}} \tag{16}$$

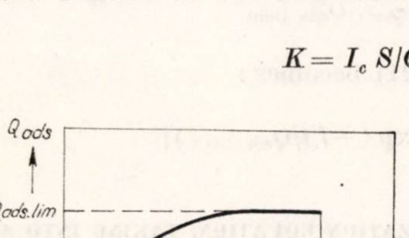

Fig. 2. — Qualitative variation of Q_{ads} against the time.

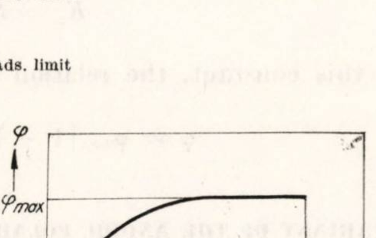

Fig. 3. — Qualitative variation of φ against the time.

Replacing (16) in (14) it results:

$$Q_{\text{ads}} = Q_{\text{ads. limit}}\,[1 - \text{Exp}\,(-I_c\,t/Q_{\text{ads. limit}})] \tag{17}$$

We can also calculate the thermal desorption current $I_{t.d.}$, replacing (14) in (5):

$$I_{t.d.} = I_c[1 - \mathrm{Exp}\,(-I_ct/Q_{\mathrm{ads.\,limit}})] \tag{18}$$

This relation, like (14) and (17), suits perfectly from the qualitative point of view, namely we observe that the thermal desorption current increases asymptotically from zero (for $t = 0$) up to a maximum value equal to I_c (fig. 3).

Admitting the hypothesis that the potential φ is proportional to the adsorbed chlorine concentration on the active surface, we can write:

$$\varphi = K_\varphi c_s \tag{19}$$

But, in agreement with (4),

$$\varphi = K_\varphi Q_{\mathrm{ads}}/S \tag{20}$$

Replacing Q_{ads} from (17) in (20) it results:

$$\varphi = (K_\varphi Q_{\mathrm{ads.\,limit}}/S)\,[1 - \mathrm{Exp}(-I_ct/Q_{\mathrm{ads.\,limit}})] \tag{21}$$

The constant K_φ can be obtained by placing the time to the infinity $t \to \infty$; then $\varphi \to \varphi_{\max}$ (corresponding to a given charging current I_c).

From (22) it results:

$$\varphi_{\max} = K_\varphi\, Q_{\mathrm{ads.\,limit}}/S \tag{22}$$

From this:

$$K_\varphi = S\ \varphi_{\max}/Q_{\mathrm{ads.\,limit}} \tag{23}$$

With this constant, the relation (21) becomes:

$$\varphi = \varphi_{\max}[1 - \mathrm{Exp}\,(-I_ct/Q_{\mathrm{ads.\,limit}})] \tag{24}$$

2. A VARIANT OF THE ANODIC POLARIZATION EQUATION, TAKING INTO ACCOUNT THE VARIATION OF THE ACTIVE SURFACE DURING THE CHARGING PROCESS

We admit, also in this case, as the starting point, the equation (1):

$$I_cdt = dQ_{\mathrm{ads}} + dQ_{t.d.} \tag{25}$$

Since, during the anodic polarization, the active surface of the carbon increases, at a given instant there coexist different zones of the electrode surface having different concentrations. Those zones which have worked from the beginning of the process as active surfaces will have a maximum concentration; and those zones which started to work as active surfaces later, will have a smaller concentration.

We admit that the active carbon electrode potential φ is proportional to the chlorine concentration on those zones which are the most active (that is, those zones which are active from the beginning of the anodic polarization process). On these zones the concentration will be maximum at the instant t, comparatively with the other zones. We will denote this instant maximum concentration $c_{\max,t}$. In this case, we can write :

$$\varphi = K\, c_{\max,t} \tag{26}$$

The "losses" by thermal desorption can be expressed aggregately in a manner similar to the equation (6) :

$$dQ_{t.d.} = I_{t.d.}\, dt \tag{27}$$

but in this case (in the presence of the concentration gradient on the active surface of the carbon electrode) we admit that $I_{t.d.}$ is proportional to the maximum concentration at the considered instant t:

$$I_{t.d.} = K_1 c_{\max,t} \tag{28}$$

Taking into account the relation (26), $I_{t.d.}$ becomes :

$$I_{t.d.} = K_1 \varphi / K \tag{29}$$

Q_{ads} can be expressed by means of the average concentration at the instant t, $c_{\text{med},t}$, on the total adsorption surface of the active carbon $S_{\max}$:

$$Q_{\text{ads}} = c_{\text{med},t}\; S_{\max} \tag{30}$$

or :

$$Q_{\text{ads}} = c_{\max,t}\, S_{\max}\;\; c_{\text{med},t}/c_{\max,t} = S_{\max}(\varphi/K)c_{\text{med},t}/c_{\max,t} \tag{31}$$

From this relation :

$$dQ_{\text{ads}} = (c_{\text{med},t}/c_{\max,t})\,(S_{\max}/K)d\varphi = (1/\alpha)\,(S_{\max}/K)d\varphi \tag{32}$$

where we have denoted (see fig. 4)

$$\alpha = c_{\max,t}/c_{\text{med},t} \geqslant 1 \tag{33}$$

With (27) and (32) in (25):

$$I_c dt = (1/\alpha)\,(S_{\max}/K)d\varphi + (K_1\varphi/K)dt \tag{34}$$

By separating variables :

$$\alpha dt = (S_{\max} d\varphi/K)\;/\;(I_c - K_1\varphi/K) \tag{35}$$

Integrating, we obtain:

$$\alpha t = -(S_{\max}/K_1)\ln(I_c - K_1\varphi/K) + \text{const} \tag{36}$$

The integration constant can be found by imposing the following condition: at the moment $t = 0$, the potential φ must be equal to the remanent potential ($\varphi = \varphi_{\text{rem}}$). It results for the constant the expression:

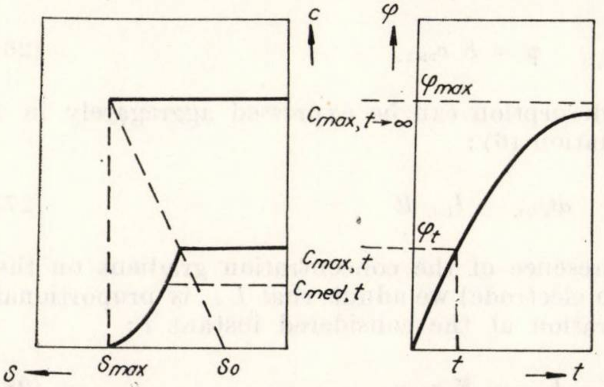

Fig. 4. – Chlorine concentration distribution against the active surface S at different instants during the charging process.

$$\text{const} = (S_{\max}/K_1)\ln(I_c - K_1\varphi_{\text{rem}}/K) \tag{37}$$

With (37) in (36) we obtain:

$$\varphi = (K/K_1)\,I_c[1 - \text{Exp}\,(-K_1\alpha t/S_{\max})] + \\ + \varphi_{\text{rem}}\,\text{Exp}\,(-K_1\alpha t/S_{\max}) \tag{38}$$

for $t \to \infty$, $\varphi \to \varphi_{\max}$

$$\varphi_{\max} = K\,I_c/K_1 \tag{39}$$

Consequently:

$$K_1 = K\,I_c/\varphi_{\max} \tag{40}$$

In order to find K we can use the equation (26) in that point where φ becomes maximum and Q_{ads} becomes $Q_{\text{ads. limit}}$:

$$\varphi_{\max} = K\,Q_{\text{ads. limit}}/S_{\max} \tag{41}$$

Therefore:

$$K = \varphi_{\max}\,S_{\max}/Q_{\text{ads. limit}} \tag{42}$$

With (42) in (40):

$$K_1 = S_{\max}I_c/Q_{\text{ads. limit}} \tag{43}$$

With (39) and (43) in (38) it results:

$$\varphi = \varphi_{\max}\,[1 - \text{Exp}\,(-\alpha I_c\,t/Q_{\text{ads. limit}})] + \\ + \varphi_{\text{rem}}\,\text{Exp}\,(-\alpha I_c\,t/Q_{\text{ads. limit}}) \tag{44}$$

We have tried to check up in what measure the equation of anodic polarization curve (44) is in agreement with experimental data at the following temperatures: 400°, 500°, 600°, in the system $AgCl + KCl$ for different values of charging current I_c : 0.02 A, 0.05 A, 0.1 A, 0.15 A, 0.2 A. For all the anodic polarization curves obtained experimentally, the remanent potential has been done zero by a cathodic polarization (previous to the anodic polarization) with a small current intensity [2] (I_d — discharging intensity $= 0.01$ A). Consequently, for $\varphi_{\text{rem}} = 0$, the equation (44) becomes:

$$\varphi = \varphi_{\max} \left[1 - \operatorname{Exp}\left(-\alpha I_c t / Q_{\text{ads. limit}}\right)\right] \tag{45}$$

In this equation we will denote:

$$\beta = \alpha I_c / Q_{\text{ads. limit}} \tag{46}$$

with which (45) becomes:

$$\varphi = \varphi_{\max} \left[1 - \operatorname{Exp}\left(-\beta t\right)\right] \tag{47}$$

If $\varphi_{\max}$ and one couple of the values φ_1, t_1 are known from the experimental data, it results from the equation (47) the value of K:

$$\beta = (1/t_1) \ln \left[\varphi_{\max} / (\varphi_{\max} - \varphi_1)\right] \tag{48}$$

With this value, using now equation (47), we can compute the values of φ, for any instant t. Because we have found that the β values for different values of the couple φ, t have a certain variation (generally a small decrease with the increase of time t), in the data processing we have computed several values of β corresponding to several pairs φ, t. Then, with these values of β we have found the average value of β, presented in table 1, for the temperatures, 400°, 500°, 600° and for different current

We observe that for charging times greater than 10—20 minutes, the deviations become equal to some per cents. The greater deviations which appear at the small charging times can be explained by the fact that α — defined by the relation (33) — is greater than α_{medium} (corresponding to β_{medium}) at the small times. This fact is in agreement with the hypotheses admitted when we have defined the coefficient α (33). A better proof of these hypotheses consists in estimating the magnitude order of the coefficient α. In order to do that we can use the relation (46):

$$\alpha = \beta Q_{\mathrm{ads.\,limit}} / I_c \qquad (49)$$

We observe that $Q_{\mathrm{ads.\,lim}}$ can be estimated approximately (neglecting the thermal desorption losses during the cathodic polarization process) by using the following formula:

$$Q_{\mathrm{ads.\,limit}} \cong I_d(t_d + \Delta t_{\mathrm{rem}}) \qquad (50)$$

Table 5

Values of the coefficient α as a function of temperature

T [°C]	I_c[A]	t_c[min]	$\varphi_{\max}$ [mv]	I_d[A]	t_d[min]	Δt_{rem}	β	α
400	0.1	80	890	0.1	29	8.2	0.07081	2.64
500	0.1	100	875	0.1	35	5	0.04639	1.85
600	0.1	175	810	0.1	50	1.6	0.02331	1.20

With the values presented in table 5, for three charge — discharge processes (anodic and cathodic polarization) at 400°, 500° and 600°, with $I_c = I_d = 0.1$ A we obtain for α the values corresponding to α_{approx} (in the approximation specified in relation (50)):

$$\alpha_{\mathrm{approx}} = \beta I_d(t_d + \Delta t_{\mathrm{rem}})/I_c \qquad (51)$$

First of all we observe that α_{approx} is greater than the unit, as it was expected in agreement with the hypotheses we admitted (33), and is closer to the unit when the temperature increases. This behaviour is explained by the fact that the molten salts wet better and better the carbon surface during the increase of the temperature, so that greater surfaces become efficient for the adsorption process right from the beginning of the anodic polarization peocess. That is, S_0 is closer to $S_{\max}$ with the increase of the temperature (see fig. 4).

We remark that the α_{approx} values from table 5 are a little smaller than the effective values of α, because of the fact that $Q_{\mathrm{ads.\,lim}}$ was estimated approximately (50). If we knew the efficiency of the cathodic polarization:

$$\eta_d = Q_d / Q_{\mathrm{ads.\,limit}} \qquad (52)$$

we could calculate the α value corresponding to its definition (33) with the relation:

$$\alpha = \beta\,(t_d + \Delta t_{\mathrm{rem}})\, I_d / \eta_d I_c \qquad (53)$$

The development of this possibility and the attempt to improve the anodic polarization curve taking into account the dependence of α on time will be presented in a subsequent paper.

L'ÉTUDE GALVANOSTATIQUE DU PROCESSUS DE L'ADSORPTION ÉLECTROCHIMIQUE SUR L'ÉLECTRODE D'IODE-CHARBON ACTIF DANS LES SELS FONDUS. II[1]

INFLUENCE DE LA TEMPÉRATURE

S. STERNBERG et I. GALASIU

Centre de chimie Physique, 31, str. Galaţi, Bucarest

Reçu le 5 juillet 1973

On a déterminé les courbes potentiel — temps pendant la polarisation anodique et cathodique galvanostatique de l'électrode d'iode-charbon actif dans les sels fondus aux températures de 300°, 400°, 500°, 600° et 700°. A basses températures, sur les courbes de polarisation cathodique galvanostatique existent des paliers caractéristiques qu'on peut attribuer à une condensation capillaire de l'iode dans les pores du charbon actif et qui diminuent quand la température augmente. A basses températures et aux potentiels éloignés du potentiel réversible le rendement du dépôt de l'iode sur l'électrode est de 100 % et il diminue quand la température augmente ou à mesure que le potentiel s'approche du potentiel réversible.

Dans un travail antérieur [1] on a déterminé les courbes de polarisation anodique et cathodique de l'électrode d'iode-charbon actif dans les sels fondus dans des conditions galvanostatiques à la température de 300° en fonction de l'intensité de courant. Le présent travail continue cette étude pour l'intervalle de températures de 300° à 700°.

PARTIE EXPÉRIMENTALE

Pour le dépôt de l'iode sur l'électrode de charbon actif on a fait l'électrolyse d'un mélange eutectique $AgI + KI$. L'anode est une barre de charbon actif à surface spécifique de 10 à 20 m^2/g et dont le poids est de 2,23 g (ayant les dimensions 12 × 12,5 × 17 mm), la cathode une barre en argent de 3 mm de diamètre. Le potentiel de la cellule a été mesuré à l'aide d'un oscilographe cathodique à trace rémanente. Pour la polarisation anodique, ainsi que pour la polarisation cathodique de l'électrode de charbon on a utilisé une méthode galvanostatique.

---

[1] Ire partie : S. Sternberg et I. Galasiu, *Rev. Roumaine Chim.*, 19, 523 (1974).

L'électrode de charbon dépourvue totalement d'iode a été soumise à une polarisation anodique galvanostatique jusqu'au potentiel désiré tout en enregistrant entre temps la courbe de polarisation anodique galvanostatique. Puis, on a commuté la cellule sur un circuit de polarisation cathodique galvanostatique jusqu'à l'éloignement total de l'iode de l'électrode, enregistrant aussi la courbe de polarisation cathodique galvanostatique.

Les quantités d'iode déposées sur l'électrode par l'électrolyse ou désorbées de l'électrode ont été calculées des relations :

$$Q = i.t \text{ et } a = \frac{Q}{F}$$

où :

Q = quantité de courant exprimée en coulombs ;
F = constante de Faraday ;
i = intensité du courant ;
t = temps de la polarisation ;
a = atomes — grammes d'iode.

Durant les expériences on a barboté dans l'électrolyte un puissant courant d'argon de sorte que l'iode gazeux soit éliminé continuellement de la cellule d'électrolyse.

Le schéma de l'installation et la manière de préparer les électrodes de charbon actif ont été donnés dans nos travaux antérieurs [2–5].

La surface apparente de l'électrode est de 11,33 cm^2. La surface réelle de l'électrode de charbon actif est beaucoup plus grande, mais inconnue à cause du fait qu'on ne connaît pas exactement la surface de contact entre l'électrode et l'électrolyte et par conséquent on ne peut pas accorder une valeur sûre aux densités de courant employées.

RÉSULTATS ET DISCUSSIONS

Dans la figure 1 on donne les courbes de polarisation anodique obtenues au dépôt de l'iode sur une électrode de charbon actif à la température de 700°. La polarisation anodique a été faite avec des courants de 20 mA, 50 mA, 100 mA et 200 mA. Comme potentiel de référence (zéro) nous avons choisi le potentiel réversible de l'électrode d'iode dans le même mélange et à la même température, calculé d'après l'équation [6] :

$$E = 0{,}5885 - 0{,}225 . 10^{-3} \, (T - 873) \tag{1}$$

Ainsi que nous l'avons déjà montré dans un travail antérieur[1] pour la température de 300° l'allure générale des courbes potentiel (φ) — temps est la suivante. A une intensité de courant donnée, le potentiel de l'électrode augmente en temps, après quoi il arrive à une valeur stationnaire, inférieure à celle du potentiel réversible. A basses températures la valeur du

[2] S. Sternberg et I. Galasiu, *Rev. Roumaine Chim.*, **13**, 991 (1968).
[3] S. Sternberg et I. Galasiu, *Rev. Roumaine Chim.*, **15**, 1169 (1970).

[6] S. Sternberg, J. Adorian et I. Galasiu, *Electrochim. Acta*, **11**, 385 (1966).

potentiel stationnaire est rapprochée de la valeur du potentiel réversible mais quand la température augmente, la différence entre ces deux valeurs augmente elle aussi pour toutes les intensités de courant employées.

Après l'achèvement de la polarisation anodique galvanostatique, on a toujours fait une polarisation cathodique à une intensité de courant égale à celle utilisée dans la polarisation anodique pour mesurer la quantité d'iode absorbée sur l'électrode. La polarisation anodique a été aussi faite « par portions »[1].

Dans les figures 2—6 on a représenté les courbes de polarisation anodique « par portions » pour $i = 100$ mA à diverses températures. Chaque polarisation anodique a été suivie d'une polarisation cathodique ayant la même intensité de courant. Après la première polarisation cathodique on a repris la polarisation anodique jusqu'à $t_2 > t_1$, etc. On a constaté que la courbe de polarisation anodique « par portions » se superpose très bien à celle obtenue dans un seul temps (voir fig. 2—6).

Le rendement de charge-décharge (fig. 7—8) a été calculé d'après la relation :

$$\eta = \frac{Q_{(\text{polarisation cathodique})}}{Q_{(\text{polarisation anodique})}} \, 100$$

où :

$Q_{(\text{polarisation cathodique})}$ est la quantité d'électricité utilisée à la polarisation cathodique ;

$Q_{(\text{polarisation anodique})}$ est la quantité d'électricité employée à la polarisation anodique.

Ainsi que nous l'avons déjà montré dans un travail antérieur,[1] sur la première portion de la courbe de polarisation anodique (fig. 1), tout le courant est employé pour « charger » l'électrode avec de l'iode adsorbé. Le courant employé pour charger de l'iode sur l'électrode a été dénommé courant d'adsorption, $i_{(\text{adsorption})}$. C'est ensuite que le rendement du dépôt de l'iode sur l'électrode a commencé à diminuer à cause de la « désorption thermique », ce qui fait que l'augmentation du potentiel en temps devienne plus lente. On a dénommé ce courant qui correspond à la désorption thermique, courant de désorption, $i_{(\text{desorption})}$. Sur la dernière partie de la courbe de polarisation anodique, où le potentiel reste constant, le courant de désorption devient égal au courant total de polarisation et $i_{(\text{adsorption})} = 0$.

Pour chaque température on, a continué la polarisation anodique jusqu'à ce que $Q_{(\text{polarisation cathodique})}$ reste constant[1] (c'est-à-dire jusqu'à ce que $i_{(\text{adsorption})} = 0$). A une polarisation anodique plus prolongée, la courbe de polarisation cathodique se superpose à la précédente.

A cause des hautes températures auxquelles on effectue l'électrolyse des sels fondus, le courant de désorption arrive à de grandes valeurs, à de centaines de milliampères. Ce courant de désorption est en réalité égal à la vitesse de désorption de l'halogène de l'électrode de charbon.

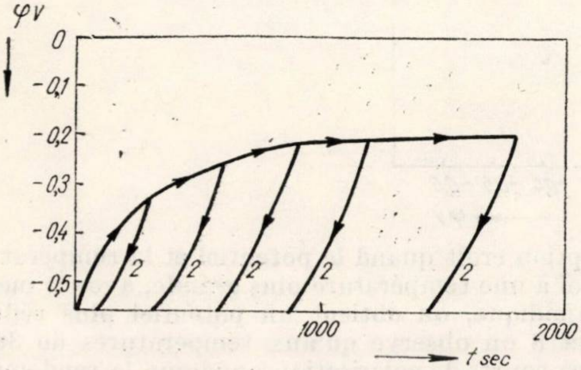

Fig. 6. — Courbes de polarisation anodique (*1*) et cathodique (*2*) cú $i=100$ mA ; $t = 700°$.

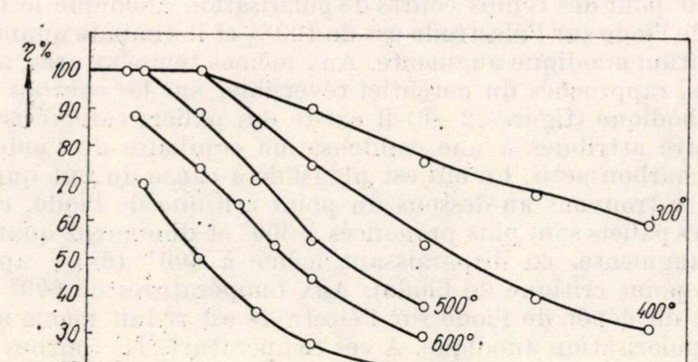

Fig. 7. — Le rendement $\eta = \frac{Q_{\text{décharge}}}{Q_{\text{charge}}}$ en fonction de la quantité d'électricité employée à la polraisation anodique à diverses températures : $i_{\text{charge}} = i_{\text{décharge}} = 100$ mA.

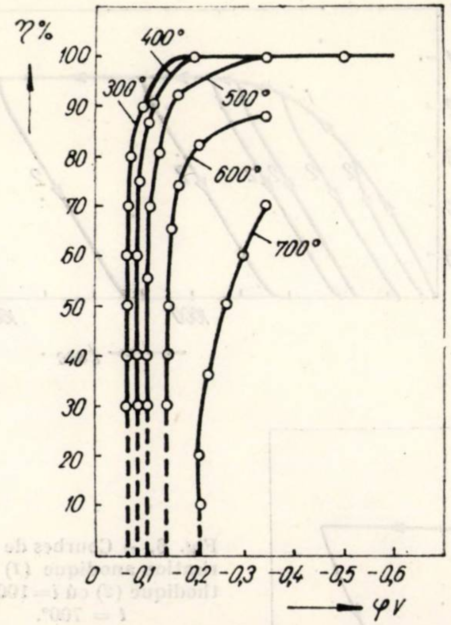

Fig. 8. – Le rendement $\eta = \frac{Q_{\text{décharge}}}{Q_{\text{charge}}}$ en fonction du potentiel à diverses températures : $i_{\text{charge}} = i_{\text{décharge}} = 100$ mA.

Le courant de désorption croît quand le potentiel et la température augmentent. C'est pourquoi à une température plus grande, avec le même courant de polarisation anodique, on obtient un potentiel plus réduit.

Dans les figures 7 et 8 on observe qu'aux températures de 300°, 400° et 500° pour des temps courts de polarisation anodique le rendement du dépôt de l'iode sur l'électrode est de 100 % et il diminue quand le temps de polarisation anodique augmente. Aux mêmes températures, aux potentiels élevés, rapprochés du potentiel réversible, sur les courbes de polarisation cathodique (figures 2–6) il existe des paliers caractéristiques qui peuvent être attribués à une condensation capillaire de l'iode dans les pores du charbon actif. Ce qui est plausible à cause du fait que ces températures se trouvent au-dessous du point critique de l'iode, celui-ci est de 511°. Ces paliers sont plus prononcés à 300° et diminuent quand la température augmente, en disparaissant même à 600° (donc après avoir dépassé le point critique de l'iode). Aux températures de 600° et 700° le rendement du dépôt de l'iode sur l'électrode est réduit même aux temps courts de polarisation anodique. A ces temperatures les courbes de polarisation cathodique changent leur concavité, ce que nous avons déjà montré dans un travail antérieur [3].

Dans la figure 9 on a représenté la dépendance du potentiel φ de la quantité d'électricité consommée à la polarisation anodique pour la température de 600°. Les quantités Q ont été calculées des courbes φ — temps de polarisation anodique. On a représenté seulement les portions des courbes qui se trouvent avant le palier, pour lesquelles le rendement est maximum. On constate que ces courbes ne se superposent pas entre elles. Donc, on peut obtenir le même potentiel φ avec différentes quantités d'halogène adsorbé. Ou, pour la même quantité d'électricité Q passée par l'électrode

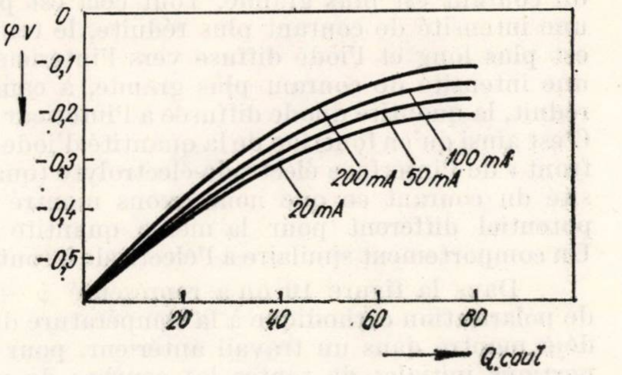

Fig. 9. — Courbes de polarisation anodique (φ — Q) de l'électrode d'iode-charbon actif à diverses intensités de courant ; t = 600°.

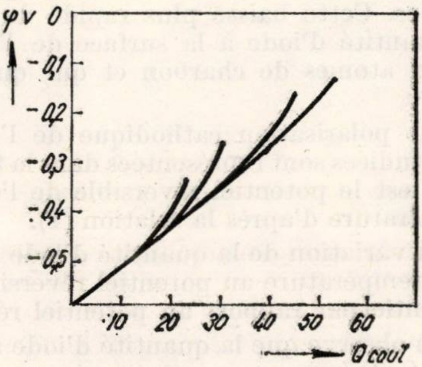

Fig. 10. — Courbes φ — Q de polarisation cathodique t = 600° ; i = 100 mA.

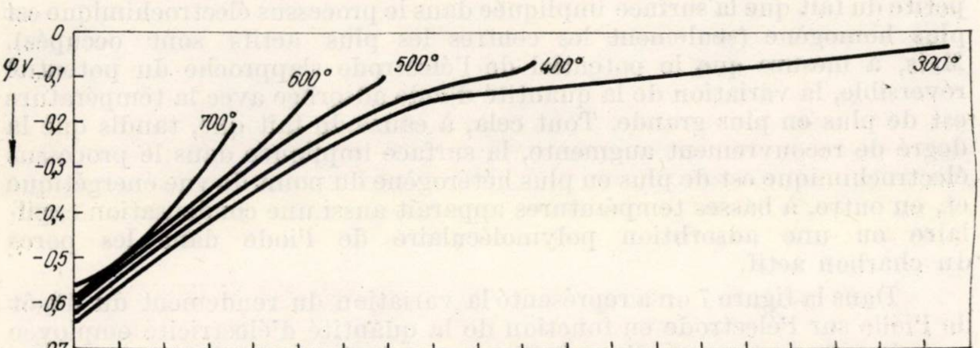

Fig. 11. — Courbes φ — Q de polarisation cathodique à diverses températures ; i = 100mA.

on obtient un potentiel φ qui sera d'autant plus élevé que l'intensité du courant est plus grande. Tout cela est probablement dû au fait qu'à une intensité de courant plus réduite, le temps de polarisation anodique est plus long et l'iode diffuse vers l'intérieur de l'électrode, tandis qu'à une intensité de courant plus grande, à cause du temps de polarisation réduit, la quantité d'iode diffusée à l'intérieur de l'électrode est plus petite. C'est ainsi qu'en fonction de la quantité d'iode qui se trouve sur le « premier front » de l'interface électrode-électrolyte (quantité qui dépend de l'intensité du courant ce que nous avons montré plus haut) on obtient un potentiel différent pour la même quantité totale d'iode sur l'électrode. Un comportement similaire a l'électrode à toutes les températures étudiées.

Dans la figure 10 on a représenté $\varphi - Q$ sur la base des courbes. de polarisation cathodique à la température de 600°. Ainsi que nous avons déjà montré dans un travail antérieur, pour la température de 300°, les portions initiales de toutes les courbes de polarisation cathodique présentent une baisse plus rapide du potentiel, après quoi toutes se joignent dans « une courbe de base ». L'électrode a aussi le même comportement aux autres températures étudiées. Cette baisse plus rapide du potentiel est probablement due à une quantité d'iode à la surface de l'électrode qui est plus faiblement liée aux atomes de charbon et qui quitte plus facilement l'électrode.

« Les courbes de base » de polarisation cathodique de l'électrode d'iode à toutes les températures étudiées sont représentées dans la figure 11. Le potentiel de référence (zéro) est le potentiel réversible de l'électrode d'iode calculé pour chaque température d'après la relation (1).

Dans la figure 12 on voit la variation de la quantité d'iode adsorbée sur l'électrode en fonction de la température au potentiel réversible (OV) et à plusieurs différences de potentiel par rapport au potentiel réversible.

Dans les figures 11 et 12 on observe que la quantité d'iode adsorbée sur l'électrode diminue quand la température augmente. Aux potentiels éloignés du potentiel réversible cette variation avec la température est très petite du fait que la surface impliquée dans le processus électrochimique est plus homogène (seulement les centres les plus actifs sont occupés). Mais, à mesure que le potentiel de l'électrode s'approche du potentiel réversible, la variation de la quantité d'iode adsorbée avec la température est de plus en plus grande. Tout cela, à cause du fait que, tandis que la degré de recouvrement augmente, la surface impliquée dans le processus électrochimique est de plus en plus hétérogène du point de vue énergétique et, en outre, à basses températures apparaît aussi une condensation capillaire ou une adsorbtion polymoléculaire de l'iode dans les pores du charbon actif.

Dans la figure 7 on a représenté la variation du rendement du dépôt de l'iode sur l'électrode en fonction de la quantité d'électricité employée pour la polarisation anodique à diverses températures. On observe qu'à 300°, 400° et 500° pour de petites quantités d'électricité passées par la cellule, le rendement du dépôt de l'iode sur l'électrode est de 100% et ensuite il diminue. Pour les températures de 600° et 700° les rendements sont beaucoup plus réduits.

Ce qui est très intéressant, c'est la dépendance du rendement du dépôt d'iode sur l'électrode de potentiel. D'après la figure 8, à basses températures, pour un grand intervalle de potentiel, le rendement est de 100%, ensuite il diminue rapidement à zéro. Pour des températures plus élevées (au-dessus du point critique de l'iode), même aux potentiels réduits le rendement est au-dessous de 100%. De plus, la diminution du rendement quand le potentiel augmente est beaucoup plus lente si la température est plus élevée.

La figure 8 montre encore qu'à un courant d'électrolyse donné et à une température donnée, après avoir obtenu un certain potentiel (le potentiel stationnaire), donc après avoir obtenu un certain degré de recouvrement, cesse pratiquement l'adsorption d'iode sur l'électrode.

Dans la figure 13 on observe l'influence du barbotage d'argon dans l'électrolyte sur la forme des courbes de polarisation anodique et cathodique. On voit aussi dans cette figure que sur une grande partie de la courbe de polarisation anodique le barbotage d'argon n'a aucune influence parce que tout l'iode déposé par électrolyse est adsorbé par l'électrode. Du moment où une partie de l'iode se désorbe thermiquement en se dissolvant dans l'électrolyte qui entoure l'électrode, les courbes de polarisation anodique obtenues avec ou sans barbotage d'argon ne se superposent plus, à la polarisation anodique obtenue sans barbotage d'argon étant enregistré un potentiel plus élevé. De même, sur la courbe de polarisation cathodique obtenue sans barbotage d'argon il existe un palier plus prononcé, le temps de polarisation cathodique étant plus long. Une influence similaire sur le comportement de l'électrode a aussi le barbotage d'argon aux autres températures étudiées.

En conclusion on peut faire les observations suivantes :

A basses températures sur les courbes de polarisation cathodique (voir fig. 2–6)

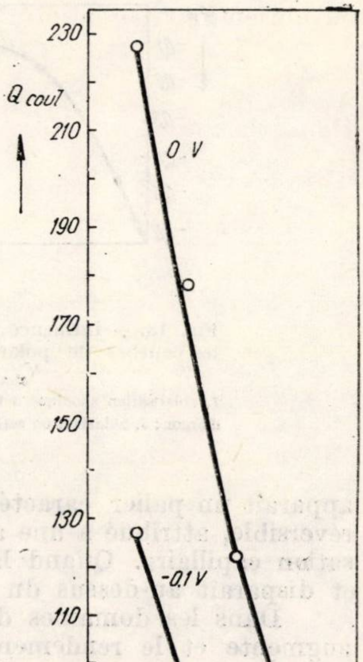

Fig. 12. – Variation de la quantité d'iode adsorbée par l'électrode en fonction de la température au potentiel réversible (O V) et à plusieurs différences de potentiel par rapport au potentiel réversible.

Revue Roumaine de Chimie, 19, 6, 967–976 (1974)

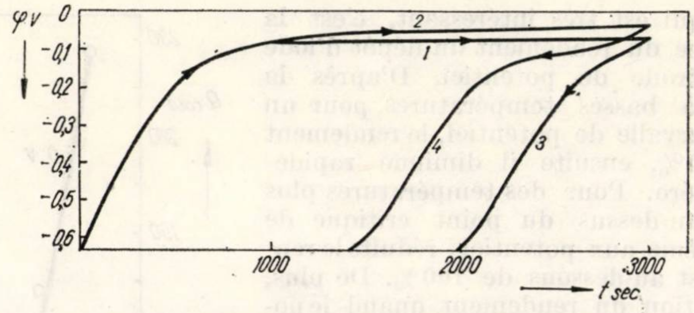

Fig. 13. — Influence du barbotage d'argon dans l'électrolyte sur les courbes de polarisation anodique et cathodique ; $t = 400°$
$i_{\text{charge}} = i_{\text{décharge}} = 100$ mA :
1, polarisation anodique à barbotage d'argon ; *2*, polarisation anodique sans barbotage d'argon ; *3*, polarisation cathodique à barbotage d'argon ; *4*, polarisation cathodique sans barbotage d'argon.

apparaît un palier caractéristique aux potentiels rapprochés de celui réversible, attribué à une adsorption polymoléculaire, ou à une condensation capillaire. Quand la température augmente ce palier diminue et disparaît au-dessus du point critique de l'iode.

Dans les domaines de potentiel étudiés, le courant de désorption augmente et le rendement diminue quand la température augmente.

THERMODYNAMIC EXCESS MAGNITUDES OF BINARY SYSTEMS OF ORGANIC LIQUIDS

RODICA VÎLCU and ALEXANDRINA SIMION

Bucharest University, Chair of Chemical Thermodynamics and Electrochemistry, Bd. Republicii 13

Received February 22, 1973

The densities and the ultrasonic velocities were measured in acetic acid+benzene and acetic acid+ethylmethylketone systems, at 25°, 35° and 45°. The densities were determined by the pycnometer method and the velocities with a two quartz crystal interferometer built up by the authors. The excess volumes and the excess adiabatic compressibilities of these solutions at various concentrations were calculated.

INTRODUCTION

Ultrasonic methods find more and more applications owing to their ability of characterizing the physico-chemical behaviour of liquid systems, from the absorption and propagation velocity data.

The measurement of the ultrasonic velocity in solutions formed by liquid components allows to establish : their degree of deviation from ideality, eventual molecular associations in solutions, as well as important correlations with various magnitudes such, as compressibility (adiabatic and isothermal), ratio of heat capacities [1], free volume and internal pressure [2] corrective constants *a* and *b* of Van der Waals equation of state [3,4].

In the case of electrolyte solutions ionic associations [5] and hydration numbers [6] may be evidenced.

The equilibrium sonic velocity is correlated with the adiabatic compressibility β_s of the medium by the relation :

$$c^2 = \frac{1}{\rho\beta s} \qquad (1)$$

where ρ is the density.

The measurement of the adiabatic compressibility of liquids at various pressures constitutes a method of establishing certain equations of state.[7]

Important correlations[8] can equally be established between ultrasonic velocities, compressibilities and the derivatives of the thermodynamic functions.

For the measurement of the ultrasonic velocity in liquids various experimental techniques have been used; they make use of either continuous waves or pulses. The first ones, interferometric, determine the wavelength of vibrations of known frequency, generally, by either optical or electronic determinations, with progressing or standing waves. The latter ones may be of the time of flight, ,,sing around'' or interferometric type.

For our measurements we have chosen o two crystal continuous wave interferometric technique[9] with variable path.

EXPERIMENTAL

The variable path interferometer consisted of an emitting crystal (lower) connected to a signal generator and a receiving crystal (upper) whose signal was displayed on the y axis of an oscilloscope.

Both crystals were χ-cut quartz. The upper crystal was movable; its displacements were made by help of a micrometric screw. Both the screw and a dial indicator were used for displacement measurements (measurements of changes in optical path). The sweeping of the oscilloscope was triggered by the signal generator (fig. 1) and so Lissajou's ellipses were displayed on the screen; a change in acoustical path of one wavelength (λ) corresponds to a 360° rotation of the figure on the screen. If for a Δl displacement of the upper crystal one counts n full rotations of the Lissajou figure, c is:

$$c = \lambda\nu = \frac{\Delta l}{n}\,\nu \tag{2}$$

where ν is the frequency of ultrasounds.

Experiments were carried out at 1 MHz which was the resonance frequency of the two crystals (40 mm in diameter and 4 mm thick).

The interferometer (fig. 2) consists of a stainless steel vessel (A) (80 mm diameter, 150 mm height). The flange E supports the micrometric screw system C and serves as lid of the vessel; it is sealed on collar B. The two crystal holders H are identical but the upper one is attached to the micrometric screw while the lower one is mounted on the bottom of the vessel; special alignment precautions were taken with them.

Mounting of crystals in holders was made so as to ensure electrical contact and prevent leaks. Both crystals G were mounted in special profile polyethylene rings I and their sides facing the liquid were covered with polyethylene films; a small pressure was applied upon them by the mounting metal rings through teflon seals. The liquid was introduced either in the steel vessel or in a smaller flat bottom glass vessel whose acoustical contact with

the lower crystal was improved by a film of oil; the latter alternative was used in the cases the amount of liquid available would not suffice. The interferometer was placed in a thermostat which maintained the temperature within ±0.1°.

Temperature was measured by a thermometer within ±0.1°. The precision of acoustical path change measurements was ±0.01 mm which gives a maximum error in individual speed measurements of ±0.3%. The standard deviation of the average is ±0.05% for 20 measurements.

Taking into account the maximum error of velocity measurement a maximum error in β_S of ±0.6% is obtained. The maximum error in density measurements was of ±0.004% which gives a maximum error in V^E of ±0.01 $cm^3\ mol^{-1}$.

RESULTS AND DISCUSSION

Verification measurements of the interferometer on several liquids were carried out before each series of runs.

Some of the results are listed in table 1.

Table 1

The literature is very rich in results of measurements on binary liquid mixtures characterized by various types of interactions. Not so much was done on binary systems of carboxylic acids with organic solvents. These systems are interesting due to their tendency to form molecular associations and to have, accordingly, non-ideal behaviour.

In the present work the study of binary systems of acetic acid with benzene (non-polar) and ethylmethylketone (polar) as solvents was carried out.

The densities (pycnometric method) and ultrasound velocities were determined at 25°, 35° and 45° for mole fractions between 0 and 1 acetic acid ; n from equation (2) was usually equal to 5. The densities and molar excess volumes V^E for the two systems are given in tabels 2 and 3.

Table 2

Densities and excess volumes in the acetic acid+benzene system

Mole fraction of the acid	ρ (g cm^{3})			V^E (cm^3 mol^{-1})

V^E is given by the equation :

$$V^E = V^{sol} - V^{vid} = \frac{\widetilde{M}}{\rho} - x_1 V_1 + x_2 V_2)$$

where :

$\widetilde{M} = x_1 M_1 + x_2 M_2$ is the average molecular mass ;

x_1, x_2 are the mole fractions ;

M_1, M_2 are the molar masser of components ;

V_1, V_2 are the molar volumes of components ;

ρ is the solution density.

For the acetic acid + benzene system the excess volumes are positive; the molecules of the components are not similar either as to their form or to their size; that is why they mix with a volume growth. The variation of the excess volumes with the mole fraction is not symmetrical.

In the acetic acid + ethylmethylketone system the excess volumes are negative. This effect is the consequence of the strong interactions between the two polar components, the mixing of which takes place with a volume contraction. In figures 3 and 4, the ultrasonic velocities of the two systems are plotted. From these values, we deduced by means of eq. 1, the adiabatic compressibilities β_S, that are listed in table 4.

As can be seen from fig. 3 and table 4 the ultrasonic velocity decreases with increasing acid concentration while the adiabatic compressibility increases and reaches its maximum for the mole fraction 0.6. According to the Rao's results[14] these data could be accounted for by the planar

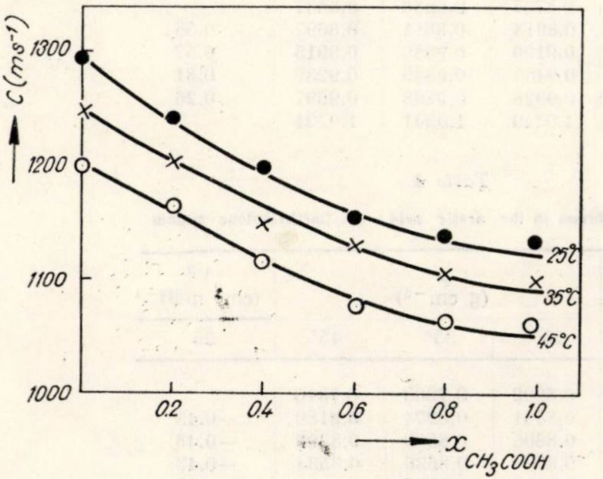

Fig. 3. — Ultrasonic velocity *vs* mole fraction of acetic acid, for the acetic acid + benzene system.

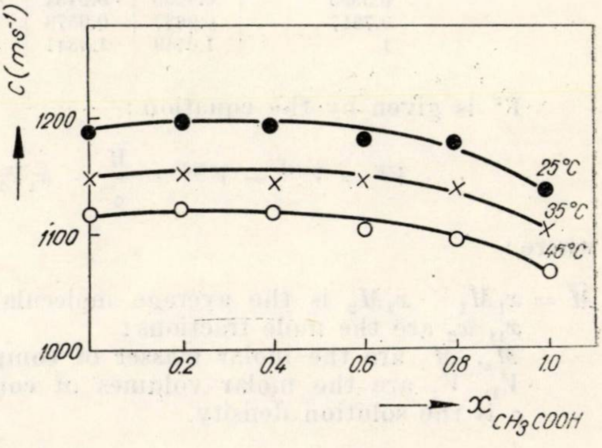

Fig. 4. — Ultrasonic velocity *vs* mole fraction of acetic acid, for the acetic acid + ethylmethylketone system.

Table 4

Adiabatic compressibilities in the acetic acid + benzene and acetic acid + ethylmethylketone systems

acetic acid + benzene				acetic acid + ethylmethylketone			
Mole fraction of the acid	$10^{12}\beta_s$ (cm^2 dyne^{-1})			Mole fraction of the acid	$10^{12}\beta_s$ (cm^2 dyne^{-1})		
	25°	35°	45°		25°	35°	45°
0	67.9	74.2	80.9	0	78.5	95.6	101.5
0.1999	72.7	78.5	84.4	0.1998	83.6	89.9	97.6
0.3975	76.6	83.5	90.0	0.3806	86.5	88.0	90.0
0.5999	79.5	83.3	93.1	0.5995	78.2	82.9	88.0
0.7998	77.9	93.1	90.9	0.7617	74.3	80.2	87.5
1	74.4	79.8	86.2	1	74.4	79.8	86.2

structure and by the high polarizability of benzene. Taking into consideration the polarizing effect, it is possible that the induction forces occurring between the benzene and acetic acid molecules increase the cohesive force between these molecule and meanwhile diminish the cohesive forces between the molecules of acid. The effect could be equally accounted for by the acetic acid molecules being accomodated into the volume occupied by benzene molecules.

The velocity curve for the system acetic acid + ethylmethylketone (fig. 4) differs from that of acetic acid + benzene (fig. 3) its convexity being directed upwards. The variation of the adiabatic compresibility β_s is also different.

In table 5, the excess adiabatic compressibilities are listed.

Table 5

Excess adiabatic compressibilities 10^{12} β_S^E (cm^2 dyne)

acetic acid + benzene				acetic acid + ethylmethylketone		
XCH^{3}COOH	25°	35°	45°	25°	35°	45°
0.2	4.7	3.8	2.8	6.1	−3.4	−1.7
0.4	7.5	7.5	7.5	9.6	−3.1	
0.6	9.1	6.4	9.6	9.8	−5.0	−6.1
0.8	8.7	1.4	7.4	0.0	−4.7	−4.9

The excess adiabatic compressibilities were calculated by equation

$$\beta_S^E = \beta_S^{sol} - \beta_S^{id}$$

where

$$\beta_S^{id} = \Phi_1\beta_{S1} + \Phi_2\beta_{S2}$$

Φ_1, Φ_2 are the volume fractions of components β_{S1}, β_{S2} the adiabatic compressibilities of components.

For the acetic acid + benzene system, the excess compressibilities are positive and seem to reach a maximum for mole fraction 0.6 of acetic acid. The β_S^E behaviour parallels the behaviour of V^E In the other system (acetic acid + ethylmethylketone), at 25°, β_S^E is positive while V^E is negative; at 35 and 45°. β_S^E is positive.

CONCLUSIONS

The non-ideal behaviour of the two above mentioned systems is observed both in the non-linear variation of ultrasonic velocities *vs* mole fraction and in deviations from ideality of compressibilities as well as of molar volumes.

The interactions, different in the two studied systems are revealed both by the aspect of the velocity *vs* concentration curves and by the excess volumes. The excess compressibilities have generally the same sign as the excess volumes and vary, approximately, in the same manner.

VAPOUR PRESSURES OF MOLTEN $CdBr_2$, CdI_2, $MgBr_2$ AND MOLECULAR ASSOCIATION IN GASEOUS PHASE

LETIȚIA TOPOR and IVONA MOLDOVEANU

Center of Physical Chemistry,
Str. Galați 31, Bucharest, Romania

Received October 19, 1973

The vapour pressures and molecular association in the gaseous phase of molten $CdBr_2$ and CdI_2 have been determined by the transpiration method and of molten $MgBr_2$ by Rodebush-Dixon and transpiration methods. A low percentage of gaseous polymers was found in the $CdBr_2$ and CdI_2 saturated vapours and a higher one in $MgBr_2$ saturated ones. The heat of vaporization of $MgBr_2$ monomers and dimers was deduced.

The study on the vapour pressures of molten halides from the second group [1,2] and the association of their vapours is being continued with measurements carried out on molten $CdBr_2$, CdI_2 and $MgBr_2$.

The vapour pressure of molten $CdBr_2$ and CdI_2 has been previously determined by the boiling point and Rodebush-Dixon methods.[1,3–5] In view of obtaining indications on the existence of polymers in gaseous phase in equilibrium with liquid $CdBr_2$ and CdI_2, a combination of absolute pressure measurements and transpiration data is necessary. The available transpiration data cannot be used for this purpose since Greiner and Jellinek [6] obtained only one value of the vapour pressure for $CdBr_2$ at 752°, Schmidt and Walter [7] examined CdI_2 around the melting point (390°–450°) and Tolmacheva and Andrinovskaya's data [8] are lower than the absolute vapour pressure measurements. We have determined the vapour pressure of molten $CdBr_2$ and CdI_2 by the transpiration method.

Information concerning the vapours composition have been obtained by using the transpiration data and the previous absolute vapour pressure values [1]. The vapour pressure of molten $MgBr_2$ has not been determined experimentally as yet. We have used the Rodebush-Dixon and transpiration methods to determine the vapour pressure of molten $MgBr_2$ and the mean molecular mass of the vapours.

EXPERIMENTAL

The transpiration and Rodebush-Dixon setups, their operation and the method used for purifying and dehydration of $CdBr_2$ and CdI_2 have been previously described. [19,10] However, anhydrous $MgBr_2$ was more difficult to obtain. Firstly we have tried the dehydration by the procedure recently presented by Østvold.[11] As the results were not satisfactory we have prepared anhydrous $MgBr_2$ directly from Br_2 and Mg in freshly distilled anhydrous diethyl ether.[12,13] We have dropped the freshly distilled liquid bromine in anhydrous ether containing pure metallic Mg turnings. The flask was cooled below room temperature. The unreacted metallic Mg was removed by filtering through G 2 – frit and the crystallization of the $MgBr_2$ trietherate was initiated by cooling the solution below 0°. The white crystals formed were rapidly filtered off by a water jet aspirator and introduced directly in the cell. To obtain anhydrous $MgBr_2$, the trietherate was decomposed in vacuum by rising its temperature from room temperature to 150°–175° (in two hours); it was then kept at 175° for 30 minutes, after which it was melted in dry pure argon.

RESULTS AND DISCUSSION

The vapour pressures of molten $CdBr_2$ and CdI_2 have been determined by the transpiration technique. From the experimental data the following equations were obtained by the least squares method, using an IBM computer:

$CdBr_2$ (607.5°–703.8°)

$$\log p = -\frac{(6106.2 \pm 22.1)}{T} + (8.312 \pm 0.024) \quad (1)$$

CdI_2 (528.3° – 628.5°)

$$\log p = -\frac{(5600.7 \pm 23.7)}{T} + (8.333 \pm 0.028) \quad (2)$$

The vapour pressure values obtained by the transpiration method are greater than the absolute pressures measured by Rodebush-Dixon

method.[1] Since the differences are too large to be attributed to experimental errors, they suggest that some associations occur in the vapours. If we assume the existence of the monomers and dimers in the gaseous phase, like in $CdCl_2$ vapours[2,14] from absolute vapour pressures and transpiration data we can calculate the mean molecular mass of the vapours.

The vapour pressure values of molten $CdBr_2$ and CdI_2 obtained at different temperatures by transpiration (p_{trans}) and Rodebush-Dixon (p) methods, the mean molecular mass of vapcurs ($\overline{M}$), the mole fractions of dimer x_2 and their mean $\overline{x_2}$ are presented in tables 1 and 2.

* The CdI_2 molecular mass is 366.23.

The only existent vapour pressure values for molten $MgBr_2$ have been calculated by Brewer.[15,16] The vaporization entropy and boiling point values have been established by comparison with the neighbouring halides, particulary MgF_2 and MgI_2.

The $MgCl_2$, $MgBr_2$ and MgI_2 vapours in equilibrium with the solid have been examined in the mass spectrometer.[17] The results have indicated the presence of a small amount of dimers in these conditions (~1%).

We have determined the vapour pressure of molten $MgBr_2$ from 846° to 994° by the Rodebush-Dixon method. The experimental vapour pressure values were fitted by the Σ plot method [18] and the equation for vapour pressure variation as a temperature function has been deduced by the least squares method at an IBM computer. The difference between the heat capacities for the gas and the liquid phase, ΔC_p, was assumed

-9.3 cal mole^{-1} deg^{-1}. We have obtained :

$$\log p = -\frac{(10504.9 \pm 57.3)}{T} - 4.682 \log T + (24.736 \pm 0.048) \quad (3)$$

The standard deviation of vapour pressure values is 2.26%. The heat of vaporization at temperature T, ΔH_T, calculated from equation (3) is :

$$\Delta H_T = (48.1 \pm 0.3) - 9.3 \times 10^{-3} T \quad (4)$$

We have utilized the transpiration method too. From absolute vapour pressures and transpiration data we have calculated the mean molecular mass of the vapours by using the relations previously reported.[2,10] The temperatures, the mean molecular mass $\overline{M}$, the mole fractions and partial pressures of monomers and dimers x_1, x_2, p_1, p_2 are listed in table 3.

Table 3

The mean molecular mass, mole fractions and partial pressures of monomers and dimers in the vapours of molten $MgBr_2$ *

T (*K*)	$\overline{M}$	x_1	x_2	p_1 (mm Hg)	p_2 (mm Hg)
1101.0	243.51	0.678	0.322	6.09	2.89
1123.0	257.18	0.604	0.396	7.62	4.96
1145.7	254.15	0.620	0.380	10.80	6.62
1164.7	260.33	0.587	0.413	13.35	9.39
1182.7	271.56	0.525	0.475	15.24	13.79
1205.7	272.08	0.521	0.477	20.43	18.79

* The $MgBr_2$ molecular mass is 184.16.

The presented values are averaged over 3–6 experiments.

From these data an important amount of dimers in $MgBr_2$ vapours results (between 32 mole % and 47 mole %). This percentage is higher than in $MgCl_2$ vapours [2] (29–33 mole %).

The temperature variation of partial vapour pressures is given by the equations :

$$\log p_1 = -\frac{(6681.2 \pm 247.2)}{T} + (6.649 \pm 0.214) \quad (5)$$

$$\log p_2 = -\frac{(10201.6 \pm 393.9)}{T} + (9.743 \pm 0.342) \quad (6)$$

The heats of vaporization of the liquid $MgBr_2$ into monomers and dimers are from equations (5) and (6): $\Delta H_{1v} = 30.6$ kcal.mole^{-1} and $\Delta H_{2v} = 46.7$ kcal.mole^{-1}.

The only existing value of the heat of vaporization for $MgBr_2$ obtained by Brewer[15] from calculation is $\Delta H_v = 35$ kcal.mole^{-1}. From equation (4) the heat of vaporization at 1000 K is 38.8 kcal. mole^{-1}. For monomers and dimers the heat of sublimation has been determined previously by mass spectrometry technique ($\Delta H_{1s} = 50.3$ kcal.mole^{-1} and $\Delta H_{2s} = 63.2$ kcal.mole^{-1}).[17] We have calculated the heat of sublimation of monomers and dimers from the heat of vaporization and the heat of fusion (8.3 kcal.mole^{-1}) and we have obtained, $\Delta H_{1s} = 38.6$ kcal.mole^{-1} and $\Delta H_{2s} = 62.9$ kcal.mole^{-1}, respectively. The value obtained for the monomers is very different from the previous one, but the one for dimer is very similar.

Revue Roumaine de Chimie, **19**, *6*, 991–996 (1974)

MOLECULAR INTERACTIONS IN SOLUTIONS
CALCULATIONS OF THE INTERACTION POTENTIAL ENERGY IN THE CARBON DISULPHIDE – CHLOROFORM SYSTEM *

SIMONA BĂDILESCU

Petrochemical Works, Pitești, Romania

Received August 22, 1973

The interaction potential energy was calculated in the carbon disulphide – chloroform system based on a reticular model. The vibration frequency ν_3 of the carbon disulphide molecule in a chloroform environment was calculated and compared to the experimentally determined frequency.

In a recent work, Devaure et al.[1] reported that the shape of some CO, HCl, CH_4 bands at 1500 atm. or at −23° in the plastic phase of carbon tetrachloride is identical to the shape of those bands in dilute solutions of the same solvent. The results obtained by Devaure et al. show that the utilization of some solid-state models to describe the perturbations suffered by a vibrator under the influence of molecular interactions in solution may be very fruitful.

In the present paper, we calculated the frequency shift $\Delta\nu$ of the band corresponding to the anti-symmetric stretching vibration ν_{as} of the carbon disulphide molecule in chloroform solution (a shift with respect to the value of the frequency corresponding to the isolated molecule).

Calculations were made based on a reticular model suggested by Galatry et al.[2-4] and the results obtained were compared to our experimental data.[5] The expression of "sphericalized"[6] potential energy was used to describe the interactions dissolved substance – solvent, permitting a numerical estimation of the influence of the perturbating molecules aggregate.

When estimating the potential energy, the interactions are considered binary and additive, considering the dispersion and repulsion energy.

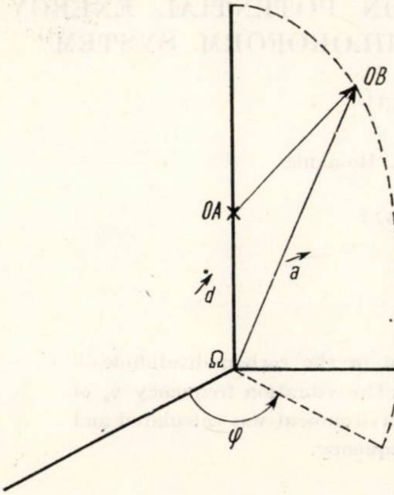

Fig. 1. — Reduced coordinates in reticular model.

The potential energy is expressed in the reduced coordinates τ $\left(\text{which represent a reduced shift compared to the center } \Omega \text{ of the cell, } \tau = \frac{\vec{d}}{a}\right)$ and φ (fig. 1), and the expression of the potential energy is :

$$\overline{V}^0(\tau, \varphi) = \overline{V}_1^0(\tau) + \overline{V}_2^0(\tau)\cos^2\varphi \qquad (1)$$

The terms $\overline{V}_1^0(\tau)$ and $\overline{V}_2^0(\tau)$ in equation (1) are of the form;

$$\overline{V}_1^0(\tau) = -\left[12\,\Delta^{Ab}\alpha_A\alpha_b a^{-6} + 24\,\Delta^{Bb}\alpha_B\alpha_b a^{-6}\right]\frac{1-\tau^2}{(1-\tau^2)^4} - $$

$$- \frac{24\,\Delta^{Bb}\alpha_B\alpha_b s^2 a^{-8}}{(1-\tau^2)^8}(5 - 16\tau^2 + 2\tau^4 + 4\tau^6 + 3\,\tau^8) +$$

$$+ \frac{12}{5}\,\varepsilon_{a-b}\left(\frac{R_{a-b}}{a}\right)^{12}\frac{20 + 240\,\tau^2 + 504\,\tau^4 + 240\,\tau^6 + 20\,\tau^8}{(1-\tau^2)^{10}} \qquad (2)$$

and

$$\overline{V}_0^2(\tau) = -\frac{\Delta^{Bb}\alpha_b s^2 a^{-8}}{(1-\tau^2)^8}(1344\tau^2 - 1824\tau^4 + 48\tau^6 + 576\tau^8) \qquad (3)$$

The significances of the terms in equations (2) and (3) are:

$$\Delta^{Ab} = \Delta^{\mathrm{C-CHCl_3}} = \frac{3\,U^{\mathrm{C}}\,U^{\mathrm{CHCl_3}}}{2\,(U^{\mathrm{C}} + U^{\mathrm{CHCl_3}})}$$

and

$$\Delta^{Bb} = \Delta^{\mathrm{S-CHCl_3}} = \frac{3\,U^{\mathrm{S}}\,U^{\mathrm{CHCl_3}}}{2(U^{\mathrm{S}} + U^{\mathrm{CHCl_3}})}$$

in which U^{C} and U^{S} represent the ionization potentials of carbon and sulphur atoms, and $U^{\mathrm{CHCl_3}}$, the ionization potential of the chloroform molecule; $\alpha_B = \alpha_{\mathrm{S}}$ and $\alpha_A = \alpha_{\mathrm{C}}$ are the atomic polarizabilities, $\alpha_b = \alpha_{\mathrm{CHCl_3}}$ the solvent polarizability, s – the carbon – sulphur interatomic distance, a – the cell parameter and ε and R are the Lennard-Jones parameters of the molecular couple.

The numerical values of the terms used in the calculation of the potential energy are given in table 1 and the values of Lennard-Jones constants, calculated according to the known combinational rules,[9] are:

$$\varepsilon_{\mathrm{CHCl_3-CS_2}} = 308\ \mathrm{cm^{-1}} \text{ and } \sigma_{\mathrm{CHCl_3-CS_2}} = 4.93\ \text{Å}$$

Table 1

Numerical values used in the calculation of potential energy

Term	Value	Ref.
U^{C}	11.256 eV	7
U^{S}	10.357 eV	7
$U^{\mathrm{CHCl_3}}$	11.42 eV	8
α_{C}	$1.35.10^{-25}$ cm^3	6
α_{S}	$71.3.10^{-25}$ cm^3	6
α_{CHCl3}	$82.3.10^{-25}$ cm^3	9
s	$1.56.10^{-8}$ cm	6
$\varepsilon_{\mathrm{CS_2}}$	340 cm^{-1}	9
$\varepsilon_{\mathrm{CHCl3}}$	279 cm^{-1}	9
$\sigma_{\mathrm{CS_2}}$	$4.438.10^{-8}$ cm	9
σ_{CHCl3}	$5.43.10^{-8}$ cm	9

[9] J. O. Hirschfelder, Ch. F. Curtiss and R. B. Bird, "Molecular Theory of Gases and Liquids", Wiley, New York, 1954, Russian Edition, Izdatel'stvo Innostranoi Literatury, Moscow, 1961.

The cell parameter a is :

$$a = \left(\frac{M\sqrt{2}}{Nd} \right)^{1/3} \tag{4}$$

in which d is the solvent density, M — the molecular weight and N the Avogadro number.

The $\Delta\nu_3$ shift of the ν_3 vibration frequency of the chloroform molecule was calculated using expression [6]:

$$\Delta\nu_3 = \frac{\nu_3}{K_3} \left(\frac{\partial^2 \overline{V}}{\partial z^2} \right)_0 \tag{5}$$

in which ν_3 is the frequency value of the anti-symmetric vibration mode of the C — S bond in gaseous carbon disulphide molecule [10] (1536.5 cm^{-1}), k_3 is the corresponding force constant and $\left(\frac{\partial^2 \overline{V}}{\partial z^2} \right)_0$ denotes the "sphericalized" expression of the second derivative of the potential energy in relation to the vibration coordinate z.

The term $\left(\frac{\partial^2 \overline{V}}{\partial z^2} \right)_0$ takes the form :

$$\left(\frac{\partial^2 \overline{V}}{\partial z^2} \right)_0 = k_1(\tau) + k_2(\tau) \tag{6}$$

in which

$$k_1 = \left(\Delta^{Ab} \alpha_A \alpha_b a^{-8} + \frac{2M}{m} \Delta^{Bb} \alpha_B \alpha_b a^{-8} \right) \left[\frac{-240 + 96\tau^2 + 144\tau^4}{(1 - \tau^2)^6} \right] \tag{7}$$

and

$$k_2 = -\left(144\, \Delta^{Ab} \alpha_A \alpha_b a^{-8} + \frac{2M}{m} \cdot 288\, \Delta^{Bb} \alpha_B \alpha_b a^{-8} s \right) \times$$

$$\times \frac{18\tau^2 + 2213\tau^4 + 2\tau^6 + 2\tau^8}{(1 - \tau^2)^8} \tag{8}$$

RESULTS AND DISCUSSION

The variation curves of the potentials $\overline{V}_1^0(\tau)$ and $\overline{V}_2^0(\tau)$ calculated for the reduced shift values τ comprised between 0 and 0.3 are plotted in figures 2 and 3. Table 2 records the values of $\left(\frac{\partial^2 \overline{V}}{\partial z^2}\right)_0$ calculated by eqn. (5) for some values of τ, and the $\Delta\nu$ shifts of the ν_3 vibration frequency of CS_2 molecule in chloroform solution.

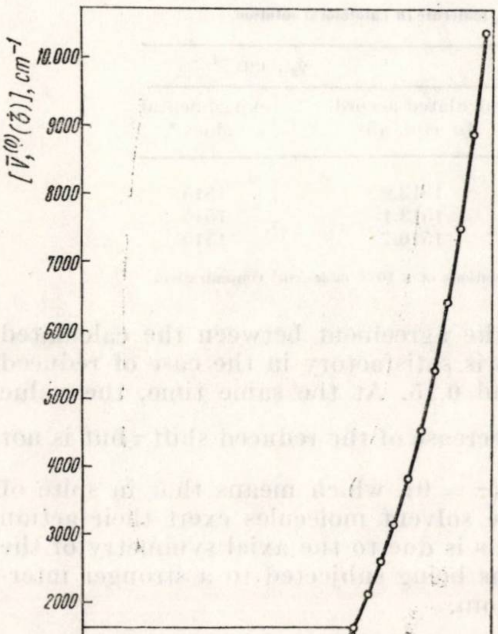

Fig. 2. — Variation of potential energy $\overline{V}_1^0(\tau)$ along with reduced shift τ.

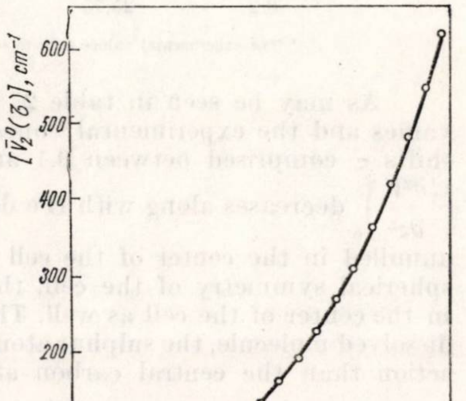

Fig. 3. — Variation of potential energy $\overline{V}_2^0(\tau)$ along with reduced shift τ.

Figures 2 and 3 illustrate that $\overline{V}_2^0(\tau)$ has an important weight in the expression of the total potential energy at low values of the reduced shift ($\tau < 0.15$), whereas at $\tau > 0.15$, $\overline{V}_1^0(\tau)$ becomes preponderant and it rapidly increases. This manner of variation can be explained by the specific nature of the two energies, $\overline{V}_2^0(\tau)$ representing the orientation energy and $\overline{V}_1^0(\tau)$ the translation energy. Around the value $\tau = 0.15$ both energies reach the value of the thermal motion energy (313 cm^{-1} at 300°K).

The probability density that the gravity center of the dissolved substance may be found at a distance τ from the center of the cell (determined by expression $\tau^2 e - \frac{\overline{V}^0(\tau)}{kT}\Big)$ attains a maximum at $\tau = 0.15$.

At any value of the reduced shift, the potential energy $\overline{V}_2^0(\tau)$ is much higher than the rotation constant B of the dissolved molecule, which means that the rotation levels are strongly perturbated.

Table 2

Vibration frequency ν_3 of CS_2 molecule in chloroform solution

τ	$\Delta\nu$ cm^{-1}	ν_3, cm^{-1}	
		calculated accord. to eqn. (5)	experimental values *
0.1	-22.6	1513.9	1515
0.15	-23.4	1513.1	1515
0.2	-25.75	1510.7	1515

* The experimental values refer to solutions of a 10^{-5} moles/cm^3 concentration.

As may be seen in table 2, the agreement between the calculated values and the experimental [5] ones is satisfactory in the case of reduced shifts τ comprised between 0.1 and 0.15. At the same time, the value $\left(\frac{\partial^2 \overline{V}}{\partial z^2}\right)_0$ decreases along with the decrease of the reduced shift τ but is not annulled in the center of the cell ($\tau = 0$), which means that in spite of spherical symmetry of the cell, the solvent molecules exert their action in the center of the cell as well. This is due to the axial symmetry of the dissolved molecule, the sulphur atoms being subjected to a stronger interaction than the central carbon atom.

GÉNÉRALISATIONS DU TRIANGLE DE GIBBS POUR LES SYSTÈMES QUATERNAIRES ET QUINAIRES

D. RIMER
Séminaire Mathématique « A. Myller »,
Université « Al. I. Cuza », 11, str. 23 August, Jassy, Roumanie

Reçu le 3 septembre 1973

On construit dans le plan, un modèle géométrique des systèmes quaternaires et l'un des systèmes quinaires, en réalisant une représentation plane suffisamment exacte de tels systèmes. Dans ces modèles on résout graphiquement les mêmes types de problèmes qui sont résolus dans le triangle de Gibbs pour les systèmes ternaires.

I. INTRODUCTION

On connaît les multiples utilisations du triangle de Gibbs dans la chimie physique et la technologie chimique, pour la représentation géométrique des systèmes ternaires, ainsi que pour la solution graphique de divers problèmes concernant ces systèmes.[1-3]

On connaît aussi les difficultés qui surviennent en passant aux systèmes quaternaires, parce qu'il faut utiliser le tétraèdre.

En effet, c'est beaucoup moins commode et c'est peut-être pourquoi on n'a étudié qu'un nombre restreint de systèmes quaternaires.[4]

Le problème de l'étude des systèmes quinaires à l'aide d'un pentatôpe, — le correspondant du triangle, dans un espace à quatre dimensions — n'est pas considéré, habituellement, à cause de la difficulté de matérialiser les figures de l'espace euclidien à quatre dimensions.

Nous estimons avoir vaincu ces difficultés en réalisant, *dans un plan*, une représentation biunivoque et continue (les points distincts sont représentés par des points distincts et les points voisins sont représentés par des points voisins) d'un tétraèdre [5,6] ou d'un pentatôpe,[7] dont nous

avons ôté seulement les points à deux, respectivement à trois coordonnées, nombres irationnels.

Ces figures ont été dénommées par nous *pseudo-tétraèdre*, respectivement *pseudo-pentatôpe*.

Nous avons élaboré la base mathématique de cette représentation en étudiant ses divers aspects ; tout de même nous avons considéré aussi certaines applications.[8,9]

Mentionnons que *dans le pseudo-tétraèdre et dans le pseudo-pentatôpe on peut résoudre graphiquement tous les types de problèmes que l'on résout dans le triangle de Gibbs.*

II. LE PSEUDO-TÉTRAÈDRE QUI GÉNÉRALISE LE TRIANGLE DE GIBBS

A. Soit, dans un plan (fig. 1) un repère $(0\,;\,\bar{e}_1, \bar{e}_2)$ et un vecteur $\bar{u}$, donné par la relation

$$\bar{u} = a\bar{e}_1 = b\bar{e}_2 \ (a \in R-Q,\ b \in R), \quad (1)$$

où R est l'ensemble des nombres réels, Q celui des nombres rationnels et, donc, $R-Q$ est l'ensemble des nombres irationnels.

Dans la figure 1 nous avons considéré :

$$\bar{u} = (-\,6/\sqrt{75}\,)\,\bar{e}_1 - (\sqrt{13}\,/5)\,\bar{e}_2 \approx -\,0{,}69\,\bar{e}_1 - 0{,}72\bar{e}_2.$$

Nous renotons ces vecteurs par

$$\bar{v}_1 = \bar{u}, \quad \bar{v}_2 = \bar{e}_1, \quad \bar{v}_3 = \bar{e}_2 \quad (2)$$

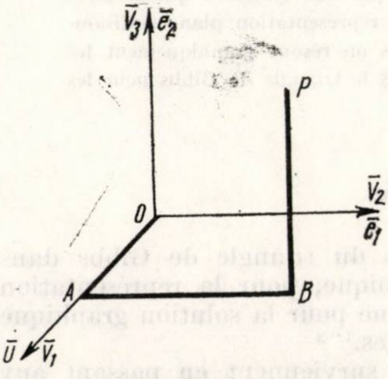

Fig. 1. — Repère d'un espace pseudo-affine à trois dimensions, construit dans un plan.

Considérons maintenant $(0\,;\,\bar{v}_1, \bar{v}_2)$ comme un repère du plan et imaginons-nous tous les points du plan qui ont, par rapport à ce repère, toutes les deux coordonnées, des nombres rationnels. Par chacun de ces points, nous considérons la droite, parallèle à $\bar{v}_3$.

Nous avons démontre,[7] que ces droites sont distinctes, c'est-à-dire qu'il n'y a pas, parmi elles, deux droites confondues ou — c'est la même chose — aucune d'entre elles ne passe par deux tels points. L'ensemble des points de ces droites nous l'appelons *espace pseudo-affine à trois dimensions construit dans un plan* et $(0\,;\,\bar{v}_1, \bar{v}_2, \bar{v}_3)$ est le *repère* de cet espace.

Puisqu'on ne peut pas tracer l'ensemble de toutes ces droites, nous nous contenterons à représenter les points par rapport à ce repère, en gardant le contour de coordonnées respectif. Ainsi, étant donné un triplet ordonné de nombres (x_1, x_2, x_3), dont $x_1, x_2 \in Q$, $x_3 \in R$, nous construisons

---

[8] D. Rimer, *Bull. Soc. Franc. Minéral. Cristallogr., Paris,* **91**, 513 (1968).
[9] D. Rimer, *Bull. Soc. Franc. Minéral. Cristallogr., Paris,* **92**, 508 (1969).

ainsi le point correspondant : nous prenons (fig. 1) le point A sur Ov_1 tel que $OA = x_1$, puis $AB = x_2$, parallèlement à $\bar{v}_2$ et enfin $BP = x_3$, parallèlement à $\bar{v}_3$. Réciproquement, étant donné le point P avec le contour de coordonnées OABP, nous mesurons, sur le dessin, les coordonnées $x_1 = OA$, $x_2 = AB$, $x_3 = BP$.

Les nombres x_1, x_2, x_3 ($x_1 \in Q$, $x_2 \in Q$, $x_3 \in R$) sont denommés les *coordonnées pseudo-affines* du point P par rapport au repère $(0, \bar{v}_1, \bar{v}_2, \bar{v}_3)$. Le point P peut être écrit : $P = x_1\bar{v}_1 + x_2\bar{v}_2 + x_3\bar{v}_3$.

Si l'on considère, dans cet espace pseudo-affine, rapporté à ce repère, tous les points P, donnés par :

$$P = x_1\bar{v}_1 + x_2\bar{v}_2 + x_3\bar{v}_3, \; (x_1, x_2 \in Q, \; x_3 \in R, \; x_1, x_2, x_3 \geqslant 0, \qquad (3)$$
$$x_1 + x_2 + x_3 \leqslant 100),$$

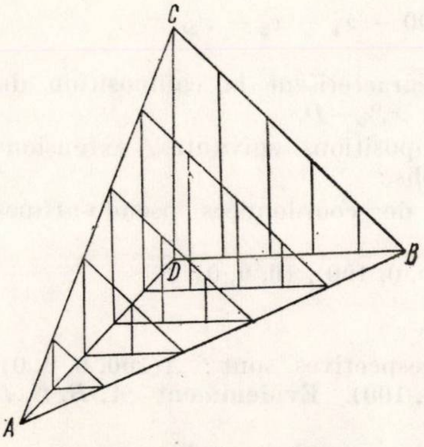

Fig. 2. – Pseudo-tétraèdre.

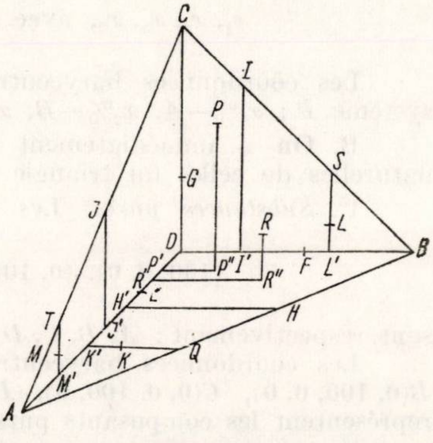

Fig. 3. – Représentation des systèmes binaires, ternaires et quaternaires dans un pseudo-tétraèdre.

on obtient une figure plane que nous avons dénommée *pseudo-tétraèdre*. Dans la figure 2, nous avons matérialisé seulement les points du pseudo-tétraèdre pour lesquels on a : $x_1 = 20\,k$, $x_2 = 20k'$ ($k, k' = 0, 1, 2, 3, 4, 5$), $0 \leqslant x_3 \leqslant 100 - x_1 - x_2$.

Les autres points du pseudo-tetraèdre qui nous intéresseraient peuvent être construits selon les nécessités, par interpolation. Evidemment, il est utile de construire aussi des pseudo-tétraèdres plus grands, où l'on puisse matérialiser tous les points ayant, par exemple $x_1 = 10k$, $x_2 = 10k'$ ($k, k' = 0, 1, 2, \ldots, 10$), $x_1 = 5k$, $x_2 = 5k'$ ($k, k' = 1, 2, \ldots \ldots, 20$), etc.

Dans tout ce qui suit nous considérerons un repère pseudo-affine ayant l'origine D, les axes DA, DB, DC et les unités : $\frac{1}{100}\,DA$, $\frac{1}{100}\,DB$, $\frac{1}{100}\,DC$. Un point arbitraire du pseudo-tétraèdre (fig. 3) sera construit vu ses coordonnées pseudo-affines par rapport à ce repère, en traçant effectivement le contour de coordonnées, ainsi que nous l'avons fait dans la figure 1.

Naturellement, il faut considérer aussi, à côté des coordonnées pseudo-affines, les coordonnées barycentriques classiques : si un point P du pseudo-tétraèdre a les coordonnées pseudo-affines :

$$x_1,\ x_2,\ x_3\ (\text{avec } x_1, x_2 \in Q,\ x_3 \in R,\ x_1, x_2, x_3 \geqslant 0,\ x_1 + x_2 + x_3 \leqslant 100)$$

alors il a les coordonnées barycentriques

$$x_1,\ x_2,\ x_3,\ x_0,\ \text{avec } x_0 = 100 - x_1 - x_2 - x_3.$$

Les coordonnées barycentriques caractérisent la composition du système P : $x_1\%-A$, $x_2\%-B$, $x_3\%-C$, $x_0\%-D$.

B. On a immédiatement les propositions suivantes, extensions naturelles de celles du triangle de Gibbs :

1°. *Substances pures.* Les points de coordonnées pseudo-affines

$$(100, 0, 0),\ (0, 100, 0),\ (0, 0, 100),\ (0, 0, 0)$$

sont, respectivement : A, B, C, D (fig. 3).

Les coordonnées barycentriques respectives sont : $A(100, 0, 0, 0)$, $B(0, 100, 0, 0)$, $C(0, 0, 100, 0)$, $D(0, 0, 0, 100)$. Evidemment A, B, C, D représentent les composants purs.

2°. *Systèmes binaires*

α) Les points de coordonnées pseudo-affines

$$(a, 0, 0),\ (0, b, 0),\ (0, 0, c),\ 0 < a, b,\ c < 100,$$

sont illustrés, respectivement, par E, F, G (fig. 3). Ils ont, respectivement les coordonnées barycentriques

$$E(a, 0, 0\ , d,)\ F(0, b, 0, d')\ G(0, 0, c, d''),$$

$$d = 100-a,\ d' = 100-b,\ d'' = 100-c$$

et représentent des systèmes binaires, comme il suit :

$$E(a\%-A,\ d\%-D),\ F(b\%-B,\ d'\%-D),\ G(c\%-C,\ d''\%-D).$$

β) Les points de coordonnées pseudo-affines

$$(a_1, b_1, 0), (0, b_2, c_2), (a_3, 0, c_3)\ a_1 + b_1 = 100, b_2 + c_2 = 100, a_3 + c_3 = 100$$

sont illustrés dans la figure 3, par H, I, J, avec les contours de coordonnées respectifs : $DH'H$, $DI'I$, $DJ'J$.

Voici l'explication du fait que H est situé sur l'arrête AB du pseudotétraèdre. De la relation $a_1 + b_1 = 100$, il résulte $b_1 = 100 - a_1$ et, en prenant : $DH' = a_1$ on a : $H'A = 100 - a_1 = b_1$. Le triangle DAB étant isoscèle, on a : $H'H = H'A = b_1$; il résulte que le point H est situé sur AB. De la même manière on démontre que I et J sont situés sur BC, respectivement AC.

Les coordonnées barycentriques des points H, I, J sont, respectivement :

$$H(a_1, b_1, 0, 0),\quad I(0, b_2, c_2, 0),\quad J(a_3, 0, c_3, 0).$$

Ces points représentent des systèmes binaires

$$H(a_1\%-A, b_1\%-B), I(b_2\%-B, c_2\%-C), J(a_3\%-A, c_3\%-C).$$

3°. *Systèmes ternaires.* α) Les points de coordonnées pseudo-affines

$$(a', b', 0),\quad (0, b'', c''),\quad (a''', 0, c'''),\quad a' + b' < 100,\ b'' + c'' < 100,$$
$$a''' + c''' < 100$$

sont illustrés, dans la figure 3, par K, L, M avec les contours de coordonnées respectifs : $DK'K$, $DL'L$, $DM'M$. En notant : $d' = 100 - a' - b'$, $d'' = 100 - b'' - c''$, $d''' = 100 - a''' - c'''$, les points K, L, M ont les coordonnées barycentriques

$$K(a', b', 0, d'), L(0, b'', c'', d''), M(a''', 0, c''', d''')$$

et représentent les systèmes ternaires

$$K(a'\%-A, b'\%-B, d'\%-D), L(b''\%-B, c''\%-C, d''\%-D),$$
$$M(a'''\%-A, c'''\%-C, d'''\%-D).$$

Les nombres d', d'', d''' sont représentés dans la figure 3 par les segments : $KQ = d'$, $LS = d''$, $MT = d'''$.

β) Un point de coordonnées pseudo-affines

$$(a, b, c),\ a + b + c = 100$$

est illustré, dans la figure 3 par P, avec le contour de coordonnées $DP'P''P$. Evidemment, ici $d = 0$ et les coordonnées barycentriques du point P sont :

$$P(a, b, c, 0)$$

Il représente un système ternaire

$$P(a\%-A,\ b\%-B,\ c\%-C)$$

Les points K, L, M, P sont situés sur les « faces » du pseudo-tétraèdre :

$$K - \text{sur } ABD,\ L - \text{sur } BCD,\ M - \text{sur } ACD,\ P - \text{sur } ABC$$

4°. *Systèmes quaternaires.* Le point de coordonnées pseudo-affines

$$(a, b, c),\ a + b + c < 100$$

est illustré dans la figure 3 par R, avec le contour de coordonnées $DR'R''R$. En notant $d = 100 - a - b - c$, ses coordonnées barycentriques sont (a, b, c, d). R représente un système quaternaire, avec la composition

$$R(a\%-A,\ b\%-B,\ c\%-C,\ d\%-D)$$

C. Tel qu'il résulte, le pseudo-tétraèdre constitue un *modèle géométrique* des divers systèmes binaires, ternaires et quaternaires, qu'on peut réaliser avec quatre substances.

Nous passons maintenant à la résolution de quelques problèmes typiques, extensions naturelles obtenues en partant du triangle de Gibbs.

1°. Etant donné un système ternaire, par exemple, $E(a\%-A, b\%-B, d\%-D)$ et la substance pure restée C, (fig. 4), les systèmes

$$R = E + C, \text{ avec } e\%-E,\ c\%-C,\ e + c = 100$$

sont des systèmes quaternaires avec la composition

$$R(a'\%-A,\ b'\%-B,\ c'\%-C,\ d'\%-D), \text{ tel que}$$

$$a'/a = b'/b = d'/d = e/100 \tag{4}$$

Les points R sont situés naturellement sur le segment CE, et

$$RC/RE = e/c,\ e + c = 100.$$

Les relations (4) résultent des couples de triangles semblables : CDE et RFE, DHE et DGF et les propriétés des suites de rapports égaux. Cette propriété est analogue à celle connue dans le triangle de Gibbs.[4]

Dans la figure 4 nous avons considéré les données suivantes : $E(40, 48, 0, 12)$, $e/c = RC/RE = 62{,}5/37{,}5$. Il a résulté, suivant les relations (4) : $a' = 40 . 62{,}5/100 = 25$, $b' = 30$, $d' = 7{,}5$ et ensuite $c' = 37{,}5$; les mêmes résultats peuvent être lis sur la figure 4 : $DG = 25$, $GF = 30$, $FR = 37{,}5$.

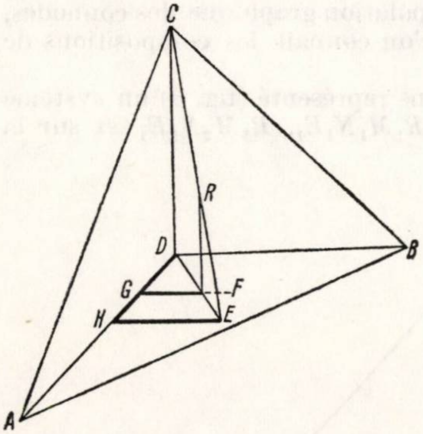

Fig. 4. — Système quaternaire obtenu d'un système ternaire et un composant pur.

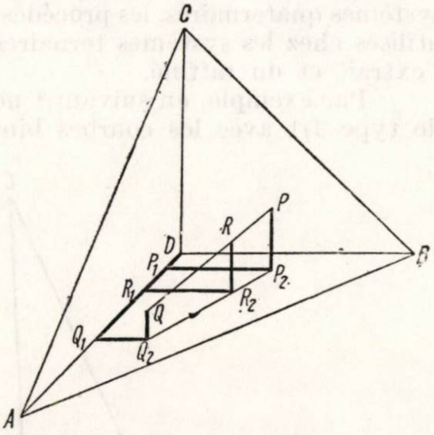

Fig. 5. — Système quaternaire obtenu de deux systèmes quaternaires.

2°. Etant donné deux systèmes (binaires, ternaires ou quaternaires) P et Q (fig. 5), un système R, obtenu de P et Q, pris dans le rapport $p/q (p + q = 100)$, est représenté dans le pseudo-tétraèdre, par un point du segment PQ, tel que l'on ait :

$$RQ/RP = p/q$$

propriété analogue à celle du triangle de Gibbs.[4]

Etant connu les compositions (a_1, b_1, c_1, d_1) et (a_2, b_2, c_2, d_2) de P et Q, et le rapport p/q, $(p + q = 100)$, on construit (fig. 5) les points P et Q avec les contours de coordonnées $D\,P_1P_2P$, $D\,Q_1Q_2Q$ et le point R sur le segment PQ ; afin de trouver graphiquement les coordonnées du point R, on mène $RR_2 \| DC$, $R_2 \in P_2Q_2$, $R_2R_1 \| DB$, $R_1 \in P_1Q_1$. Alors DR_1R_2R définit les coordonnées pseudo-affines du point R : $a = DR_1$, $b = R_1R_2$, $c = R_2R$; en prenant $d = 100 - a - b - c$, on a la composition (a, b, c, d) du système R.

Réciproquement, étant donné les systèmes P et Q dont les compositions sont connues et afin de réaliser avec P et Q un système R ayant une certaine composition $(a\% - A,\ b\% - B,\ c\% - C,\ d\% - D)$, il faut déterminer graphiquement les nombres p et q, tels que $R = (p\% - P) + (q\% - Q)$, $(p + q = 100)$. Dans ce but, on construit — de la manière décrite plus haut — les points P, Q, R en utilisant les coordonnées pseudo-affines respectives et, si le problème est possible du point de vue chimique, le point *R* sera situé sur le segment *PQ* et l'on aura : $p/q = RQ/RP$.

3°. Tout de même, dans les problèmes d'extraction liquide-liquide, on peut représenter assez exactement dans un pseudo-tétraèdre, les courbes binodales, la surface binodale et les courbes d'intersection de la surface binodale avec certains plans, ce qui permet de prolonger, aux systèmes quaternaires, les procédés d'interpolation graphique des connodes, utilisés chez les systèmes ternaires lorsqu'on connaît les compositions de l'extrait et du raffiné.

Par exemple, en suivant,[4] nous avons représenté (fig. 6) un système de type 4/1 avec les courbes binodales $R_1M_1N_1E_1$, $R_1M_2N_2E_1$ et sur la

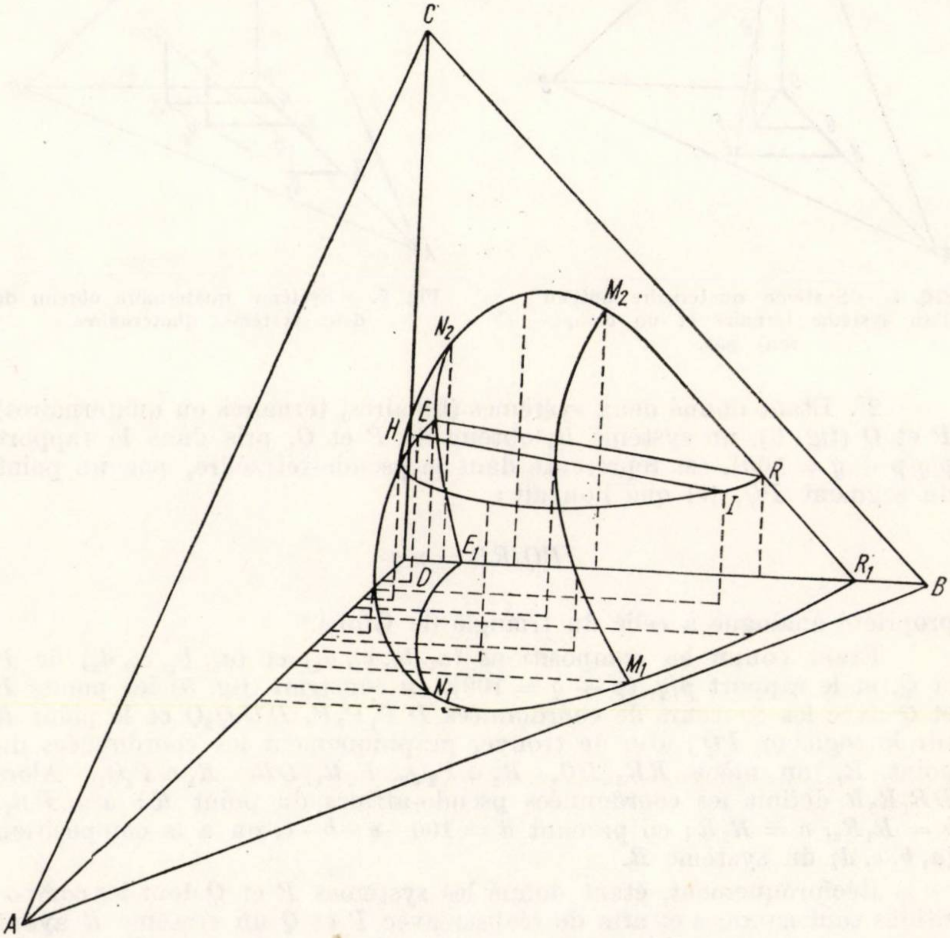

Fig. 6. — Courbes tracées sur une surface binodale.

surface binodale déterminée par elles — les courbes M_1M_2, N_1N_2, la section RIHE de cette surface par un plan et la connode *IH*. Mais tandis qu'un dessin habituel peut nous donner seulement une idée qualitative sur cette configuration, ici nous avons une représentation presque exacte, parce qu'on peut mesurer, sur le dessin, les coordonnées des divers points et faire des interpolations graphiques, on peut donc déterminer du dessin les points appartenant au domaine d'hétérogénéité, ainsi que les points appartenant au domaine d'homogénéité, ce qui nous peut dispenser d'un grand nombre d'expériences.

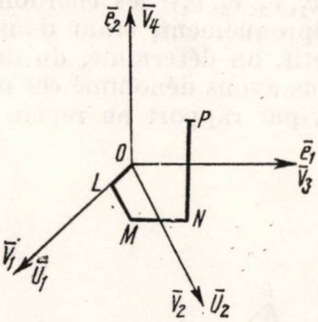

Fig. 7. – Repère d'un espace pseudo-affine à quatre dimensions construit dans un plan

D'ailleurs, ce que nous avons présenté plus haut contient les éléments suffisants pour la résolution graphique de tout problème concernant les systèmes quaternaires.

III. LE PSEUDO-PENTATÔPE QUI GÉNÉRALISE LE TRIANGLE DE GIBBS

Dans un plan rapporté à un repère $(0\,;\bar{e}_1, \bar{e}_2)$ (fig. 7) on considère les vecteurs $\bar{u}_1$, $\bar{u}_2$ donnés par :

$$\bar{u}_1 = a_1\bar{e}_1 + b_1\bar{e}_2,\ \bar{u}_2 = a_2\bar{e}_1 + b_2\bar{e}_2\,;\ \ a_1, a_2 \in R-Q, (a_1/a_2) \in R-Q$$

$$b_1, b_2 \in R \tag{5}$$

Dans la figure 7 nous avons pris : $\bar{u}_1 = (-6/\sqrt{75})\bar{e}_1 - (\sqrt{13/5})\,\bar{e}_2 \approx$ $\approx -\,0{,}69\ \bar{e}_1 - 0{,}72\ \bar{e}_2\,;\ \bar{u}_2 = (1/\sqrt{5})\ \bar{e}_1 - (2/\sqrt{5})\ \bar{e}_2 \approx 0{,}45\ \bar{e}_1 - 0{,}9\ \bar{e}_2$, c'est-à-dire $a_1 = -\ 6/\sqrt{75}$, $a_2 = 1/\sqrt{5}$, $a_1/a_2 = -\ 6/\sqrt{15}$ et donc : a_1, a_2, $(a_1/a_2) \in R-Q$.

Nous renotons ces vecteurs :

$$\bar{v}_1 = \bar{u}_1,\ \bar{v}_2 = \bar{u}_2,\ \bar{v}_3 = \bar{e}_1,\ \bar{v}_4 = \bar{e}_2 \tag{6}$$

Nous faisons une construction analogue à celle de l'espace pseudo-affine à trois dimensions et nous obtenons *l'espace pseudo-affine à quatre dimen-*

sions construit dans un plan ; $(0\,;\,\bar{v}_1, \bar{v}_2, \bar{v}_3, \bar{v}_4)$ est un repère de cet espace.* Etant donné un système ordonné de quatre nombres (x_1, x_2, x_3, x_4), $(x_1, x_2, x_3 \in Q,\ x_4 \in R)$, nous faisons le contour de coordonnées $OLMNP$ (fig. 7) : $OL = x_1$, $LM \| \bar{v}_2$, $LM = x_2$; $MN \| \bar{v}_3$; $MN = x_3$; $NP \| \bar{v}_4$; $NP = x_4$. Nous avons ainsi obtenu le point P, qui a, par rapport au repère $(0\,;\,\bar{v}_1, \bar{v}_2, \bar{v}_3, \bar{v}_4)$, les coordonnées x_1, x_2, x_3, x_4 avec $x_1, x_2, x_3 \in Q$, $x_4 \in R$. Réciproquement, étant donné le point P, avec le contour polygonal respectif, on détermine, du dessin, les nombres x_1, x_2, x_3, x_4. C'est pourquoi nous avons dénommé ces nombres les *coordonnées pseudo-affines* du point P, par rapport au repère $(0\,;\,\bar{v}_1, \bar{v}_2, \bar{v}_3, \bar{v}_4)$.[7]

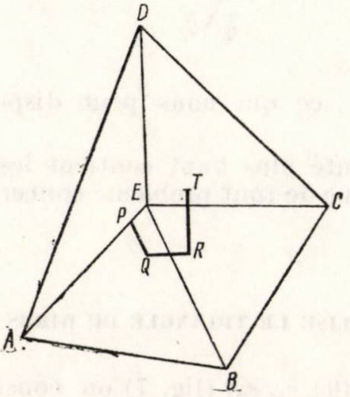

Fig. 8. – Représentation d'un système quinaire dans un pseudo-pentatôpe.

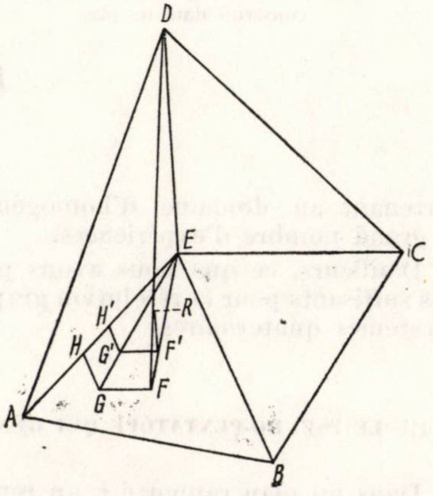

Fig. 9. – Système quinaire obtenu d'un système quaternaire et un composant pur.

Soit l'espace pseudo-affine à quatre dimensions construit dans un plan, rapporté à un repère (fig. 8) ayant E pour origine et $\bar{v}_1 = \dfrac{1}{100}\overrightarrow{EA}$, $\bar{v}_2 = \dfrac{1}{100}\overrightarrow{EB}$, $\bar{v}_3 = \dfrac{1}{100}\overrightarrow{EC}$, $\bar{v}_4 = \dfrac{1}{100}\overrightarrow{ED}$ pour vecteurs unité.

---

* Voici cette construction :

Nous considérons (fig. 7) $(0\,;\,\bar{v}_1, \bar{v}_2)$ comme un repère du plan et l'ensemble des points M du plan, $M = x_1\bar{v}_1 + x_2\bar{v}_2$, ayant, par rapport à ce repère, les coordonnées x_1, x_2, nombres rationnels. Par chacun de ces points M, on considère la droite parallèle à $\bar{v}_3$ (selon que nous avons déjà montré, ces droites sont distinctes) ; sur ces droites nous considérons les points N, donnés par : $N = x_1\bar{v}_1 + x_2\bar{v}_2 + x_3\bar{v}_3$, avec x_1, x_2, $x_3 \in Q$. Par chacun des points N on considère la droite parallèle à $\bar{v}_4$. Nous avons démontré que ces droites sont aussi distinctes. On considère sur ces droites tous les points P donnés par : $P = x_1\bar{v}_1 + x_2\bar{v}_2 + x_3\bar{v}_3 + x_4\bar{v}_4$ $(x_1, x_2, x_3 \in Q,\ x_4 \in R)$. L'ensemble des points P est un espace pseudo-affine à quatre dimensions construit dans un plan.

Considérons l'ensemble des points P donnés par

$$P = x_1\bar{v}_1 + x_2\bar{v}_2 + x_3\bar{v}_3 + x_4\bar{v}_4,\ x_1, x_2, x_3 \in Q,\ x_4 \in R,\ x_i \geqslant 0, \qquad i = 1, 2, 3, 4\ ;\ \sum_{i=1}^{4} x_i \leqslant 100. \tag{7}$$

Cette figure a été dénommée par nous *pseudo-pentatôpe*[7] ; elle constitue un *modèle géométrique* de divers systèmes qu'on peut réaliser avec cinq substances.

Précisons que la position d'un point dans le pseudo-pentatôpe est fixée par les quatre coordonnées pseudo-affines x_1, x_2, x_3, x_4 qui satisfont aux conditions (7) et que, afin de passer aux coordonnées barycentriques, on introduit une cinquième coordonnée, $x_0 = 100 - x_1 - x_2 - x_3 - x_4$. En notant les cinq coordonnées barycentriques par *(a, b, c, d, e), ces nombres expriment la composition du système,* $a\%-A$, $b\%-B$, $c\%-C$, $d\%-D$, $e\%-E$.

Le procédé de représentation d'un système par un point unique est le même que dans le pseudo-tétraèdre, c'est pourquoi nous allons nous résumer seulement au cas d'un système quinaire. Soit, donc, un système T ayant la composition : $a\%-A$, $b\%-B$, $c\%-C$, $d\%-D$, $e\%-E$, $a, b, c, d, e > 0$, $a + b + c + d + e = 100$. Alors on construit le contour de coordonnées $EPQRT$ (fig. 8) avec : $EP = a$, $PQ \| EB$, $PQ = b$; $QR \| EC$, $QR = c$; $RT \| ED$, $RT = d$. Réciproquement, étant donné dans le pseudo-pentatôpe le point T avec son contour de coordonnées, on détermine directement dans la figure les coordonnées et l'on a, ainsi, la composition du système T. En particulier, les points P, Q, R représentent respectivement : P — un système binaire ; $a\%-A$, $e'\%-E$ $(a + e' = 100)$, Q — un système ternaire : $a\%-A$, $b\%-B$, $e''\%-E$ $(a + b + e'' = 100)$, R — un système quaternaire : $a\%-A$, $b\%-B$, $c\%-C$, $e'''\%-E$ $(a + b + c + e''' = 100)$.

Reprenons certains types de problèmes analogues aux problèmes usuels chez les systèmes ternaires :

1°. Étant donné un système quaternaire, $F(a\%-A,\ b\%-B,\ c\%-C,\ e\%-E)$ et la substance pure D, (fig. 9) un système $R = F + D(f\%-F,\ d\%-D,\ f + d = 100)$ est un système quinaire de composition $R(a'\%-A,\ b'\%-B,\ c'\%-C,\ d'\%-D,\ e'\%-E)$, avec $a'/a = b'/b = c'/c = e'/e = f/100$ et le point R est situé sur le segment DF, tel que : $RF/FD = d/f$.

Réciproquement, étant donné un point R sur DF, il représente un système quinaire dont la composition s'obtient graphiquement en traçant le contour de coordonnées : la parallèle par R à DE coupe EF en F' ; la parallèle par F' à GF coupe EG en G' et la parallèle par G' à HG coupe EH en H'. Alors $a = EH'$, $b = H'G'$, $c = G'F'$, $d = F'R$ donnent la composition de R en ce qui concerne A, B, C, D ; le reste jusqu'à 100 est le nombre e, qui indique la composante E.

2°. Etant donné deux systèmes quinaires, représentés par les points

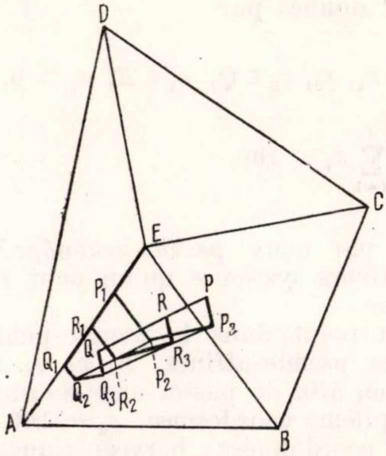

Fig. 10. — Système quinaire obtenu de deux systèmes quinaires.

P et Q (fig. 10), alors le segment PQ est le lieu géométrique des points R qui représentent les systèmes obtenus de P et Q, dans les proportions $p\%-P$, $q\%-Q$ $(p+q=100)$ où $p/q = RQ/RP$. Si $E\,P_1P_2P_3P$ et $EQ_1Q_2Q_3Q$ sont les contours de coordonnées des points P et Q, alors le contour de coordonnées de R est $ER_1R_2R_3R$, tel que l'on ait $R_1P_1/R_1Q_1 = R_2P_2/R_2Q_2 = R_3P_3/R_3Q_3 = RP/RQ = q/p$.

Il résulte que, si l'on connaît les compositions de P et Q et le rapport p/q on a directement, du diagramme, la composition de R et réciproquement, les compositions des systèmes P, Q et R étant connues, on détermine du diagramme, directement, le rapport p/q.

CONTRIBUTIONS TO THE STUDY OF THE $NiO-SiO_2-TiO_2$ TERNARY SYSTEM

CONST. GH. MACAROVICI * and MARIA ZAHARESCU **

* Institute of Chemistry, str. Donath 65–103, Cluj
** Centre of Physical Chemistry, str. Dumbrava Roșie 23, Bucharest

Received September 6, 1973

Studies were carried out on the reaction mechanisms and phase equilibrium relations in the $NiO-SiO_2-TiO_2$ system in the subsolidus field, starting from reactive mixtures obtained by quantitative coprecipitation.

The $MO-SiO_2-TiO_2$ type oxide systems (where M = transitional metal) have been investigated in a very reduced number of papers,[1,2] although their properties proved to be very interesting both from a theoretical and an applicative standpoint.[3-5]

Taking into account this fact, the present paper deals with the study of the $NiO-SiO_2-TiO_2$ ternary system, which, according to bibliographical data, has not been studied until now. However, there are numerous pieces of information referring to the component binary systems SiO_2-TiO_2, $NiO-SiO_2$, and $NiO-TiO_2$.

We shall present below the results of investigations made into the $NiO-SiO_2-TiO_2$ system, with regard to reaction mechanisms and phase equilibrium relations in the subsolidus field, starting from reactive mixtures obtained by quantitative coprecipitation.

Attempts to obtain reactive mixtures in systems containing NiO by precipitation from solution were previously reported.[6-10] However, some of these methods are not quantitative [6,7] and others make use of sodium hydroxide or carbonate[8-10] as a precipitation reagent, which is difficultly washed and disturbs the subsequent determinations.

The choice of quantitative coprecipitation in view of obtaining reactive mixtures in the system under consideration was due, in the first place, to the difficulties in obtaining a mixed complexation of Si^{4+} ion. On the other hand, by comparison to the method for obtaining mixed complex combinations,[11] which performed a homogenization at a molecular scale, but which are quantitative only for certain stoichiometric, well determined relations of the components, oxide mixtures in any proportion may be obtained through coprecipitation.

1. EXPERIMENTAL METHODS

1.1. QUANTITATIVE COPRECIPITATION

$Ni(NO_3)_2$, $TiCl_4$ and $SiCl_4$ solutions were used, having 0.5 m concentration and the precipitation reagent consisted of a 1 % dimethyl glyoxime alcoholic solution in ammoniacal medium.

The precipitation reagent for masses in the $NiO-TiO_2$, $NiO-SiO_2$ binary systems and in the $NiO-SiO_2-TiO_2$ ternary system had to be dimethylglyoxime since the common reagents, such as ammonia, ammonium carbonate, tetramine-hexamethylene, etc. do not precipitate Ni^{2+} quantitatively. Ammonia addition was necessary for establishing a weakly ammoniacal medium, indispensable for the formation of the $Ni-(C_4H_7N_2O_2)_2$ complex and also for the quantitative precipitation of Ti^{4+} as $TiO_2 . xH_2O$ and of Si^{4+} as $SiO_2 . xH_2O$.

$Ni(NO_3)_2$, $TiCl_4$ and $SiCl_4$ solutions were mixed in predetermined proportions and heated allowing to boil while continuously stirring. Dimethylglyoxime solution was then added and finally ammonia was added dropwise. Conditions were thus established for the concomitant precipitation of the three ions.

The completed precipitation was tested in the filtrate, using H_2O_2 in sulphuric acid medium for the identification of Ti^{4+} ion, dimethylglyoxime reaction for the Ni^{2+} ion, and for Si^{4+} ion, its reaction with $SnCl_2$ ammoniacal solution.[12]

It was found that under the above conditions, precipitation is quantitative for any ratio of the three components of the mixture.

The reddish-pink precipitate obtained was filtered, washed with distilled water until the Cl^- was freed and then dried at approx. 100°.

1.2. THERMOGRAVIMETRIC AND THERMODIFFERENTIAL ANALYSIS

The thermogravimetric and thermodifferential analysis of each separate coprecipitated sample was performed in order to observe the reaction mechanism of the studied mixtures from the precipitate to the oxide form. An OD-102 type Erdey-Paulik derivatograph was used, with a 5°/minute heating rate up to a temperature of 1000°.

1.3. CHEMICAL ANALYSIS

The chemical analysis of oxide masses resulting from the thermal treatment was based on the following reactions :

— SiO_2 insolubilisation, applying the classical HCl method[13];

[13] A. Lassieur, *Z. analyt. Chem.*, **72**, 160 (1927).

— Ti^{4+} reaction with H_2O_2 in sulphuric oxide medium and formation of peroxi-sulphate-titanium $TiO_2(SO_4)_2^{2-}$-complex anion, having a yellow-orange-brown colour, according to the concentration ;

— complexometric titration of Ni^{2+} with 10^{-2} m complexon III in presence of the murexide as indicator.[14]

1.4. DETERMINATION OF PHASE COMPOSITION

The phase analysis of unheated and thermally treated coprecipitated mixtures was carried out by applying the röntgenographic and IR-spectroscopic methods, the optical microscopy and electron microprobe analysis.

1.4.1. *The röntgenographic analysis* was performed on powders by the Debye-Scherrer method, using Cu_{K_α} radiation on a TUR M-60 apparatus.

1.4.2. *The microscopic analysis* was performed on powders and thin sections using the MC-1-type IOR research microscope and the MIN-5 polarizing microscope.

1.4.3. *The IR-spectroscopic analysis* was performed on a UR-10-type Zeiss apparatus in an 1800—400 cm^{-1} interval, applying the pelleting technique in KBr.

1.4.4. *The electron microprobe analysis* was carried out on cylindrical samples, having the size of approx. 8 × 8 mm and a polished surface similar to samples for metallographic studies, which was carbon metallized in view of preventing overheating and local overchanging. A JXA 3A Jeol apparatus was used at 16 kV electron acceleration voltage.

2. EXPERIMENTAL RESULTS

The oxide and equilibrium phase composition of the mixtures studied in the $NiO-SiO_2-TiO_2$ ternary system is presented in table 1.

2.1. COMPOSITION OF THE COPRECIPITATED MIXTURES

The röntgenographic and IR-spectroscopic analysis of the coprecipitated mixtures in the studied ternary system revealed that the quantitative coprecipitation of components takes place both in the case of binary and ternary mixtures.

The röntgenographic analysis permits the positive identification of the $Ni-(C_4H_7N_2O_2)_2$ complex in the mixture and also of the hydrated microcrystalline anatase by the presence of the principal characteristic diffraction lines of $Ni-(C_4H_7N_2O_2)_2$ and of the most pronounced line of the anatase (d = 3.520).

The occurrence of the hydrated microcrystalline anatase by precipitating Ti^{4+} ion with ammonia from a $TiCl_4$ solution by allowing to boil was reported in a previous work.[15]

The third component in precipitates, $SiO_2.H_2O$, is not crystallized and cannot be röntgenographically detected. Its presence in mixtures

2.2. REACTION MECHANISMS IN THE FORMATION OF DEFINED COMPOUNDS AND OF TERNARY OXIDE MIXTURES

2.2.1. NiO . TiO$_2$ formation

The mechanism of NiO . TiO$_2$ formation from coprecipitated mixtures was established in a previous work,[15] which highlighted the particularly important effect of coprecipitation on the reactivity of oxide mixtures in the NiO . TiO$_2$ system, manifested by a decrease of the temperature of the NiO . TiO$_2$ formation from over 1000° to 410°.

2.2.2. 2NiO . SiO$_2$ formation

The thermodifferential and thermogravimetric analysis curves of the coprecipitated mixture corresponding to the formation of 2NiO . SiO$_2$ are presented in figure 2.

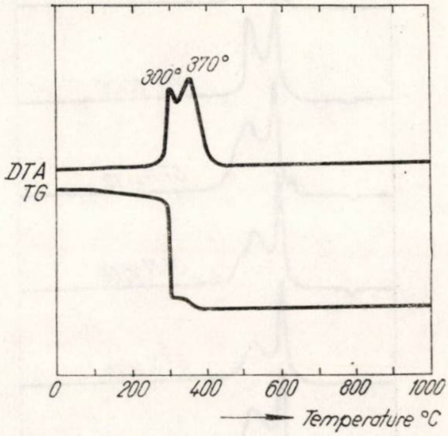

Fig. 2. — Thermogravimetric and thermodifferential analysis curves of the coprecipitated mixture corresponding to the 2NiO . SiO$_2$ formation.

The occurrence of two exothermic effects on the DTA curve is observed at 300 and 370° ; they are identical to those reported in the case of the decomposition of the Ni$-$(C$_4$H$_7$N$_2$O$_2$)$_2$ complex.[15] The appearance of other thermic effects up to 1000°, which would indicate a reaction between the two resulting oxides, has not been observed. This was also tested by röntgenographic approach.

In view of achieving the reaction between SiO$_2$ and NiO, the samples resulted after the thermogravimetric and thermodifferential analysis were compressed and maintained at a temperature of 1000° for prolonged time intervals. It was found that at this temperature 2NiO . SiO$_2$ formation was not completed even after a 96-hour thermal treatment, the presence of NiO and SiO$_2$ in significant amounts being röntgenographycally identified, alongside with 2NiO . SiO$_2$.

The result obtained is in agreement with the data from the literature which point to the low reactivity of NiO against SiO_2. [6, 17, 18]

At a temperature of 1400° a $2NiO.SiO_2$ formation was detected only after an hour of thermal treatment and was completed after 5 hours, while at a temperature of 1450° the complete reaction was already reached after one hour of thermal treatment.

The results presented indicate that in the case of the $NiO-SiO_2$ system, the effect of coprecipitation on oxides' reactivity is less obvious.

2.2.3. Formation of thernary oxide mixtures

The thermodifferential analysis curves of the principal ternary mixtures studied are presented in figure 3.

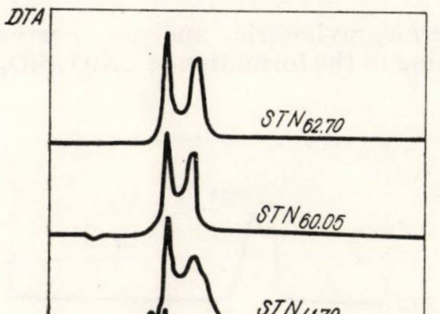

Fig. 3. — Thermodifferential analysis curves of the principal ternary mixtures coprecipitated in the $NiO-SiO_2-TiO_2$ system.

The review of these curves shows that they do not contain additional thermic effects, compared to those recorded for the formation of defined compounds in the case of binary mixtures.

---

[17] P. Tarte, *Spectrochim. Acta*, **19**, 25 (1963).

[18] H. Hayashi and S. Naka, *Nagoya Kogyo Shikensho Hohokoku*, **9**, 196 (1960); *Chem. Abstr.*, **54**, 10620 (1960).

A first conclusion, which has been röntgenographycally confirmed (table 1), is that no ternary compounds are formed under the conditions of the mentioned thermal treatment.

However, considering the very slow formation rate of $2NiO.SiO_2$ at a temperature of 1000°, it was estimated that the phases resulting from the thermal analysis are not equilibrium phases. Due to this fact, the same samples were compactly compressed and burnt again at 1000° for 24 hours. Neither in this case was the formation of ternary compounds revealed.

Results obtained by observing the formation of defined compounds in the $NiO-SiO_2-TiO_2$ ternary system at higher temperatures (1400°) were identical to those found after calcination at 1000°.

The absence of ternary compounds was verified by analysing the $STN_{21.76}$ mixture by means of electron microprobe.

By applying the semiquantitative method of the linear scanning of the electron fascicle after a direction, the variation of the TiO_2 concentration was found to be inverse to the variation of the SiO_2 concentration, which is indicative of the fact that no chemical bond was achieved between the two oxides through NiO, therefore the formation of a ternary compound is excluded (figure 4).

2.3. PHASE EQUILIBRIUM RELATIONS IN THE $NiO-SiO_2-TiO_2$ SYSTEM

In order to establish the phase equilibrium relations, the division of $NiO-TiO_2-SiO_2$ into coordination subsystems was studied, supposing that no ternary compounds exist.

The results of the röntgenographic analysis, indicated in table 1, confirmed the hypothesis that the two binary compounds coordinate as follows :

1. $NiO.TiO_2-SiO_2$
2. $NiO.TiO_2-2\,NiO.SiO_2$

dividing the $NiO-SiO_2-TiO_2$ ternary system into three subsystems :

I. $TiO_2-SiO_2-NiO.TiO_2$
II. $SiO_2-NiO.TiO_2-2NiO.SiO_2$
III. $NiO.TiO_2-2NiO.SiO_2-NiO$

The results concerning the phase equilibrium relations and the division of the system in paragenesis subsystems are presented in figure 5.

The conditions under which the ternary masses belong to these three paragenesis subsystems are defined by the equations presented in table 3.

Table 3

Belonging conditions of the ternary masses in the component subsystems of the $NiO-SiO_2-TiO_2$ system

Subsystem	Belonging conditions
I. $TiO_2-SiO_2-NiO.TiO_2$	$N - 0.946\,T < 0$
II. $SiO_2-NiO.TiO_2-2NiO.SiO_2$	$S - 1.3N + 63.22 > 0$
III. $NiO.TiO_2-2NiO.SiO_2-NiO$	$S - 1.3N + 63.22 < 0$

3. CONCLUSIONS

— A unique method was developed for quantitative coprecipitation with dimethylglyoxime and ammonia in view of obtaining initial oxide mixtures with a high reactive capacity in both the component binary systems and the $NiO-SiO_2-TiO_2$ ternary system.

— The formation of defined compounds was followed starting from the coprecipitate mixtures, establishing that no ternary defined compounds are formed in the $NiO-SiO_2-TiO_2$.

— Phase equilibrium relations were established in the ternary system in the subsolidus field by determining the coordination of the binary compounds and the division of the system into paragenesis subsystems.

Co(II) CHELATES WITH 1-METHYL-2-CARBETHOXY--GLYOXALANIL-(1)-TOLYLHYDRAZONES-(2)

A. C. BANCIU and P. SPACU

Centre of Chemical Physics, str. Dumbrava Roșie 23, Bucharest, Romania

Received October 26, 1973

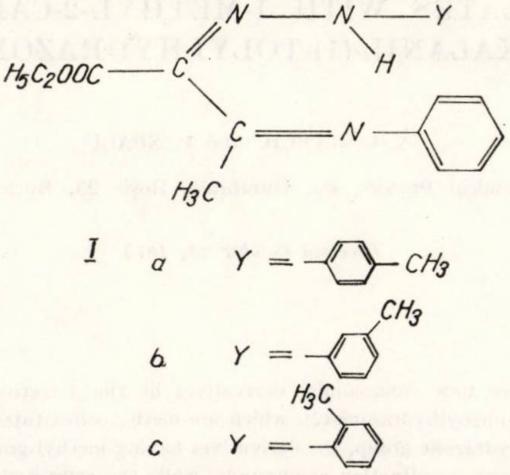
Among the three new compounds, derivatives of the 1-methyl-2-carbethoxy-glyoxalanil-(1)-phenylhydrazone-(2), which are methyl-substituted to the phenyl radical of the hydrazone group, the derivatives having methyl groups on *para* or *meta* position form coordination compounds, while the *ortho*-derivative does not coordinate the Co(II) ion. The elemental analysis data, IR and electronic spectra as well as magnetic measurement show that both obtained compounds are tetracoordinated chelates with tetrahedral structure, high spin ground state and a significant covalency degree of the metal-ligand bonds (nephelauxetic ratio $\beta \approx 0.75$).

In a previous paper [1] we have already described some new compounds from the class of the 1-methyl-2-carbethoxy-glyoxalanil-(1)-ariylhydrazones-(2), substituted on the *para*-position to the phenyl radical of the hydrazone group. It has been shown in that paper that all these compounds behave as bidentate chelate ligands, the Co(II) and Ni(II) complexes formed with the simplest compound in this class, namely the 1-methyl-2-carbethoxy-glyoxalanil-(1)-phenylhydrazone-(2) being studied there. It seems worthwhile to follow our investigations on the complexes formed by the substituted arylhydrazones having the same group attached in different positions of the phenyl radical, this kind of study being at least equally interesting as the discussions made on the complexes formed by *para*-substituted arylhydrazones with different substituents at the hydrazone phenyl (in the previous note [1] CH_3, OCH_3, NO_2, Cl and Br). It should be expected that besides the electronic effects, dependent on the substituent positions, the different steric hindrances produced by one and the same substituent attached to the phenyl radical gradually closer to the coordinating centres, should play a significant role.

---

[1] P. Spacu, A. C. Banciu and C. I. Lepădatu, *Rev. Roumaine Chim.*, **18**, *7*, 1143 (1973).

Besides the already described compound Ia,[1] this note presents, for this reason, the syntheses of the compound Ib and Ic :



and the preparation methods of the Co(II) complexes with all these three mentioned possible ligands.

EXPERIMENTAL

Reagents. Ethyl acetoacetate (Merck, reagent for synthesis, min. content 98 %), *p*-toluidine (Carlo Erba, min. content 99 %), *m*-toluidine (Schuchardt, *p.a.*), *o*-toluidine (Loba-Chemie, *p.a.*), anhydrous $NaCH_3COO$ (Austranal, *p.a.*), $CoCl_2 . 6H_2O$ (Reactivul, Bucharest, *p.a.*), $NaNO_2$ (Reactivul, Bucharest, *p.a.*).

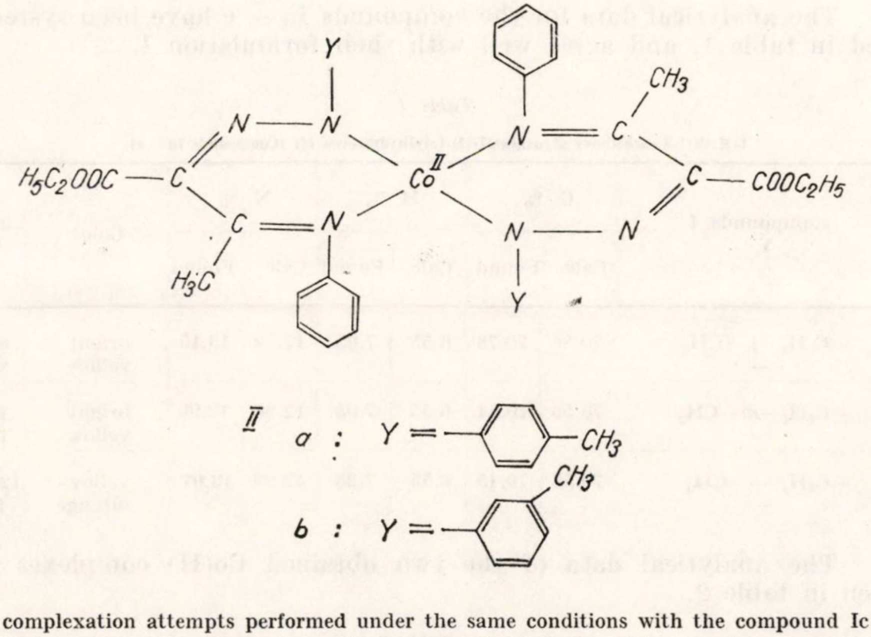
Synthesis of the compounds Ia – c has been similar to that already described,[1] starting from acetylacetic ester, by condensation with aniline. The compounds Ia – c were finally obtained from the resulting anil,[2] through azoic coupling reactions with solutions of the diazonium salts of toluidines, freshly prepared and instantly buffered with an addition of solid $NaCH_3COO$, brought up to pH = 3. All these products were separated as solidificated oils and after their drying on a porous plate, followed by repeated washings with small amounts of cooled methanol, they could be brought into the dried form, able to be recrystallized. After recrystallizations, performed from ethanol in the presence of charcoal, the pure compounds Ia – c were obtained, with scarce yields, of 12 %, 27 % and 20 % from the theoretical ones, respectively. The complexes were synthesized using the compounds thus obtained, but for their chemical analyses and the recording of their spectra, they were repeatedly recrystallized, the product being dried under vacuum on di-P_2O_5.

Preparation of chelates. Similar attempts were made to prepare the Co(II) chelates, as earlier emphasized,[1] under the conditions of refluxing alcoholic solutions of the reagents in the presence of small amounts of triethylamine (cca 1 ccm), using 1/100 m amounts of ligand and 1/200 m $CoCl_2 . 6H_2O$ plus an excess of 15 % from this theoretical value of the last reagent, in order to ensure the completeness of the reaction. After the reaction mixture cooling and the partial evaporation of the solvent, if the complexation has taken place dark blue, almost black-coloured crystals of complex were separated, impurified by products resulted from the ligand degradation (which are obviously of a lighter colour than the used ligand, i.e. yellowish instead of bright orange-yellow). This heterogeneous mass was repeatedly washed with 3 % acetic acid, warmed at 40°, in order to remove completely the unreacted Co(II) ions, two further recrystallizations being afterwards performed from alcoholic solutions in the presence of charcoal. If, after drying under vacuum on di-P_2O_5, the elemental analysis data showed a carbon content which surpassed the theoretical one with more than the experimental errors of the microcombustion, the recrystallization, drying and analyses were once more repeated.

---

[2] L. KNORR, *Ber. dtsch. chem. Ges.*, **20**, 1397 (1887).

When the compounds Ia and Ib were used as ligands, the complexes IIa and IIb were obtained :



The complexation attempts performed under the same conditions with the compound Ic did not lead to any result, since on cooling the reaction mixture this organic compound was entirely separated and therefore practically unreacted.

The elemental analyses of C, H and N were made by microcombustion. The Co amount was measured by disintegration with H_2SO_4 and H_2O_2 followed by precipitation as $Co(C_5H_5N)_4(SCN)_2$, according to G. Spacu.[3]

The absorption spectra of compounds were recorded on a VSU-2 Carl Zeiss (Jena) spectrophotometer on $0.5 \times 10^{-4} - 0.5 \times 10^{-3}$ mol/l solutions in absolute ethanol and acetone.

[3] G. SPACU and I. DICK, *Z. analyt. Chem.*, **71**, 97 (1927).

The reflectance spectra of the chelates were recorded on a VSU-1 Carl Zeiss (Jena) spectrophotometer using MgO as standard.

The IR spectra of the compounds were recorded within the 400–4000 cm^{-1} range by means of a UR-10 Carl Zeiss (Jena) spectrophotometer, using KBr pellets.

The magnetic susceptibilities were measured at the room temperature, according to the Faraday method, using $Hg[Co(NCS)_4]$ as standard. The magnetic moments were calculated from $\mu = 2.828\ (\chi'_M \cdot T)^{1/2}$, where : $\chi'_M = \chi_M - \chi_{dia}$ is the corrected molar susceptibility. In the case of both isomer chelates the diamagnetic correction was $\chi_{dia} = -366 \times 10^{-6}$ (c.g.s.u.).

RESULTS AND DISCUSSIONS

The analytical data for the compounds Ia – c have been systematized in table 1, and agree well with their formulation I.

Table 1

1-Methyl-2-carbethoxy-glyoxalanil-(1)-tolylhydrazones-(2) (Compounds Ia – c)

Compounds I Y	C %		H %		N %		Color	m.p. °C
	Calc.	Found	Calc.	Found	Calc.	Found

The analytical data of the two obtained Co(II) complexes are given in table 2.

Table 2

Co(II) chelates. Analytical data

Chelate	Co %		C %		H %		N %		m.p. °C
	Calc.	Found	Calc.	Found	Calc.	Found	Calc.	Found	
IIa	8.37	8.09	64.86	64.45	5.73	6.03	11.94	12.38	169–171
IIb	8.37	8.12	64.86	64.59	5.73	6.14	11.94	12.23	160–162

Based on these results and on the IR spectral data, the chelatic structural formulas IIa – b for these complexes have been ascribed.

The fact that these virtual ligands behave strikingly different, the compounds Ia and Ib being real chelatic bidentate ligands, while the compound Ic is deprived of the specific properties of such a ligand, shows us how much different may be the influence of the same substituent exerted on the complexation, as a function of its different position on the phenyl radical of the hydrazone group of the ligands, as earlier described. The fact that the CH_3 substituent in the *para* and *meta* positions does not markedly influence the Co(II) chelation, while the same substituent in the *ortho* position does brake it, may be explained only through steric hindrances induced in this last position. This is not surprising, if one takes into account the fact that in the *ortho* position the substituent is placed in the immediate neighbourhood of one the two donor nitrogen atoms in the molecule, as well as the fact that the CH_3 group, although much smaller than other substituents, is however relatively bulky, having (as a measure of its spatial extent) the van der Waals radius of cca 2 Å, greater than that of Cl (1.8 Å) and Br (1.95 Å) and only a little smaller than that of I (2.15Å).[4]

The IR spectra of one of the ligands, namely the 1- methyl-2-carbe ethoxy-glyoxalanil-(1)-*p*-tolylhydrazone-(2) (Ia), and of the corresponding Co(II) chelate (IIa) are systematized in table 3.

Obvious changes may be observed in the IR spectra of the ligand and the Co(II) chelate within 1280 – 1370 cm^{-1}. In this range of frequencies two bands of medium intensity, namely the first comprised between 1270 and 1340 cm^{-1}, with maxima at 1280, 1310 and 1330 cm^{-1}, and the second between 1365 and 1385 cm^{-1}, with a maximum at 1370 cm^{-1}, occur in the free ligand IR spectrum. Due to the perturbations caused by coordination, a single broadened band comprised between 1270 and 1390 cm^{-1}, with maxima at 1290, 1315, 1340 and 1360 cm^{-1} occurs in the Co(II) chelate IR spectrum, which is the most intense in the whole IR range of the chelate. It is well known that in the case of secondary aromatic amines ($C_6H_5 - NH -$) an absorption band appears in the region 1280 – 1350 cm^{-1} and in almost the same range (1310 – 1360 cm^{-1}) a strong band occurs in the case of tertiary aromatic amines ($C_6H_5 - N =$), both frequencies being produced by the C – N stretching vibration inside the amine groups.[5] Because of the coordination of the nitrogen atom from the hydrazone group, diretly attached to the phenyl radical, changes should be expected in the IR spectra of those absorption maxima ascribed to the vibration modes where the nitrogen atom was involved. It should be important to mention that in the range 1690 – 1720 cm^{-1} no other changes take place in the IR spectrum of the chelate compared with that of the free ligand. The intense band with a maximum at 1705—1710 cm^{-1} occurring in the IR spectra of both compounds is ascribed [5] to the ester group ($COOC_2H_5$). Its unmodified presence in the spectrum of the chelate shows this that group does not participate to coordination, even though this possibility could not be *a priori* excluded. If that group had played a certain role in coordination, its band would have been obviously shifted[5] to 1635 – 1665

cm^{-1}, but this is obviously not the case here. One may therefore conclude that the strong changes taking place in the region 1280 – 1370 cm^{-1} and the lack of any modifications within 1690 – 1720 cm^{-1} in the spectrum of the chelate, compared with that of the free ligand, show that the chelation takes place exclusively *via* nitrogen atoms, the esteric group playing no role, in agreement with the chemical formulations IIa and IIb for the Co(II) chelates.

The small differences between the bands in the absorption spectra of the chelates recorded on solutions (absolute ethanol and acetone) and in the reflectance spectra recorded on the solid state of the compounds, show that the chelate dissolution in the mentioned solvents is not accompanied by important structural changes (dissociations, etc.), the same molecular species being present either in solution or in solid state.

ELECTRONIC SPECTRA AND MAGNETIC PROPERTIES

The electronic spectra of the two chelates were recorded on acetonic solutions of $0.5 \times 10^{-4} - 0.5 \times 10^{-3}$ mol/l and they are plotted in figure 1.

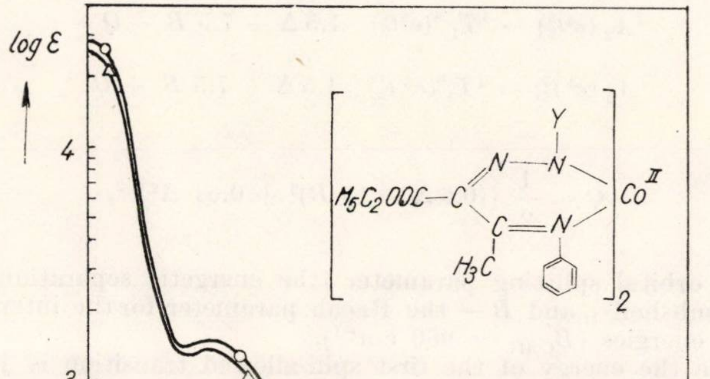

Fig. 1. — The visible and near IR spectra of the Co(II) chelates.

1, $Y = p-CH_3-C_6H_4$
2, $Y = m-CH_3-C_6H_4$

At the first sight one may observe that the differences between them are obvious but nevertheless small enough, and this fact shows that the CH_3 substituent placed at the phenyl radical of the hydrazone group exerts an influence only through its inductive effect, electron repellent, and only to a small extent on the spectral properties of the chelates. The absorption bands at 560 nm (17,860 cm^{-1}) and $\sim$ 1000 nm (10,000 cm^{-1}), which can be assigned to the d — d transitions proper to a d^7 tetrahedral configuration, are of chemical interest for the characterization of the metal-ligand bond.

The energetic expressions for the spin-allowed transitions for the d^7 (T_d) configuration obtained in a weak field coupling are as follows[6-8]:

$$^4A_2\,(e^4t_2^3) \rightarrow {}^4T_2\,(e^3t_2^4) \quad \Delta$$

$$^4A_2\,(e^4t_2^3) \rightarrow {}^4T_1{}^{a}(e^3t_2^4) \quad 1.5\,\Delta + 7.5\,B - Q$$

$$^4A_2\,(e^4\,t_2^3) \rightarrow {}^4T_1{}^{b}(e^3\,t_2^4) \quad 1.5\,\Delta + 7.5\,B + Q$$

where :

$$Q = \frac{1}{2}\,[(0.6\,\Delta - 15\,B)^2 + 0.64\,\Delta^2]^{1/2},$$

Δ is the orbital splitting parameter (the energetic separation between t_2 and e subshells), and B — the Racah parameter for the interelectronic repulsion energies ($B_{Co(II)} = 980\ cm^{-1}$).

Since the energy of the first spin-allowed transition is just equal to Δ, taking into account that $\Delta_{T_d} = 4/9\ \Delta_{O_h}$ and $\Delta_{O_h} = 10{,}000 - 15{,}000$ cm^{-1} (a relationship also valid in the framework of LCAOMO theory[9]) it results that this transition must occur in infrared, beyond the measuring possibility of the used instrument.

The two absorption bands appearing in spectrum may therefore be attributed to the other spin-allowed transition, as follows :

$$\nu_2\ ({}^4A_2 \rightarrow {}^4T_1{}^{a}) = 9{,}800\ cm^{-1}\ \text{for both chelates}$$

$$\nu_3\ ({}^4A_2 \rightarrow {}^4T_1{}^{b}) = 17{,}700\ cm^{-1}\ \text{for chelate IIa}$$

$$= 17{,}860\ cm^{-1}\ \text{for chelate IIb.}$$

Solving the energetic expressions for these transitions, one obtains the values :

$$\Delta = 5{,}550\ cm^{-1}\ \text{for chelate IIa,}$$

$$= 5{,}540\ cm^{-1}\ \text{for chelate IIb}$$

---

[7] Y. TANABE and S. SUGANO, *J. Phys. Soc. Japan*, **9**, 753 (1954).

[8] E. KÖNIG, *Struct. and Bonding*, **9**, 175 (1971).

[9] H. H. SCHMIDTKE, *Z. Naturforsch.*, **19a**, 1502 (1964).

and with these quantities,

$$B = 720\ \text{cm}^{-1} \text{ for chelate IIa}$$

$$= 740\ \text{cm}^{-1} \text{ for chelate IIb}$$

and

$$\beta = \frac{B}{B_0} = 0.74 \text{ for chelate IIa}$$

$$= 0.75 \text{ for chelate IIb.}$$

The Δ and *B* values thus obtained reproduce the absolute values of the absorption maxima and the differences between them.

One observes that a small, hardly detectable spectral shift, of 5 nm, of the ν_3 transition, i.e. from 565 to 560 nm going from the chelate IIa to the IIb one, reflected in a shift of 160 cm^{-1} of the wavenumbers, does not practically lead to any modification of the Δ value, but to a 20 cm^{-1} change in the *B* value (740 cm^{-1} instead of 720 cm^{-1}) which affects the β value with one centesimal digit (0.75 instead of 7.44). This fact may be directly seen in the formula according to which the *B* parameter was estimated :

$$B = \frac{(\nu_2 + \nu_3)/2 - 1.5\,\Delta}{7.5}$$

where, besides the value — in our case practically constant — of the Δ parameter, there is the half sum of ν_2 and ν_3 wavenumbers.

It is important to see whether these slight differences in the *B* and β values have any significance, or whether they are included with in the limit of the experimental errors. For this reason, the electronic spectra of both chelates were recorded on solutions of absolute ethanol and the spectrum of the unsubstituted chelate of type I ($Y = C_6H_5$), earlier described,[1] was also recorded on acetonic solutions. The band positions, their intensities as well as the Δ, *B* and β values calculated for these bands are summarized in table 4.

One may observe that, due to a scarce solvent effect, the ν_3 band is sometimes moved with 5 nm (cca 160 cm^{-1}), even for the same complex, when its spectrum is recorded on solutions of different solvents. Because of the high width of the ν_2 band, the estimation of its maximum position implies an error of 20 nm, i.e. cca 200 cm^{-1} for this band. For these reasons, differences of about 20 cm^{-1} in the B values appearing even for the same complex lead to an estimation error of the nephelauxetic ratio β of one figure in the second decimal. One may therefore conclude that the small differences found in the *B* and β values do not overpass the limit of the experimental errors and therefore, the influence of the CH_3 substituent attached in *pata* and *meta* positions to the phenyl radical bound to the

nitrogen donor atom may be practically ignored, at least as far as the increasing of the covalency degree of the complexes is concerned. In our opinion this fact is worth being mentioned, having in view other reported papers and monographs where the nephelauxetic ratio β values are sometimes given with three exact figures (see, for instance, reference 6, p. 324, where for the tetrahedral $CoBr_4^{2-}$ ion β is given to be equal to 0.714).

Mention should also be made (see table 4) of the obvious hyperchromic shift of the two bands ν_2 and ν_3 in the spectra of the same compounds when the solvent is changed from ethanol to acetone. This fact shows, in our opinion, that the tempting proposal advanced by Cotton and Soderberg,[10,11] to plot in two dimensions the covalency degree of the tetrahedral Co(II) complexes, must be carefully regarded. According to these authors, taking on the ordinate axis the quantity $\Delta B(= B_{\text{free}}$ ion$- B_{\text{complex}}$ ion) and on the abscissa axis the oscillator strength of the ν_3 band, all tetrahedral Co(II) complexes may be represented by points, those placed up to the right corner being the strongest covalent. The hyperchromic shifts of the absorption bands, due to the solvent effects mentioned above, show how different the calculated value as well as the graphical representation of the oscillator strength of the ν_3 transition can be and therefore how inexact is its position on the abscissa, even for the same complex. An eventual comparison should be made only for absorption spectra recorded on solutions using the same solvent. More exact is therefore the β value as covalency measure, the solvent effects acting insignificantly on its value, as only one unit to the second decimal, in our case.

The Δ quantity, spectrally determined, may be used to estimate the orbital contribution term of the magnetic moment value. For the d^7 tetrahedral high spin configuration, the magnetic moment may be evaluated from the formula [12,13]:

$$\mu = \left(\mu_s - 15.59\frac{\lambda}{\Delta}\right) \text{BM}$$

where: $\lambda = -178$ cm^{-1} is the spin-orbit constant, Δ is the orbital splitting parameter and $\mu = 3.89$ BM is the spin only contribution to the value of the magnetic moment. Using the value $\Delta = 5{,}550$ cm^{-1}, practically found for both complexes, one finds that the $(-15.59\lambda / \Delta)$

[13] F. A. Cotton and M. Goodgame, *J. Amer. Chem. Soc.*, **83**, 1777 (1961).

quantity is of about 0.5 BM, and therefore the magnetic moment calculated for both complexes is 4.39 BM.

It has been experimentally found:

$$\mu = 4.31 \pm 0.08 \text{ BM for the chelate IIa}$$
and
$$\mu = 4.37 \pm 0.08 \text{ BM for the chelate IIb},$$

which are in good agreement with that spectrally evaluated. The agreement between the spectral and magnetic properties allow us to assign to the Co(II) — nitrogen bonds a preponderant tetrahedral arrangement in the case of both Co(II) chelates herein studied.

Received September 11, 1973

The paper presents new complex compounds of Pt(II) with thioamides of the phenylthioacetamide series and with unsaturated aromatic thioamides. These are of a Pt L_2Cl_2 type (L = phenylthioacetamide, *o*-tolylthioacetamide, 2,5-dimethylphenylthioacetamide, cynamthioamide and *p*-methoxycynamthioamide) and of a Pt L Cl_2 type (L = diphenylthioacetamide). The substances are characterized based on the results of the chemical analysis and also of UV, visible and IR spectra. Assignments of absorption bands are made on the basis of electronic reflexion spectra which show that they have a plane-square disposition belonging to the symmetry group D_{4h}.

Recent studies [2-7] have investigated the capability of thioamides to function as ligands to central metal ions with a pronounced class character (b), such as Cu(I), Hg(II), Pd(II), Pt(II), as well as in the case of certain metal ions with a less pronounced class character (b), such as Co(II), Ni(II), Cu(II). Ray and Sathyanarayana [2] have studied N,N-dimethylthioacetamide as a ligand, illustrating by IR spectral analysis that in complex compounds with Co(II), Cu(I) and Hg(II) both C : S and C — N groups are involved in the bond.

A similar conclusion was reached in the previous papers [1,8-10] which reported the results of the study performed on ion complex compounds of class (b) : Hg(II) and Pd(II) with thioamides.

In this paper, we present the results of chemical and physico-chemical investigations into the complex compounds of a different metal ion, a typical representative of class (b), Pt(II) with thioamides belonging to phenylthioacetamide series : phenylthioacetamide (FTAA), *o*-tolylthioacetamide (OTTAA), 2,5-dimethylpenylthioacetamide (DMFTAA), diphenylthioacetamide (DFTAA), and with two unsaturated thioamides : cynamthioamide (CTA) and *p*-methoxycynamthioamide (MCTA). [10,11]

RESULTS AND DISCUSSION

Platinum (II) complex compounds with these thioamides are microcrystalline, stable powders coloured in various yellowish-orange shades, difficultly or partially soluble in inorganic and organic solvents, having higher melting points than the corresponding ligands. They were prepared by adding a thioamide ethanol solution to the solution of platinum dichloride in a weakly acidic medium.

The elementary chemical analysis of complexes presented in table 1 leads us to the following formulations :

$Pt\ L_2Cl_2$ (L = FTAA, OTTAA, DMFTAA, CTA, MCTA)

$Pt\ L\ Cl_2$ (L = DFTAA)

Table 1

Chemical analysis of Pt(II) complexes with thioamides

Compound	S %		C %		H %		Formula *	Colour
	Calc.	Exp.	Calc.	Exp.	Calc.	Exp.		
Pt(II)–FTAA	11.33	12.14	34.03	35.82	3.18	3.63	$Pt\ L_2\ Cl_2$	yellow
Pt(II)–OTTAA	10.76	11.35	36.32	37.95	3.69	4.12	$Pt\ L_2\ Cl_2$	yellowish-orange
Pt(II)–DMFTAA	10.24	9.87	38.41	39.55	4.16	4.73	$Pt\ L_2\ Cl_2$	yellowish-orange
Pt(II)–DFTAA	6.48	7.29	34.06	35.28	2.64	3.64	$Pt\ L\ Cl_2$	yellowish-orange
Pt(II)–CTA	10.80	9.93	36.47	38.11	3.03	4.10	$Pt\ L_2\ Cl_2$	orange
Pt(II)–MCTA	9.80	10.24	36.77	38.42	3.67	3.60	$Pt\ L_2\ Cl_2$	orange

*L = ligand

A good agreement is observed with the results presented in the case of complex compounds of Pd(II) with the same thioamides.[10]

In order to be able to refer to the nature of the chemical bond achieved in these complex compounds we systematized in specific domains the results of the IR spectral analysis both for ligands [11,12] (table 2) and for the corresponding complexes with Pt(II) (table 3).

i = intense, m = medium, w = weak, sh = shoulder

The arguments concerning the achievement of the bond by the sulphur atom of the thioketo group are materialized by:

a) the modification of the band at 1220 cm^{-1}, which expresses a significant contribution of the C : S bond, appearing pronouncedly less intense or even levelled off in complexes;

b) the disappearance, in complexes, of the intense band in the 550 – 680 cm^{-1} region of the thioamide spectrum, this being generally attributed to vibration C : S.

The evidence concerning the participation of nitrogen of the thioamide group in the achievement of the bond is materialized by the following:

a) in the 3500 – 3000 cm^{-1} region, the bands characteristic of ν NH$_2$ sym. and ν NH asym. appear in complexes at modified frequencies compared to the respective thioamides, and much weaker;

b) the characteristic band of the stretching vibration of group NH$_2$ in the 1650 – 1600 cm^{-1} range appears to be situated at slightly higher frequencies in complexes, but with a variable intensity;

c) the band at $\sim$960 cm^{-1} attributed to the stretching vibration of group NH$_2$, in complexes, is reduced or totally disappears, except for complexes with CTA and MCTA in which the band at 970 cm^{-1}, typical of the unsaturated group  $\underset{\mathrm{H}}{>}\mathrm{C}=\mathrm{C}\overset{\mathrm{H}}{<}$, is maintained.

It has thus been concluded that the chemical bond implies in these complex combinations the participation of both a sulphur atom and a nitrogen atom of the thioamide group.

In view of completing our study on these complexes we achieved electronic reflexion spectra in solid powder in the UV and visible domain (figures 1, 2, 3).

We made the assignments of bands in the electronic spectra of the studied complexes on the basis of Gray and Ballhausen's article[13]; they applied the method of molecular orbitals to explain the spectra of plane-square metal complexes of the elements belonging to configuration d^8. In this case, the authors[13] proposed the following succession of orbitals 5 d : (d_{xz}, d_{yz}), d_{z^2}, d_{xy} and $d_{x^2-y^2}$, in contrast to Chatt et al.[14] and, lately, Martin et al.[15] who suggested the succession: d_{z^2}, (d_{xz}, d_{yz}), d_{xy}, $d_{x^2-y^2}$.

The correlation of bands observed in the electronic spectra of platinum (II) complexes with those of Pt Cl$_4^{2-}$ prompts us to assume the following assignments:

a) the band at 30,303 cm^{-1} (330 nm), appearing in complexes, is attributed to transition $^1A_{1g} \rightarrow {}^1E_g$;

b) the band at 25,640 cm^{-1} (390 nm), appearing in complexes, is attributed to transition $^1A_{1g} \rightarrow {}^1B_{1g}$;

[13] H. B. Gray and C. J. Ballhausen, *J. Amer. Chem. Soc.*, **85**, 260 (1963).

[14] J. Chatt, G. A. Gamlen and L. E. Orgel, *J. Chem. Soc.*, **1958**, 487.

[15] D. S. Martin, M. A. Tucker and A. J. Kassman, *Inorg. Chem.*, **1965**, 1682.

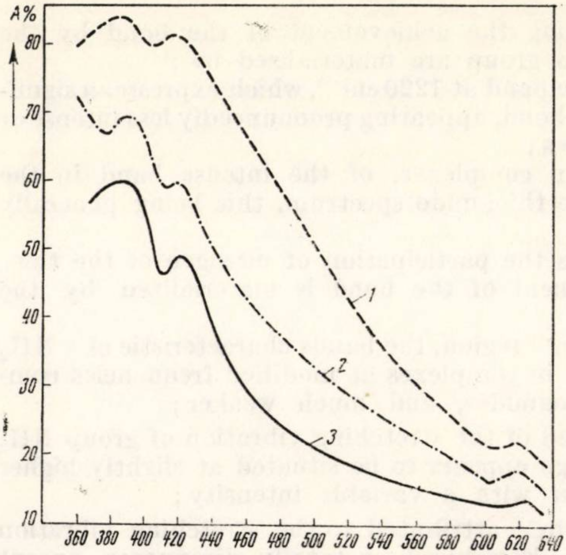

Fig. 1. — Visible electronic reflexion spectra of Pt(II) complexes with CTA (1), DMFTAA (2), and DFTAA (3).

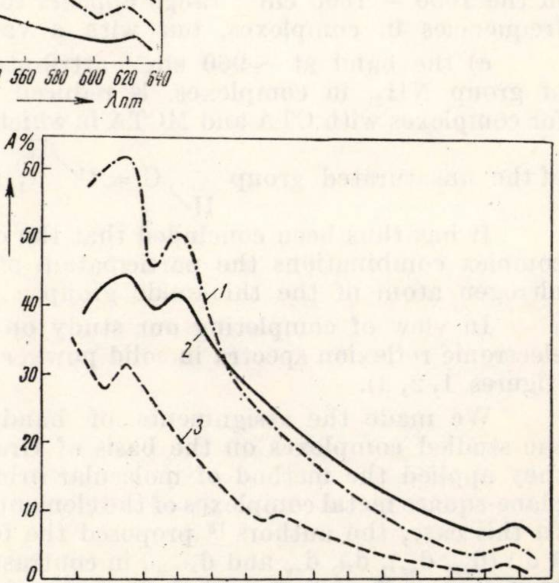

Fig. 2. — Visible electronic reflexion spectra of Pt(II) complexes with OTTAA (1), MCTA (2), and FTAA (3).

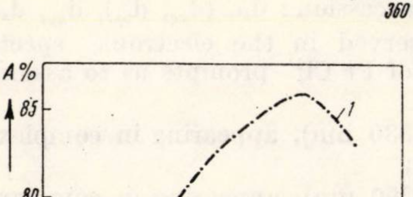

Fig. 3. — U.V. electronic reflexion spectra of Pt(II) complexes with CTA (1) and MCTA (2).

c) the band at 23,800 cm^{-1} (420 nm) or 20,830 cm^{-1} (480 nm) in complexes is attributed to transition $^1A_{1g} \rightarrow {}^1A_{2g}$;

d) the shoulder at 16,129 cm^{-1} (620 nm) in complexes is attributed to transition $^1A_{1g} \rightarrow {}^3A_{2g}$.

The correspondence of these four bands observed in the prepared complexes, with the bands described for $Pt\,Cl_4^{2-}$ makes us conclude that these have an analogous symmetry with $Pt\,Cl_4^{2-}$ and hence they are plane-square, belonging to the symmetry group D_{4h}.

EXPERIMENTAL

Reagents: an aqueous solution, acidulated with HCl of platinum dichloride and thioamide ethanol solutions.

IR spectra were recorded on a 157 Perkin Elmer device in an anhydrous KBr pellet.

The electronic spectra in the UV and visible domain were taken on a VSU_1 Zeiss-Jena spectrophotometer, in a MgO pellet.

PREPARATION OF COMPLEXES

Dichlorobisphenylthioacetamide-Pt(II) The phenylthioacetamide ethanol solution is added to the platinum dichloride hydrochloric solution while continually stirring so as to have a 1 : 2 molar ratio. A yellowish-orange precipitate is observed to appear immediately thereafter, which is allowed to stand for an hour. It is then filtered through a porosity filter G_4, washed with alcohol and ether and dried under vacuum.

The aspect of complexes is that of a microcrystalline powder of a yellowish-orang colour in various shades, which is stable over time and presents a reduced solubility in inorgani and organic solvents.

The other complexes have been prepared in a similar manner.

CONCLUSIONS

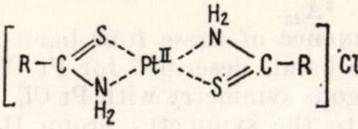
Pt(II) complex compounds with aromatic thioamides described in this paper are of the type:

$Pt\,L_2\,Cl_2$ (L = FTAA, OTTAA, DMFTAA, CTA, MCTA)

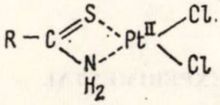
$Pt\,L\,Cl_2$ (L = DFTAA)

By correlating the data of the chemical analysis with the study of IR spectra which provide arguments on the achievement of the chemical bond both by a sulphur and by a nitrogen atom of the thioamide group, it results that the following structural formulations are possible:

PtL_2Cl_2



$PtLCl_2$



It has been observed that thioamides participate in all these complexes under the form of "thioketo".

Diphenylthioacetamide is the only ligand in this series which generates complexes of the type $M^{II} L Cl_2$, in which M^{II} may be Hg[9], Pd[10] and Pt. The binding of only one single thioamide molecule is explained by its high volume which would produce steric hindrances.

The UV and visible electronic reflexion spectra of the studied complexes prompt us to conclude that they have a plane-square disposition belonging to the symmetry group D_{4h}.

Revue Roumaine de Chimie, 19, 6, 1039–1044 (1974)

SUR LES COMPOSÉS D'ADDITION DU TÉTRACHLORURE DE THORIUM AVEC DES AZOMÉTHYNES

D. NEGOIU, ANGELA KRIZA et MARTHA NASTA

Université de Bucarest, Faculté de Chimie, Chaire de Chimie inorganique, 89, Splaiul Independenţei

Reçu le 2 octobre 1973

On a obtenu et étudié six nouveaux composés du tétrachlorure de thorium et des bases Schiff aromatiques. Les données de l'analyse élémentaire, ainsi que l'étude des spectres IR et électroniques nous permettent de conclure que les composés obtenus sont des complexes moléculaires du type $ThCl_4.2SBH$.

Dans la littérature on trouve peu de données sur la synthèse et l'étude des composés du thorium avec des bases Schiff. En 1964, Kogan, Osipov et Garnovski [1] ont obtenu quelques dérivés du tétranitrate de thorium et de la salicylal-aniline et de ses dérivés. Quoique les bases Schiff soient des ligands capables de former des complexes internes, les composés obtenus sont du type complexes moléculaires.

En 1957, Garnovski et collaborateurs ont publié une étude plus détaillée [2] sur quelques composés du titane (IV), de l'étain (IV) et du thorium avec des azométhynes dont la molécule comprend, à part l'azote azométhynique, d'autres atomes d'azote : —aminique, pyridinique, etc., comme centres donneurs.

Un travail plus récent [3] s'occupe de la synthèse des composés complexes internes du thorium avec des salicylaldimines. Les études par spectres IR, électroniques et RMN plaident dans un certain sens pour la formation des composés Chelates.

Tenant compte de ces données sur la chimie coordinative du thorium nous nous sommes intéressés au problème de la synthèse des complexes moléculaires de ce métal avec une variété plus large de bases Schiff dont la molécule contient le groupement hydroxyle.

RÉSULTATS ET DISCUSSIONS

La synthèse des composés a été faite par la réaction directe du tétrachlorure de thorium et de la base Schiff par rapport molaire 1 : 2.

---

Tenant compte de la sensibilité à l' humidité du tétrachlorure de thorium et des composés obtenus, surtout en solution, toutes les opérations de synthèse, de séparation et de purification de ces composés ont été accomplies dans des conditions d'élimination totale de l'humidité atmosphérique, dans des solvants rigoureusement anhydrisés.

En employant l'éthanol comme solvant par rapport à la séparation des composés nous avons rencontré certaines difficultés, les composés étant solubles.

Les composés obtenus, ainsi que les résultats de l'analyse élémentaire sont indiqués dans le tableau 1.

En ce qui concerne les composés obtenus à partir de la salicylal-*o*-toluidine et de la salicylal-*o*-anisidine, le produit solide s'est formé seulement après l'élimination, par distillation, de l'éthanol et l'addition d'une petite quantité de benzène anhydre.

Les composés se présentent sous forme de cristaux, colorés, stables à l'air, insolubles dans le tétrachlorure de carbone, l'éther, mais présentant une certaine solubilité dans les alcools ; le point de fusion des complexes est au-dessus de 200°, avec décomposition. Le composé obtenu à partir de la benzal-*p*-toluidine présente une stabilité moindre que ceux provenant des salicylal-arylamines.

Les composés du thorium sont beaucoup plus stables que ceux du titane et même de l'étain.

Les résultats des analyses prouvent que les composés du tétrachlorure de thorium avec des bases Schiff aromatiques sont du type : $ThCl_4.2SBH$. On a aussi essayé de détecter l'acide chlorhydrique qui pourraît être mis en liberté par suite de la réaction. Par suite de l'absence des traces d'acide chlorhydrique dans les gaz de réaction et dans le filtrat on a conclu qu'au cours des synthèses il ne se dégage pas de l'acide chlorhydrique.

Par conséquent, on peut conclure que dans les conditions de synthèse rigoureusement établies les composés obtenus sont des complexes moléculaires du type donneur-accepteur. Donc, les composés obtenus à partir des salicylal-arylamines et du tétrachlorure de thorium ne contiennent pas une liaison Th — O. Le simple fait qu'on a pu obtenir le composé avec de la benzal-*p*-toluidine, ligand qui ne contient pas le groupement hydroxyle, prouve que, pour ce type de ligands la formation des complexes peut avoir lieu sans la participation du groupement —OH.

Pour établir le type de liaison des complexes on a étudié les déplacements de certaines bandes d'absorption dans les spectres IR des composés par rapport à ceux des ligands.

Par exemple, la figure 1 présente les spectres IR des composés avec de la salicylal-*o*-toluidine et de la salicylal-*p*-anisidine, ainsi que les spectres IR des ligands respectifs.

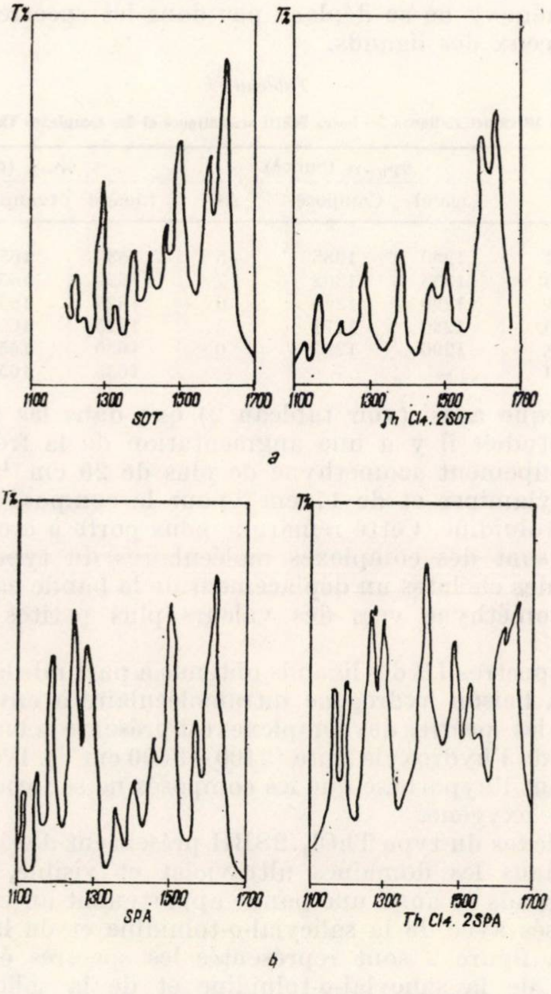

Fig. 1 a) — Spectres IR de la salicylal-*o*-toluidine et du composé $ThCl_4$. 2SOT.
b) — Spectres IR de la salicylal-*p*-anisidine et du composé $ThCl_4$.2SPA.

Dans la littérature on indique pour le groupement phénoxy-une bande caractéristique à 1285 cm^{-1}. Dans les spectres des ligands qui contiennent ce groupement on trouve une bande caractéristique à 1290 ± ± 5 cm^{-1} (tableau 2). Si les complexes étaient formés par l'intermédiaire de la liaison Th — O la bande de 1290 cm^{-1} devrait être déplacée avec environ 50 cm^{-1} vers des fréquences plus hautes, pour les composés avec des salicylalarylamines. Dans le cas des composés obtenus les variations de la fréquence caractéristique du groupement phénoxy sont très petites : ± 5 cm^{-1}. On peut donc conclure, que, pratiquement, la fréquence du groupement phénoxy ne se déplace pas dans les spectres des complexes par rapport à ceux des ligands.

Tableau 2

Bandes IR caractéristiques des bases Schiff aromatiques et des complexes $ThCl_4.2SBH$

Composé	ν_{Ph-O} (cm^{-1})			$\nu_{C=N}$ (cm^{-1})		
	Ligand	Composé	$\Delta\nu$	Ligand	Composé	$\Delta\nu$
$ThCl_4$. 2SOT	1290	1285	−5	1630	1650	+20
$ThCl_4$. 2SMT	1295	1302	+7	1629	1650	+21
$ThCl_4$. 2SPT	1290	1290	0	1625	1650	+25
$ThCl_4$. 2SOA	1280	1275	−5	1625	1650	+25
$ThCl_4$. 2SPA	1290	1290	0	1630	1650	+20
$ThCl_4$. 2BPT	—	—	—	1635	1652	+17

On remarque aussi (voir tableau 2) que dans les spectres de tous les composés étudiés il y a une augmentation de la fréquence caractéristique du groupement azométhyne de plus de 20 cm^{-1} pour les dérivés des salicylal-arylamines et de 17 cm^{-1} pour le composé obtenu à partir de la benzal-*p*-toluidine. Cette remarque nous porte à croire que les composés obtenus sont des complexes moléculaires du type : $ThCl_4.2SBH$, car dans le cas des chélates un déplacement de la bande caractéristique du groupement azométhyne vers des valeurs plus petites aurait dû être observé.

Dans les spectres IR des ligands obtenus à partir de la salicylaldéhyde on remarque la liaison hydrogène intramoléculaire à environ 2850 cm^{-1}, tandis que dans les spectres des complexes est présente la bande de vibration caractéristique de l'hydroxyle libre (3400—3600 cm^{-1}). C'est un argument de plus soutenant l'hypothèse que les composés ne se forment pas par une liaison métal — oxygène.

Les complexes du type $ThCl_4.2SBH$ présentent des bandes d'absorption intenses dans les domaines ultraviolet et visible, bandes caractéristiques des ligands et aussi une bande appartenant au complexe dans le cas des composés avec de la salicylal-*o*-toluidine et de la salicylal-*o*-anisidine. Dans la figure 2 sont représentés les spectres électroniques des composés avec de la salicylal-*o*-toluidine et de la salicylal-*p*-anisidine, ainsi que les spectres des ligands respectifs, dans le domaine 240 à 660 nm.

Les maximums d'absorption de 265 nm et de 360 à 370 nm sont des bandes propres aux ligands, caractéristiques du cycle benzénique et de la liaison du groupement azométhynique conjuguée au cycle benzénique. Par coordination de l'azote les niveaux énergétiques moléculaires π, qui sont impliqués dans les transitions électroniques, sont perturbés et conduisent aux déplacements vers des longueurs d'onde plus grandes. On remarque, par exemple, dans le cas du composé dérivé de la salicylal-

p-anisidine un déplacement très petit de 360 nm, dans le spectre du ligand, à 365 nm dans le spectre du composé.

La bande caractéristique du complexe qui apparaît à 605 nm dans le spectre du composé obtenu à partir de la salicylal-*o*-toluidine et à 640 nm dans le spectre du composé obtenu à partir de la salicylal-*o*-anisidine est probablement due à un transfert de charge L — M.

L'ion central Th(IV), à configuration d^0, ne peut pas générer des transitions électroniques *d — d* et non plus des bandes de transfert de charge *M — L*.

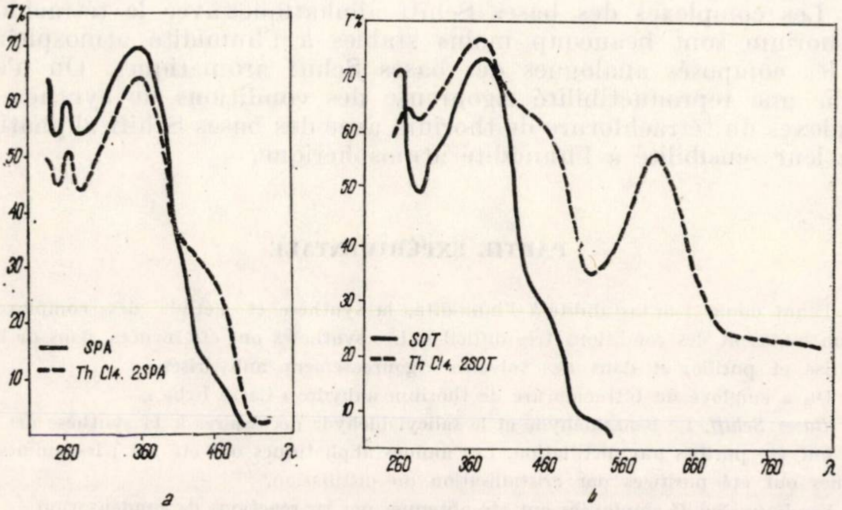

Fig. 2 a) — Spectres électroniques de la salicylal-*o*-toluidine et du composé $ThCl_4 . 2SOT$
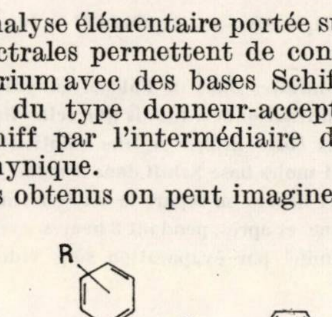
b) — Spectres électroniques de la salicylal-*p*-anisidine et du composé $ThCl_4 . 2SPA$

Les données de l'analyse élémentaire portée sur les composés obtenus, ainsi que les études spectrales permettent de conclure que les complexes du tétrachlorure de thorium avec des bases Schiff aromatiques sont des complexes moléculaires du type donneur-accepteur, entre l'atome de thorium et la base Schiff par l'intermédiaire du doublet électronique libre de l'azote azométhynique.

Pour les complexes obtenus on peut imaginer la structure suivante :



Si on fait réagir le tétrachlorure de thorium sur des bases Schif aliphatiques par rapport molaire 1 : 2 dans l'éthanol anhydre on obtient des produits solides. On a obtenu ainsi les composés du tétrachlorure de thorium avec les bases Schiff suivantes : Salicylal-éthyl-, propyl- et butylamine et benzal-butyl-amine.

Les composés obtenus sont des poudres jaunes excepté le composé de la benzal-butylamine qui est blanc. Les composés sont insolubles dans des solvants organiques ordinaires et présentent une faible solubilité dans l'éthanol.

Les complexes des bases Schiff aliphatiques avec le tétrachlorure de thorium sont beaucoup moins stables à l'humidité atmosphérique que les composés analogues des bases Schiff aromatiques. On n'a pu établir une reproductibilité rigoureuse des conditions de synthèse des complexes du tétrachlorure de thorium avec des bases Schiff aliphatiques dû à leur sensibilité à l'humidité atmosphérique.

PARTIE EXPÉRIMENTALE

Etant donné leur instabilité à l'humidité, la synthèse et l'étude des complexes du thorium imposent des conditions très difficiles. Les synthèses ont été menées dans de l'azote anhydrisé et purifié, et dans des solvants rigoureusement anhydrisés.

On a employé du tétrachlorure de thorium anhydre « Carlo Erba ».

Bases Schiff. Le benzaldéhyde et le salicylaldéhyde nécessaires à la synthèse des bases Schiff ont été purifiés par distillation. Les amines aliphatiques ont été *p.a.*; les amines aromatiques ont été purifiées par cristallisation ou distillation.

Les bases Schiff employées ont été obtenues par les réactions de condensation :

$$C_6H_4(OH)CHO + H_2N-C_6H_4R \rightarrow C_6H_4(OH)CH{=}N-C_6H_4R + H_2O$$

$$C_6H_4(OH)CHO + H_2N-R \rightarrow C_6H_4(OH)CH = N-R + H_2O$$

Les synthèses ont été conduites dans de l'alcool anhydre. Les bases Schiff solides ont été purifiées par cristallisation fractionnée, tandis que celles liquides ont été distillées.

Composés du $ThCl_4$ *et des bases Schiff.* A une solution de 0,005 moles $ThCl_4$ dissous dans de l'éthanol on ajoute 0,01 moles base Schiff dans le même solvant. On porte à l'ébullition pendant 2 à 3 heures. Après 24 heures on sépare le solide formé. Le solide a été lavé d'abord avec du tétrachlorure de carbone et après, pendant 8 heures, avec de l'éther dans un extracteur Soxhlet. Le solvant a été éliminé par évaporation sous vide.

HYDROGEN TRANSFER REACTIONS BETWEEN HYDROCARBONS AND FREE RADICALS. II[1]

THE STUDY OF MOLECULAR COMBINATIONS BETWEEN AROMATIC HYDROCARBONS AND THE 1,1-DIPHENYL-2-PICRYLHYDRAZYL FREE RADICAL (DPPH)

Received December 17, 1973

The existence of a molecular combination, in solid state, between DPPH and benzene was evidenced. The molar ratio of components and thermal dissociation enthalpy of benzene from the molecular combination DPPH-benzene were determined by gas chromatography. The molar ratio of components was found to be 1 : 1. The calculation of benzene dissociation enthalpy on the basis of equilibrium compositions at various temperatures gave the value 10 ± 0.5 kcal/mole which corresponds to an apparent bonding energy of 1.5 – 2 kcal/mole characteristic of a charge transfer molecular combination. Electronic absorption spectra (visible) have evidenced molecular combinations in solution between DPPH and benzene toluene and *o*-xylene. The possibility that molecular combinations with charge transfer occur in aromatic hydrocarbons explains the existing differences between apparent activation energies of hydrogen transfer in DPPH reaction with aromatic and olefinic hydrocarbons previously studied.

In previous papers[1-3] the reaction kinetics of hydrogen transfer from several alkyl aromatic or olefinic hydrocarbons to the stable free radical 1,1-diphenyl-2- picrylhydrazyl (DPPH) was studied. Comparison of apparent activation energies calculated for alkyl aromatic hydrocarbons with those determined in olefines showed that the former (20 – 26 kcal/mole) are considerably higher than the latter (13 – 16 kcal/mole).

To explain the difference, the hypothesis of molecular combinations between DPPH and aromatic hydrocarbons has been considered. The existence of molecular combinations of DPPH in solution has been mentioned in literature for compounds with phenols, alcohols, acids.[4,5] Likewise, in either newer or older works[6-8] the possibility of forming molecular combinations with a series of aromatic hydrocarbons or functional derivates has been evidenced. In this latter case the existing data support the idea of complex combinations with charge transfer but of low stability. Evidence has been gathered for a series of molecular combinations of DPPH with benzene in solid state of molar ratio 1 : 1[6,9] or according to other authors of 1 : 0.8,[10] with chloroform[11,12] and even with oxygen.[13,14] In this respect X ray studies on DPPH-benze molecular combinations have reached the conclusion that solvation benzene molecule is accommodated into the holes characteristic of DPPH crystal lattice and benzene-free radical interaction forces are weak.[15]

In the present experiment we aimed at investigating these solid molecular combinations between DPPH and aromatic hydrocarbons by gas chromatography.[16]

Determination of dissociation enthalpies of the new formed molecular combinations might provide indications on the nature and strength of bonds between the aromatic component and DPPH. We have also attemped to study to what extend and in which solution one may evidence molecular combinations of DPPH and alkyl aromatic hydrocarbons employed in kinetic studies.

MOLECULAR COMBINATIONS BETWEEN DPPH FREE RADICAL AND AROMATIC HYDROCARBONS IN SOLID STATE.

MOLAR RATIOS FOR THE MOLECULAR COMBINATIONS DPPH-BENZENE AND DPPH-TOLUENE

Gas chromatography[16] has been applied to determine molar ratios in molecular combinations formed in solid state between DPPH free radical on one side and benzene and toluene on the other; use has been made of a Carlo Erba chromatograph to which a microreactor has been attached (Fig. 1). Molecular DPPH-benzene combination has been obtained by solving DPPH in benzene followed by evaporation of benzene, drying at low pressure and 40° for about 5 hours, up to constant weight.

For quantitative determination of benzene included into molecular combination, the weighed complex samples have been heated in a microreactor (previously pumped out) at 170° for 60 minutes, under which conditions the crystal lattice is broken down.

The benzene dissociated from the molecular combination has been quantitatively determined against a standard diagram previously plotted for known benzene amounts. The molar ratio calculated in this case for the solid molecular DPPH-benzene combination was 1 : 1 ; it was figured out on the basis of data which will be presented in the experimental section of the present article.

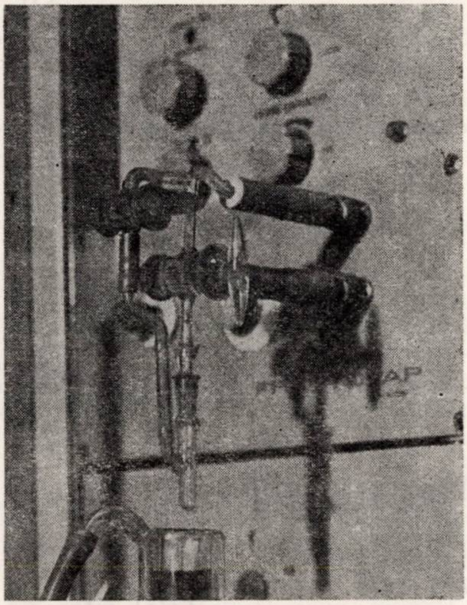

Fig. 1.—Microreactor adapted to the gas chromatograph for the study of solid complexes DPPH — benzene.

A similar procedure extended to DPPH-toluene system has been reiterated and has proved the existence of a solid molecular combination whose stability was not enough for the measurements which are being presented.

DETERMINATION OF DISSOCIATION ENTHALPIES

Gas cromatographic technique has been used for measurement of dissociation enthalpy of solid DPPH-benzene molecular combinations.

The amounts of benzene of equilibrium and several temperatures in static system have been determined in a thermoset microreactor at constant volume ; the gas phase has been evacuated into the analysis circuit of the chromatograph fast enough to prevent errors occurring from changes in solid-gas equilibrium.

The equilibrium is a monovariant one and corresponds to the heterogeneous dissociation equilibrium of the type :

$$\text{molecular combinations } (S) \rightarrow \underset{\substack{\text{support}\\\text{component}\\\text{(DPPH)}}}{C_m(S)} + \underset{\text{hydrocarbon}}{\mathrm{RH}(g)}$$

which is similar to some clathrates of coordinative combinations of aromatic hydrocarbons.[11]

This dissociation equilibrium allows calculation of dissociation enthalpy by equation

$$\lg K_p = -\frac{\Delta H}{2{,}3\, RT} + \mathrm{ct}$$

As $K_p \simeq p_{\mathrm{RH}}$, surfaces areas ($S$) of recorded gas chromatograms were measured, they are proportional to the amount of benzene delivered by the molecular combination and the partial pressures at working temperatures.

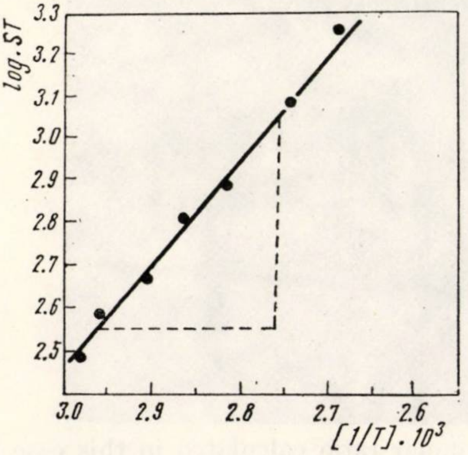

Fig. 2. — The plot of log. ST versus l/T which has been used in determining dissociation enthalpy of benzene from the DPPH-benzene complex; S = surface area under elution curve of benzene; T = absolute temperature.

One can apply the simple equations :

$$pV = \mathrm{nRT}\,;\; S = \frac{PV}{RT}\,;\; \lg S \cdot T \simeq \lg PV \simeq \lg K_p$$

The dissociation enthalpy was calculated from the slope of $\lg ST \simeq \simeq \frac{1}{T}$ plot (fig. 2).

In case of DPPH-benzene molecular combination the dissociation enthalpy of benzene was found to be 10 ± 0.5 kcal/mole resulting in a bonding energy of 1.5 — 2 kcal/mole which corresponds to charge transfer combinations.

MOLECULAR COMBINATIONS BETWEEN DPPH FREE RADICAL AND AROMATIC HYDROCARBONS IN SOLUTION

The present determinations evidenced the formation of charge transfer molecular combinations in solution between DPPH and aromatic hydrocarbons (benzene, toluene, xylene).

To obtain indications on stability and also to determine wavelengths of absorption maxima and values of molar extinction the UV and visible spectral behaviour of solutions has been studied.

At the present stage of experimental technique it is possible to obtain only qualitative appreciations on molecular combinations occurring in the systems :

— DPPH — benzene (in CCl_4)
— DPPH — toluene (in CCl_4)
— DPPH — *o*-xylene (in CCl_4)

Results are shown in fig. 3

Examination of fig. 3 shows that the spectra within 340—390 nm at DPPH concentrations of 6.39 10^{-5}M in CCl_4 (in absence and presence of small benzene concentrations — curves 1—3-do not allow evidencing new absorption maxima in addition to those mentioned in literature for pure DPPA.

However if DPPH spectra have been drawn in presence of higher aromatic hydrocarbon concentration (benzene, toluene, *o*-xylene — curves 4—7) fig. 3) and are compared to those of similar concentration of DPPH in CCl_4 solutions, new absorption maxima bathochromically shifted, to wavelength of 740—750 nm of low extinction have been found which may be ascribed to the formation of charge transfer molecular combinations. The measured absorption increases with the concentration of aromatic hydrocarbon e.g. from 0.75% at 5.62 M. benzene in CCl_4 to 1.75% at 11.21 M. The above investigation has been carried out with a Jobin Yvon spectrorecording photometer point by point. The same absorption maximum (at 750 nm) has been found with a UNICAM SP-800-automatic recording spectrometer.

The forming of such molecular combinations between DPPH and aromatic hydrocarbons could explain the difference in values of apparent activation energy of hydrogen transfer reactions under study[1-3]; values for monoalkyl aromatic hydrocarbons are considerably higher than those for olefines. The observed differences may be interpreted, in our oppinion, by non-specific physical interactions and specific chemical interactions between the stability of either a molecular combination

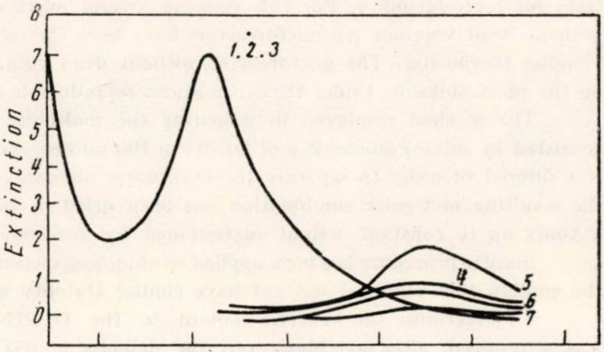

Fig. 3. — Spectra of DPPH — aromatic hydrocarbon solutions.

1, DPPH (6.39 10^{-5} M) in CCl_4; *2*, DPPH (6.39 10^{-5} M) — benzene (0.082 10^{-2} M) in CCl_4; *3*, DPPH (6.39 10^{-5} M) benzene (2.2 10^{-2} M) in CCl_4; *4*, DPPH (7.85 10^{-4} M) — benzene (5.62 M) in CCl_4; *5*, DPPH (7.85 10^{-4} M) — benzene (11.21 M); *6* DPPH (7.85 10^{-4}M) — toluene (4.71 M) in CCl_4; *7*, DPPH (7.85 10^{-4} M)-*o*-xylene (4.07 M) in CCl_4.

formed in solution or a transition complex, according to the potential energy diagram shown in fig. 8 reference.[1]

The low bonding energy of benzene with DPPH (obtained by substracting sublimation enthalpy from dissociation energy of pure benzene) agrees with the interpretation of the bond formed.

In this instance a sequence of reactions is accepted :

$$\begin{tikzcd} \mathrm{DPPH} + \mathrm{ArH} \arrow[r, shift left, "\text{fast}"] & \mathrm{DPPH} \ldots \mathrm{ArH} \arrow[l, shift left] \arrow[r, shift left] & {[\mathrm{DPPH} \ldots \mathrm{ArH}]} \arrow[l, shift left] \arrow[d, "\text{hidrogen extraction}"] \\ & & \text{DPP Hydrazine} + \mathrm{Ar}^{\cdot} \end{tikzcd}$$

Since these molecular combinations are very likely to be formed in solution at a concentration which is practically constant, following reversible rapid reactions, their formation does not influence the formal kinetics of hydrogen transfer reactions previously studied.

EXPERIMENTAL

THE TECHNIQUE APPLIED TO DETERMINATION OF MOLAR RATIOS IN MOLECULAR COMBINATIONS OF DPPH WITH BENZENE AND TOLUENE IN SOLID STATE

A type C Carlo-Erba-Fractovap gas chromatograph with ionization detector and thermistors to which a micro-reactor was added has been used.

Finding out the method has required test runs which had to establish optimal conditions for reproducibility. For this purpose several microreactors have been tried (with and without dead volume). All microreactors have been thermoset by help of a paraffin bath and Höppler thermostat. The microreactor without dead volume shown on fig. 1 has proved to be the most suitable. Under these conditions reproducible results have been obtained.

The method employed in preparing the molecular DPPH-benzene solid combination consisted in solving about 2 g of DPPH in 100 ml benzene (distilled on sodium). The solution was filtered in order to separate the eventually undissolved product. After benzene removal the resulting molecular combination has been dried in vacuo (5 mm Hg) at 40° for about 5 hours up to constant weight (determined by successive weighing).

Similar procedure has been applied to obtaining molecular combination of DPPH-toluene ; the combination obtained did not have similar stability with the benzene one.

To determine the benzene content in the DPPH-benzene combination the sample was introduced, after weighing, into the detachable test tube of the microreactor. After checking up the tightness by a pressure test the whole device was heated up to working temperature.

The chromatograph working conditions :

- Column length 1 m (15% dibutyl phtalate/celite)
- Column temperature : 55°
- Vaporizer temperature : 100°
- Eluant : nitrogen 40 ml/min.

TECHNIQUE APPLIED IN DETERMINING THE DISSOCIATION ENTHALPIES OF BENZENE FROM DPPH-BENZENE MOLECULAR COMBINATIONS

Experiments have been carried out at temperatures ranging between 60 and 100°C : within this range no DPPH degrading occurs. Above 100° appreciable thermal decomposing of DPPH takes place. Tests carried out have shown that within 1.5 hours 12% DPPH decomposes at 120° and 100% at 150°.

Procedure : 0.01 – 0.03 g of molecular combination weighed on an analytic scale is introduced into the microreactor.

The tightness is checked by a pressure test and the microreactor is cut off the chromatograph circuit by a three way tapper. The microreactor is then brought to the desired temperature which is maintained long enough for gas-solid equilibrium to take place (this is done by the thermostat). The time required for reaching equilibrium has been determined by attempts ; for the molecular combination under study it was of 30 – 60 minutes.

After this time has elapsed the reaction is connected to the analysis circuit of the chromatograph and the eluant (nitrogen) is flown through in order to evaluate the gas phase.

This operation must take a short time so that the possible changes in solid-gas equilibrium may not represent important errors.

THE EXPERIMENTAL TECHNIQUE APPLIED TO EVIDENCING MOLECULAR COMBINATIONS OF DPPH WITH ALKYL AROMATIC HYDROCARBONS IN SOLUTION

Carbon tetrachloride (Serva spectral reagent grade) was used as solvent in preparation of complex solutions. Benzene, toluene, *o*-xylene have been spectral reagent grade too.

DPPH has been synthetized and purified in our laboratory according to the method previously described.[2,3]

Recording spectra. U.V. and visible spectra have been recorded with a silica-optics Jobin Yvon spectrophotometer. Ordinary and silica glass cuvettes 1-cm thick have been used. Extinction was read on a galvanometer within ± 0.002. Use has also been made of an automatic UNICAM SP.800 spectrophotometer.

The absorption of the solvent has been looked for by using reference cuvettes filled up with CCl_4 and solution of DPPH in CCl_4 of the same concentration as mixtures under consideration.

Spectra of solutions of both pure DPPH and DPPH in aromatic hydrocarbons (benzene, toluene, *o*-xylene) at different concentrations are shown on fig. 3.

ELECTRICAL CONDUCTIVITY OF SOME SALICYLIDENANILS

SCHELY AVRAMOVICI, IOANA CIOCOIU and G. I. RUSU *

Department of Organic Chemistry, "Al.I. Cuza" University, 23 August, 11, Jassy, Romania

* Physics Department, "Al. I. Cuza" University, Jassy

Received August 21, 1973

In the present paper the electrical properties of some salicylidenanils have been investigated. Thin film samples with polycrystalline structure were used. The experiments showed that the heat treatment determined a reversible change of electrical conductivity as a function of temperature and a stable film structure. For the studied compounds, a correlation between thermal activation energies and their chemical structure was established.

1. INTRODUCTION

In recent years, numerous experimental and theoretical investigations have had the object to establish a correlation between the semiconductor properties of organic compounds and their chemical structure.[1-6]

The present paper studies the electrical conductivity for some Schiff bases, prepared from condensation of the salicyl, 5-nitrosalicyl, 5-bromsalicyl, 3-nitrosalicyl and 3-nitro-5-bromsalicylaldehydes with 2-amino-6-methylbenzthiazole, 2-amino-6-methoxybenzthiazole, 2-amino-β-naphthothiazole and *p*-aminodimethylaniline.

It is the aim of this paper to establish a dependence between chemical structure of substances and their electrical properties.

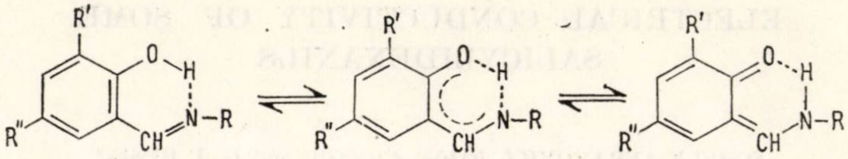
The general chemical formula of investigated compounds is :



Ia Ib Ic

where the substituents R, R′ and R″ are given in table 1.

The technique of preparation, some chemical and physical properties of substances were described in detail.[7,8] The purity of substances has been controlled by using chemical and spectral analyses.

2. EXPERIMENTAL PROCEDURE

The thin films were deposited on glass substrates from benzene solutions and thermal evaporation.

For electrical resistivity measurements, aluminium electrodes were used.

The experimental arrangement and measurement technique have been reported.[9,10] The film temperature has been measured with a Fe-constantan thermocouple. In all cases temperature rate was 2°/min. The interferometrically determined sample thickness ranged from 0.10 to 2.00 μm. The investigations showed that the electrical properties of films prepared by thermal evaporation are not essentially different from those of films obtained from benzene solutions.

We shall present the experimental results obtained by using the films prepared by the second method.

3. EXPERIMENTAL RESULTS AND DISCUSSION

The metallographic investigations showed that all films have a polycrystalline structure. The size of the film granules depends on the film thickness *d*. A structure with bigger granules was observed for high values of *d*.

For compounds I_9 and I_{12} (Table 1), the curves which give the electrical resistivity ρ depending on the film thickness *d* are presented in fig. 1.

A similar behaviour was also found for all investigated substances. The resistivity ρ decreases with film thickness and tends to a constant value.

[10] G. I. Rusu, *Anal. Şti. Univ. "Al. I. Cuza" Iaşi*, **15/2**, 149 (1969).

An analogous behaviour was remarked on other inorganic and organic semiconductors in thin films.[1,2,10,11]

We may suppose that the growth mechanism of films is identical for the respective substances.

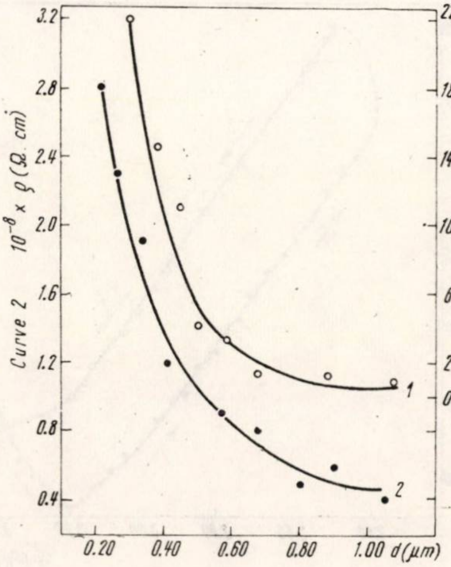

Fig. 1. — The dependence of the specific resistivity ρ as a function of film thickness d (curve 1 – compound I_9, curve 2 – compound I_{12}).

In order to obtain a structure stability and reproducibility of the electrical properties, all the investigated samples were subjected to subsequent heatings and coolings in ΔT temperature ranges indicated in table 1.

The temperature dependence of the electrical conductivity σ during this heat treatment has been studied. The curves $\ln \sigma = f\left(\frac{1}{T}\right)$ have the following aspect : at the first heating, with increasing temperature, the electrical conductivity σ decreases at the beginning ($T < 350 - 370$ K). This decrease in conductivity is probably due to the elimination of the absorbed gas as well as of the humidity. As it is known these factors have a strong influence on electrical conductivity of organic semiconducting compounds.[1,2]

For higher temperatures, the conductivity increases with temperature, obeying the usual exponential law [1,2,12]

$$\sigma = \sigma_{0e} - \frac{\Delta E}{2KT}$$

[11] V. V. Slutkaja, "Tonkie plionki v tekhnike sverkhvjsokijkh thastot", Izd. Sov. Radio, Moskva, 1967.

[12] P. Smith, "Poluprovodniki", Izd. inostr. lit., Moskva, 1962.

On cooling, electric conductivity decreases but no longer reaches original values, gases and humidity having been eliminated from the film.

Experiments have shown that by following the heat treatment curves are obtained which, within limit of errors, overlap the curve

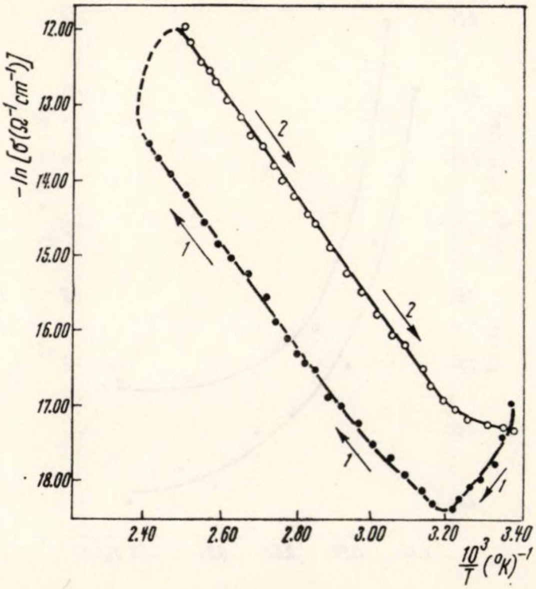

Fig. 2. — The curves $\ln\sigma = f\left(\frac{10^3}{T}\right)$ for the compound I_5 at the first heating and cooling (*1* = heating, *2* = cooling).

obtained at the first cooling. We conclude that heat treatment determined a reversible change of the electrical conductivity as a function of temperature and a stability of film structure.

In fig. 2 we represent the curves $\ln\sigma = f\left(\frac{10^3}{T}\right)$ for the compound I_5. For all studied samples there was found a similar behaviour.

For heat-treated specimens, starting with a temperature T_i, characteristic of each compound, a linear dependence of the $\ln\sigma = f\left(\frac{1}{T}\right)$ curves was observed. The values of T_i for investigated substances are given in table 1. The table also shows the specific conductivities at room temperature σ 20° C, studied temperature range ΔT, and film thickness d.

According to the sign of Seebeck coefficient the conductivity of the compounds is of p-type. For $T > T_i$ the compounds have an intrinsic conductivity. For heat-treated samples, the temperature dependence of the electrical conductivity in the intrinsic domain is represented in figs 3 and 4.

The calculated values of the thermal activation energy ΔE are given in table 1.

It can be observed that these values strongly depend on the chemical structure of compounds.

I_{12}		$-H$	$-Br$	6.6×10^{-9}	330–440	365	0.50	1.40

As a first remark we must mention that the benzthiazolic nucleus in the aminic rest of the anils determines a different behaviour as against the *p*-dimethylaminobenzoic rest in the same position. The activation energy value is much greater in the latter case.

The substituent nature in the benzthiazolic nucleus [(6)$-OCH_3$, (6)$-CH_3$, (5)$-CH=CH-CH=CH-$(6)] has not a marked influence on the activation energy value. In exchange, a greater influence is due to the substituent from the salicylaldehydic ring. Thus, if the aminic rest is unchanged by comparing the activation energy from a series of products it is found that the NO_2-group in the 5-position of the salicylaldehyde ring (prod. I_2, I_5) determines a decrease of the activation energy value, whereas the Br in the same position (prod. I_3, I_6) has an opposite effect.

Similar results were found when calculating the optical energy values from the same compounds,[7-8] especially those in polar solvents.

From the experimental results we must suppose that the NO_2-grouping in the 5-position determines a spreading conjugation, with an increase in the amount of quinoid structure (I_c), while the Br in the same position has the effect of decreasing conjugation.

The NO_2-grouping in the 3-position of the salicylaldehydic nucleus (prod. I_7) has the same effect as the Br in 5-position, but less intense.[1,13]

The existence of both substituents, NO_2 in the 3-position and Br in the 5-position, leads to the expected result, i.e. the adding up of the effects, the respective product (I_8) showing the greatest activation energy. These results agree with the data of electronic spectra by which it was established that the NO_2 grouping from the 3-position of salicylaldehydic nucleus causes a disturbance of quasiquinoidic structure, reorienting the hydrogen bridge[7].

The variation of the activation energy in relation to the nature of substituents in the salicylidenanils with *p*-dimethylaminobenzenic rest no longer follows the same course, the presence of a substituent in the salicylaldehyde nucleus leading, irrespective of its nature, to a depression of the activation energy value.

BIS-THIOETHERS. I

CONDENSATION OF SODIUM THIOPHENOLATE WITH DICHLOROMETHYLATED DERIVATIVES

M. IOVU and ANCA ANGELESCU

University of Bucharest, Faculty of Chemistry
Splaiul Independenţei 89, Bucharest, Romania

Received June 23, 1973

Using the method previously described by us in the synthesis of phenyl benzyl sulphides, which was also applied, for the first time, to the synthesis of aromatic bis-ethers, we prepared a new class of bis-thioethers with the general formula : $Ar-S-CH_2-Ar-CH_2-S-Ar$, in which Ar is a substituted or unsubstituted aromatic nucleus with methyl radical. Bis-thioethers were obtained by the condensation of the anhydrous sodium thiophenolates – which were obtained through azeotropic distillation of the water resulted from the reaction between thiophenol or *p*-methylthiophenol with sodium hydroxide – with dichloromethylated derivatives.

In the previous paper[1] we presented the results of the synthesis of some phenyl benzyl sulphides using a similar method to that also applied by us for the first time, in the synthesis of some polyethers[2] or aromatic bis-ethers.[3]

According to our method, the phenol or the thiophenol is converted into its anhydrous sodium or potasium salt, by treating it with alkali hydroxides in a solvent or in a mixture of solvents (preferably ethanol-benzene).

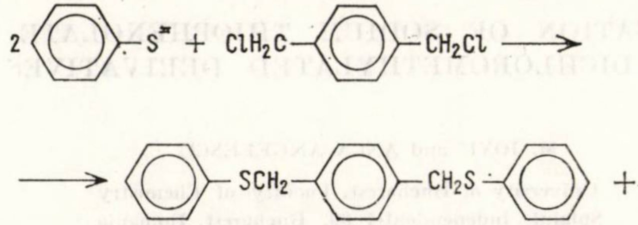
The resulting water is removed by azeotropic distillation as follow :

The thiophenolate thus obtained is then treated with chloromethylated derivative, which may be monochloromethylated as in the previous note,[1] or dichloromethylated as in other papers [2-4] or as in the present paper.

---

[1] M. Iovu and A. Angelescu, *Rev. Roumaine Chim.*, **18**, 263 (1973).
[2] M. Iovu and M. Manolescu, Romanian Patent, 61.805, 1969.
[3] M. Iovu, *Rev. Roumaine Chim.*, **16**, 1223 (1971).

The nucleophilic attack of the phenoxide or thiophenolate ion on the halogenated derivative takes place, as shown below:



After three or four hours the reaction will be considered total.

The bis-thioether precipitates and after a suitable treatment it could be purified by recrystallization.

Based upon this method we wish to report in this paper the synthesis of ten bis-thioethers, belonging to a new class, with the general formula $Ar-SCH_2-Ar-CH_2S-Ar$ in which Ar is a substituted or unsubstituted aromatic nucleus with methyl radical.

Using this new method we condensed the sodium thiophenolate and the sodium *p*-methyl thiophenolate with the: 1,4-dichloromethyl benzene; 1,4-dichloromethyl-2,5-dimethyl benzene; 1,3-dichloromethyl-4,6-dimethyl benzene; 1,3-dichloromethyl-2,4,6-trimethyl benzene and 1,4-dichloromethyl-2,3,5,6-tetramethylbenzene, obtaining ten new products.

The bis-thioethers having the general formula: $Ar-S-CH_2-Ar-CH_2-S-Ar$ have not been prepared up to now; but their isomers with the general formula $Ar-CH_2-S-Ar-S-CH_2Ar$ have been synthesized.

Thus, Campbell [5] used the reaction between disulphides and dihaloaromatic compounds, which were condensed in the presence of copper powder at 160–170° in dimethylacetamide as solvent:

$$C_6H_5-CH_2-S-S-CH_2-C_6H_5 + BrC_6H_4Br \xrightarrow{Cu}$$

$$\longrightarrow C_6H_5-CH_2-S-C_6H_4-S-CH_2-C_6H_4$$

RESULTS AND DISCUSSION

Table 1 gives the structural formulas of the synthesized sulphides, their melting points, the microanalytical results of sulphur determination, λ_{max} and ε_{max}, from UV spectrometry and the yields.

All the synthesized bis-thioethers are in a solid state. Their melting points depend on the number and the positions of the methyl substituted radicals, especially on the aromatic central nucleus.

The bis-thioethers present lower melting points, up to 30°, comparatively to the corresponding bis-ethers.[3]

A slight difference exists only between α, α′-bis-(phenylthio)-*p*-xylene (m.p. 141.5 – 143°) and α, α′-bis(phenoxy) *p*-xylene (m.p. 143.5 – 144°).

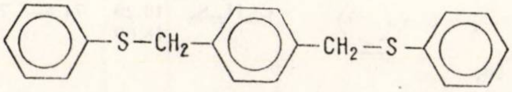
Compared to thioethers (phenyl benzyl sulphides) previously synthesized by us,[1] the bis-thioethers absorb at lower wavelength values. These results point out that higher energies would be necessary for electron transitions in the case of bis-thioethers.

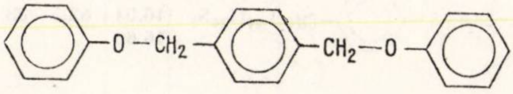
Also, the absorption bands of the bis-thioethers are larger than the absorption bands of the corresponding thioethers.

The bis-thioethers, as well as the thioethers previously synthesized by us,[1] having one valence of the sulphur atom directly connected with an aromatic nucleus and another, with a methylene group, absorb in U.V. at intermediary wavelength values (table 1) (231–258 nm), between the characteristic value of the aliphatic thioethers (210 nm) and the typical value of the aromatic thioethers (280 nm).

By comparison with bis-ethers, the absorption of bis-thioethers is shifted to lower wavelengths. It seems reasonable to suggest that a higher energy would be necessary for electron transitions in the second case.

Thus we find an important difference between λ_{max} and ε_{max}, if we compare the α, α′-bis(phenylthio)-*p*-xylene and the α, α′-bis(phenoxy)-*p*-xylene [3]:





λ_{max} nm	ε_{max} nm
251,5	$1{,}6.10^4$
271.	$3{,}8.10^3$

EXPERIMENTAL

Thiophenol and 4-methylthiophenol were obtained by reducing benzenesulphochloride and toluenesulphochloride with zinc and sulphuric acid (33%).[6]

1,4-Dichloromethyl benzene was synthesized by photochemical chlorination of *p*-xylene with sulphuryl chloride, using benzoyl peroxide as activator.

1,4-Dichloromethyl 2,5-dimethyl benzene, 1,5-dichloromethyl 2,4-dimethyl benzene were synthesized by chloromethylation of *p*-xylene and *m*-xylene, using paraformaldehyde, hydrochloric acid and phosphoric acid.

1,5-Dichloromethyl 2,4,6-trimethyl benzene was synthesized by chloromethylation of 1,3,5-trimethyl benzene (mesitylene) and 1,4-dichloromethyl 2,4,5,6-tetramethyl benzene was synthesized by chloromethylation of 1,2,4,5-tetramethyl benzene (durene) in a similar way.

---

[6] Weygand-Hilgetag, "Organisch-Chemische Experimentierkunst", 3. Auflage, Johann Ambrosius Barth-Verlag, Leipzig, 1964, 711 p.

The determination of sulphur was made by the oxidation of bis-thioethers with oxygen in the presence of platinum catalyst, and with hydrogen peroxide, followed by the volumetric determination of sulphuric acid.

UV spectra were obtained on a Hitachi Recording spectrophotometer.

SYNTHESIS OF α, α'–BIS (PHENYLTHIO)–*p*–XYLENE

In a double-necked, 50 ml flask, equipped with a reflux refrigerator and a thermometer, we insert 2.2035 g thiophenol (1/50 mol), 0.805 g NaOH (1/50 mol plus an excess of 1/5000 mol) and 30 ml of an ethanol-benzene mixture (in a 1 : 1 ratio by volume). The mixture is heated to the boiling point for 3 hours, till sodium thiophenolate has formed. The reflux refrigerator is then changed with a distillation refrigerator and 15 ml azeotropic mixtures are distilled to remove the water resulting from the reaction.

After cooling the flask, 1.7497 g, 1,4-dichloromethyl benzene (1/100 mol) are added, the distillation refrigerator is again changed with the refluxing one, to which a tube with calcium chloride has been connected and it is heated for 3 hours at 65–67°. Sodium chloride is formed, which precipitates together with the bis-thioether.

After cooling the flask to 5°, the reaction mixture is filtered, so as to separate the solid sodium chloride and the solid sulphide from the solvent and the liquid unreacted raw materials. The solid mixture is then washed with water to remove sodium chloride. The precipitate is dried in vacuum; 2.7136 g α, α'-bis(phenyl-thio)-*p*-xylene results after two recrystalizations from an ethanol benzene mixture (in a 1 : 3 ratio by volume); its melting point will be 141,5–143°.

Other compounds were obtained in a similar way, with the mention that mixtures of ethanol – benzene in different ratios were used for recrystallization.

Thus, compounds no. 2, 3, 4 (table 1) were recrystallized from the mixture of ethanol-benzene in a 1 : 3 ratio by volume.

Compounds no. 5, 6, 7, 8 (table 1) were recrystallized from the mixture of ethanol-benzene in a 3 : 1 ratio by volume.

Compounds 9, 10 (table 1) were recrystallized from benzene.

STUDY OF SOME HETEROCYCLES. XXVI*

NITRATION OF 2-ANILINO-5-PHENYL-1,3,4-OXADIAZOLE

I. SIMITI, DOINA GHIRAN, I. SCHWARTZ and R. D. POP

Institute of Medicine and Pharmacy, Laboratory of Organic Chemistry, str. V. Babeş 41,
Cluj, Romania

Received July 6, 1973

The present paper investigates the nitration of 2-anilino-5-phenyl-1,3,4-oxadiazole under various conditions. The structure of the resulted compounds was established by chemical and physico-chemical studies.

In an earlier paper we dealt with the bromination of some 2-anilino-5-(*p*-X-phenyl)-1,3,4-oxadiazoles and found that the substitution takes place in the *para* position of the aniline rest.[1]

Further studies on the nitration of 2-anilino-5-phenyl-1,3,4-oxadiazole (I) under various reaction conditions showed that this cannot be accomplished with HNO_3 ($d = 1.40$) in a glacial acetic acid medium, 50% sulphuric acid, while small amounts of nitration compounds occur in 85% H_2SO_4, the non-nitrated initial compound prevailing in the mixture. When the reaction takes place in an acetic anhydride medium, a mixture of various nitration compounds is obtained.

A systematic study led us to the conclusion that the best results can be obtained by the nitration of a 2-anilino-5-phenyl-1,3,4-oxadiazole suspension in nitrobenzene with a sulphonitric mixture at a temperature ranging between 0 and 10°, when a mixture of three nitration products (II, III, IV) is formed and a small amount of non-nitrated 2-anilino-5-phenyl-1,3,4-oxadiazole (I) also remains. These were identified by thin-layer chromatography.

Similar results are also constantly obtained if the reaction is carried out in a concentrated sulphuric acid medium. However, the separation of compounds (II, III, IV) is more difficult in this case.

In order to establish the position in which nitration took place, the following reference compounds were prepared : 2-(*p*-nitro-anilino)-5-phenyl-1,3,4-oxadiazole (II) and the *meta*-nitro-substituted derivative (IV) ; 2-anilino-5-(*p*-nitro-phenyl)-1,3,4-oxadiazole (V) ; 2-(*p*-nitro-anilino)-

* Note XXV. I. Simiti, E. Chindriş and I. Schwartz, *Rev. Chim.* (*Bucureşti*), **23**, 460 (1972).

[1] I. Simiti, D. Ghiran and I. Schwartz, *Arch. Pharm.*, **304**, 230 (1971).

-5-(*p*-nitro-phenyl)-1,3,4-oxadiazole (III) as well as their N-acetyl derivatives.

By separating the compounds from the nitration mixture we found that the largest amount consisted of 2-(*p*-nitro-anilino)-5-phenyl-1,3,4-oxadiazole (II), a very small amount was identical with (III) and a somehow larger amount of a dinitro-derivative (IV) was not identical with either of the reference compounds prepared by us.

This last compound (IV) is also obtained by nitration of 2-(*p*-nitro-anilino)-1,3,4-oxadiazole (II) alongside with a small amount of (III) and a part of the unreacted compound (II).

As expected, a large amount of compound (III) is obtained by nitration of 2-anilino-5-(*p*-nitro-phenyl)-1,3,4-oxadiazole (V).

Physico-chemical studies were performed on the above-mentioned mono- and dinitro-derivatives in view of establishing the structure of compound (IV).

By performing IR spectra in KBr pellets * of all these compounds we found a good agreement with the respective formulations except for compound III which displays, surprisingly, a band at 1680 cm^{-1} and another at 2800 cm^{-1}, which do not appear in the spectrum of other derivatives.

Table 1

Characteristic absorption bands in IR spectra

	ν NH		δ NH	$\nu C=N$	νNO_2		$\nu C-NO_2^2$
	ν a	ν s			ν a	ν s	
I	3250	3050	1615	1603	—	—	—
II	3270	3060	1625	1600	1515	1335	855
III	3300	3100 2850	1672	1625	1510 1525	1325	845 850 doublet
IV	3230	3060	1625	1605	1510 1520	1330	845 860 doublet
N-acetyl * deriv. III	—	—	—	1600	1520 1525	1335	850 865
2,4-dinitro-aniline	—	—	—	—	1510 1520	1320	830 835

* $C=0=1720\ cm^{-1}$

In the case of the acetyl-derivative of compound III, these bands disappear, which makes us believe that they are due to the —NH— grouping. This would plead for the fact that not only the band at 1672 cm^{-1} belongs to the —NH— grouping but also that at 2850 cm^{-1}, considering the fact that spectra of all derivatives constantly reflect an absorption at 1180 cm^{-1}, the band at 2850 cm^{-1} may be considered as a combination band.

---

* IR spectra were recorded on a Shimadzu 27 G spectrophotometer in KBr pellets, in the 4000 — 400 cm^{-1} spectral range.

[2] B. Franck, H. Hörmann and S. Scheibe, *Chem. Ber.*, **90**, 330 (1957).

It is worth mentioning that these bands fail to appear in the case of dinitro-derivative (IV), which proves that its structure must be different.

In order to elucidate the structure of compound IV we further made a polarographic study of the mentioned compounds.* On this occasion we found a normal behaviour,[3] all mononitro-derivatives having one single reduction wave whereas in the case of dinitro-derivatives a different

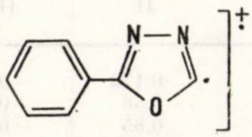
* Polarographic determinations were made on a L.P. 7 polarograph Laboratorny pristroje in an aqueous DMF solution. 2.5% LiCl was used as a basic electrolyte and maxima were recorded by means of a 1% gelatine solution. The pH levels involved were 1.2; 3.6; 5.2; 8.5; and 10.

[3] K. Kemula, *Roczniki Chem.*, **33**, 1485 (1958).

behaviour of the two waves can be observed relative to the pH. Thus, the height of polarographic waves of compound III varies relative to the pH (table 2) whereas in the case of dinitro-derivative (IV) the height of waves is independent of pH variations. The polarogram of the latter is highly similar to that of 2,4-dinitroaniline.

The structure of these compounds was also confirmed by mass spectra,* the molecular peaks being in keeping with their molecular weight.

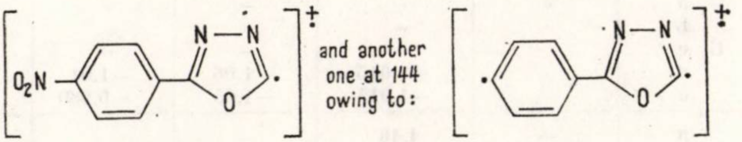
Thus all mononitro-derivatives (II, V, IV) display molecular peaks at $M^+ = 282$ whereas dinitro-derivatives (III, IV) show them at $M^+ = 327$, proving once again that compound (IV) is certainly a dinitro-derivative. Mass spectra of nonsubstituted compounds on phenyl (I, II, IV) reveal a peak at 145, characteristic of a peak also found in the spectrum of



Schema 1

compound (IV). This proves that phenyl is nonsubstituted and the two $-NO_2$ groupings are situated on the aniline rest.

In the case of compounds (III and V) with the NO_2 group on phenyl, the peak at 145 is missing, yet a large peak appears at 190 specific of :



Schema 2

which is missing with derivatives I, II, IV and VI.

Based on the polarographic study, on IR and mass spectra we may conclude that dinitro-derivative (IV), whose structure could not be elucidated by synthesis, is 2-(2′, 4′-dinitro-anilino)-5-phenyl-1,3,4-oxadiazole.

In conclusion, comparing the bromination and nitration reactions of 2-anilino-5-phenyl-1,3,4-oxadiazole it resulted that in the bromination reaction one single bromine atom is introduced in the *para* position of the aniline rest regardless of the amount of bromine, phenyl-oxadiazole behaving as a deactivator. In the case of nitration even if we use equimolecular amounts of NO_3H, we constantly obtain the mixture of the three mentioned nitro-derivatives, the prevailing amount being 2-(*p*-nitro-anilino)-5-phenyl-1,3,4-oxadiazole.

---

* Mass spectra were recorded by a M.A.T. 311 (M.A.T. Bremen-Varian) device with double focalization.

[a] Recrystallization from acetic acid

Nitration of 2-anilino-5-phenyl-1,3,4-oxadiazole (I)

2.37 g (0.01 mol) 2-anilino-5-phenyl-1,3,4-oxadiazole are suspended in 25 ml nitrobenzene and cooled at 0–10°. A mixture of 1.2 ml NO_3H d = 1.40 (approx. 2.1 mol) and 2 ml conc. H_2SO_4 is added dropwise with continuous stirring. The mixture is allowed to stand for 30 minutes at 0° and then for 2–3 h at room temperature. Nitrobenzene is decanted and the sticky residue left is handled with ice. It is then rapidly filtered and dried on a porous plate, obtaining a yellow substance which is chromatographed and shows three spots characteristic of nitro-derivatives and a weak R.f. spot identical with that of the initial compound (I). Repeated recrystallizations from acetic acid and then dioxane lead to a pure chromatographic compound with m.p. 285°, identical with 2-(*p*-nitro-anilino)-5-phenyl-1,3,4-oxadiazole (II) $C_{14}H_{10}N_4O_3$ – N% calc. 19.84, found 19.94.

The remaining portions after separation of this compound (m.p. 190–200°) also show 3 spots. By fractionated recrystallizations from ethanol, acetone, dioxane acetic acid we separated a chromatographically pure compound with m.p. 240°, $C_{14}H_9N_5O_5$ – N% calc. 21.40, found 21.79 (IV) and trace amounts of a compound with m.p. 340°, identical with 2-(*p*-nitro--anilino)-5-(*p*-nitro-phenyl)-1,3,4-oxidiazole (III) $C_{14}H_9N_5O_5$ – N%, calc. 21.40, found 21.29.

OBSERVATIONS

The reaction was carried out under similar conditions with an equimolecular amount of HNO_3 and the same results were obtained by varying the time from 1 to 24 hours. Identical results were also obtained by conducting the reaction in a medium of concentrated sulphuric acid.

Nitration of 2-(*p*-nitro-anilino)-5-phenyl-1,3,4-oxadiazole (II) was identically carried out, resulting in a mixture of II, III and IV.

Nitration of 2-anilino-5-(*p*-nitro-phenyl)-1,3,4-oxadiazole (V) results exclusively in compound III.

STUDY OF CYCLOHEXANE DEHYDROGENATION EQUILIBRIUM AND KINETICS IN PULSED REACTOR

A. POP and POMPILIA DUMITRESCU
Faculty of Chemistry, Str. Arany Ianoş 11, Cluj, România

Received August 4, 1973

The authors study the activity of a chlorinated Pt/Al_2O_3 catalyst in a reaction of cyclohexane dehydrogenation. The reaction is monitored in a pulsed reactor operating according to the gas – solid chromatography process under the conditions of the reaction reversibility and in a current of hydrogen as eluent. On this occasion the chemical equilibrium of the dehydrogenation – hydrogenation reaction was studied, establishing the following relation for the equilibrium constant in the sense of dehydrogenation : $\log K_p = 19.413 - 10751/T$ which is verified in comparison with the values obtained from the thermal data and with those obtained from the Jarkov-Frost equation, within a temperature range of 513–633 K, good results being recorded. Thus, emphasis is laid on the use of the pulsed reactor in the study of chemical equilibria. At the same time the kinetics of the reaction is studied under conditions of reversibility, in the same pulsed reactor, in the range of 547.5–584 K. An apparent activation energy of 13.0 Kcal/mole is calculated.

The pulsed reactor or the reactor operating according to the gas chromatographic technique has been used quite frequently since 1955 in the study of some heterogeneous reactions to determine the activity of the catalysts. The technique initiated by Kokes et al.[1] was followed with great interest by many other researchers and it basically consists in the following:

The reactor is a catalyst column maintained under reaction conditions; through it flows a constant current of carrier gas which can be inert to the reactant system or to one of the reactants. According to the gas chromatographic technique the reactants are introduced as pulses in this column.

The reaction resultants, leaving the reactor, pass directly into an analytical chromatographic column and are subjected to an analysis similar to that performed by Kokes et al. or they are first wholly condensed and the condensate is analysed by the same technique as that applied by several researchers.

---

[1] R. J. Kokes, H. Tobin Jr. and P. H. Emett, *J. Amer. Chem. Soc.*, **77**, 5870 (1955).

By using this technique, Bassettand Habgood [2] studied the kinetics of a first order reaction, i.e. the isomerism of trimethylene, and established the relations between the adsorption equilibrium, the reaction rate constant and the chromatographic retention values, showing that the corrected chromatographic retention time, or a proportional value of it, such as the corrected retention volume, may be considered as reaction time in kinetic calculations.

These values, correlated to the molar conversions obtained in the reaction and related to the catalyst mass unit, are used in the known kinetic equations and allow the calculation of rate constants (catalyst activity) and the corresponding activation energy.

Considering the complex phenomenon in the pulsed reactor from the point of view of contact effect and of the separation effect that occur simultaneously in the catalyst column, Roginskii et al.[3,4] established the mathematical relations of this process, based upon the mass balance for pulsation passage through a catalyst zone. Magee,[5] Hattori and Murakami,[6] Langer and Yurchak,[7] Blanton et al.[8] and other investigators have also subjected these processes to mathematical analysis. The effect of the pulse shape is studied in particular by Gaziev et al.[9]

All of them postulate that the technique of the pulsed reactor is rigorously applicable to first order reactions in which the slowest stage is represented by the surface reaction.

On the other hand, it is inferred that in the column of the pulsed reactor the reaction products being separated during their passage through the catalyst layer, the counter-reaction may be avoided for any reversible reaction of the type $A \rightleftarrows R + S$ in which equilibrium has been slowly established. Thus, in a sufficiently long catalyst column the reaction may occur until the final transformation has taken place.

A much studied reaction in the pulsed reactor is the dehydrogenation of cyclohexane. Most investigations carried out to this end employed conditions under which the counter-reaction takes place only in an insignificant proportion. Roginskii et al.[4] study the reaction with Pt/Al_2O_3 catalyst with argon as carrier gas within a temperature range of 145°–280°. Although equilibrium conversions should be obtained within this range, in fact higher conversions are obtained due to the above-mentioned separation of hydrogen from benzene when the pulse passes through the catalyst column. Gaziev et al.[9] treat the same reaction as a first order irreversible reaction on Pt/Al_2O_3 catalyst and on aluminium-silica catalyst within a temperature range of 130–200°. The same school[10] also studies the reaction on some carbides, silicides, borides in argon current at the temperature of about 500° as a first order reaction; the counter-reaction does not occur. Mathsen et al.[11] experiment the reaction in the 183°—225° range of temperatures where equilibrium conversions are reduced, in a reactor with Pt/Al_2O_3 in a helium current. They also confirm the *a priori* obvious fact that higher conversions are obtained than the equilibrium ones. Berezkin et al.[12] study the reaction at lower temperatures (90—145°), in helium or argon current. They reach the same conclusions as to the separation of reaction resultants and to the reaction order and propose the calculation of the reaction kinetics on the basis of the outlet peaks of the reactor resultants, particularly that of hydrogen. Recently Barbul et al.[13] have studied the kinetics of this reaction in a pulsed reactor and in the straight through reactor in a hydrogen current. They did not take into account the counter-reaction which undoubtedly takes place in the studied range of temperatures.

The authors of this work, concerned with the obtaining of some active alumina, tested their behaviour after impregnating them with finely dispersed platinum, in the same reaction of cyclohexane dehydrogenation. The testings were carried out in a pulsed reactor employing hydrogen as carrier gas, as reactant and also as reaction medium. The testing range of temperatures was 274.5 — 311°, and the pressure range was 1.2 — 1.8 atm. Under these conditions no secondary reaction occurs. The adsorption and desorption rates both of the reactants and the resultants are high and the surface reaction is the slowing down stage.

Since this reaction is of zero order in relation to hydrogen, it means that from the point of view of kinetics it may be interpreted in both ways following the first order equation.

The known equation of such reactions at a given temperature value is:

$$\frac{k\,a}{x_e} = \frac{1}{t} \ln \frac{x_e}{x_e - x} \tag{1}$$

where a = initial molar concentration;

x_e = modification of the initial concentration, under conditions of equilibrium;

x = modification of initial concentration after reaction time t, before reaching equilibrium.

Noting by $\alpha_e = x_e / a$ the equilibrium conversion, in moles/mole, and by $\alpha = x/a$ the conversion at time t, in moles/mole, equation (1) becomes

$$\frac{k}{\alpha_e} = \frac{1}{t} \ln \frac{\alpha_e}{\alpha_e - \alpha} = \frac{2{,}303}{t} \log \frac{\alpha_e}{\alpha_e - \alpha} \tag{2}$$

[13] M. Barbul, Gh. Şerban, I. Ghejan and T. Filotti, *Petrol şi Gaze Bucureşti*, **19**, 181 (1968).

At a determined temperature and at constant pressure, α_e is constant and may be easily and readily determined in the pulsed reactor. It results that an $\alpha_e/(\alpha_e - \alpha)/-t$ diagram allows the calculation of the specific rate k and then of the apparent activation energy of the reaction.

The equilibrium conversions for various temperatures may be calculated using the values of the equilibrium constants, which in turn are calculated according to empirical equations such as:

$$\log K_p = f(T)$$

Such equations were established on the basis of the thermal data of the reaction.

The need for knowing such an equation prompted us to establish it, in the case of this reaction, by achieving the following equilibrium in the pulsed reactor:

$$C_2H_{12} \rightleftharpoons C_6H_6 + 3\,H_2 \tag{3}$$

According to reaction (3), and considering that this system behaves perfectly, the known expression of the equilibrium constant is:

$$K_p = \frac{p_2 \cdot p_3^3}{p_1} = \frac{p_2 \cdot p_3^3}{p_1} \tag{4}$$

where:

p_1 = partial pressure of cyclohexane vapors
p_2 = partial pressure of benzene vapors
p_3 = partial pressure of hydrogen in the system.

In the absence of an inert gas, the total pressure in the system will be:

$$P = p_1 + p_2 + p_3 \tag{5}$$

If we identify by p_{1i} the partial pressure of cyclohexane vapors in the initial pulse, prior to the reaction, we get

$$p_{1i} = p_1 + p_2 \text{ and}$$

$$P = p_{1i} + p_3 \text{ while}$$

$$p_3 = P - p_{1i}$$

so that

$$K_p = \frac{p_2(P - p_{1i})^3}{p_{1i} - p_2} \tag{6}$$

Simplifying the right hand side of (6) by p_{1i} and marking with $p_2/p_{1i} = \alpha_e$ the equilibrium conversion, it results:

$$K_p = \frac{\alpha_e}{1 - \alpha_e}\,(p - p_{1i})^3 \tag{7}$$

In general, within a not very broad range of temperatures and with quite a good approximation the equilibrium constant of a reaction is:

$$\log K_p = \frac{a}{T} + b \tag{8}$$

Writing equation (7) in log form and then comparing it with (8) we obtain:

$$\log \frac{\alpha_e}{1 - \alpha_e} = \frac{a}{T} + b - \log (P - p_{1i})^3 \tag{9}$$

It results that if α_e' is measured for various temperatures while maintaining the $P - p_{1i}$ difference constant, a plot

$$\log \alpha_e / (1 - \alpha_e) + 3 \log (P - p_{1i}) = f(1/T)$$

will allow the calculation of constants a and b.

Value P is measured experimentally, and value p_{1i} is calculated based on the pulse quantity.

As mentioned before, this work was carried out in hydrogen as reaction medium and the pulse quantity did not exceed 1% of P; therefore the $P - p_{1i}$ difference may be considered equal to P in a first approximation. For more accurate calculations it will be corrected with the p_{1i} value, calculated as shown in the experimental section below.

EXPERIMENTAL

1. INSTRUMENTATION AND WORKING PROCEDURE

The apparatus used is similar to the apparatus described by Kokes et al.[1] The detection in chromatographic flux was made by thermal conduction cell. The reactant (cyclohexane or benzene) sample is introduced with a microsyringe in a 1.5–2 μl amount. The chromatographic spectrum of the reaction resultant is shown in fig. 1.

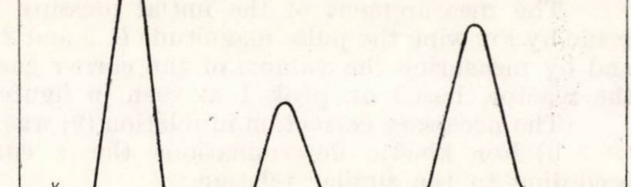

Fig. 1. — Chromatogram of the reaction resultant: *1*, reactant+reaction resultant; *2*, cyclohexane; *3*, benzene.

The temperature in the catalytic layer was maintained constant with a ± 1° error. The carrier gas flow was kept constant at the value of 53 ± 0.5 ml/min.

In fig. 1 peak 1 represents the zone composed of the reactant and the reaction resultant, at the outlet of the reactor. No separation of components is found.

Peaks 2 and 3 are the peaks of cyclohexane and respectively of benzene separated in the analytical column.

In case of equilibrium measurements, cyclohexane and benzene pulses were alternately introduced in the reactor to verify the attainment of the equilibrium. The differences of the respective conversions, measured by comparison with cyclohexane, were maintained within the limits of ± 0.1 per cent.

The analytical column: l = 1.5 m, Ø = 44.0 mm, brick C_{22} 60–80 mesh, ethylene benzoate impregnation,[14] 10% by weight.

2. THE CATALYST

A Pt/Al_2O_3 type catalyst of own manufacture was used. Its features are :

- composition : 0.4 per cent Pt
- specific surface 220–240 sqm/g
- total acidity (after calcination at 500°) 2.1 milliequiv. pyridine/g.

Amount of catalyst

- For equilibrium measurements, 1 g, i.e. a 1.2 cm high column
- For kinetic measurements, 0.0773 g in a ca. 1 mm high column

The catalyst was activated by heating the reactor in a hydrogen current for 6–12 hours at a temperature of 500°.

3. CALCULATIONS

a) In equilibrium measurements, the α_e conversion was calculated according to relation :

$$\alpha_e = \frac{A_{3e}}{A_{2e} + A_{3e}} \tag{10}$$

where A_{2e} and A_{3e} are the areas of the peaks 2 and 3 corresponding respectively to the non-reacted cyclohexane and to the obtained benzene, under equilibrium conditions. It is obvious that the areas were corrected relative to a standard mixture.

The measurement of the initial pressure of the reactant p_{1i} was made by knowing the pulse magnitude (1.5 and 2 microliters, respectively) and by measuring the volume of the carrier gas in which this pulse left the reactor, based on peak 1 as seen in figure 1.

The necessary correction in relation (9) was made with a mean value.

b) For kinetic determinations the α conversion was calculated according to the similar relation :

$$\alpha = \frac{A_3}{A_2 + A_3} \tag{11}$$

---

[14] A. Pop and P. Dumitrescu, *Rev. Roumaine Chim.* "Omagiu Raluca Ripan", 1966, p. 449.

One considered as reaction time t (relation (2)), a conventional time, the spatial time t_s, as defined by relation

$$t_s = \frac{m\, p_r\, T_r}{D_v\, p_a\, T_a} \tag{12}$$

where

m = the mass of catalyst in the reactor
D_v = the volumetric flow (ml/s) measured at air pressure and room temperature
p_a, p_r = the mean pressure in the catalytic layer and the air pressure, respectively
T_r, T_a = the reactor and the room temperatures, respectively, measured in Kelvin degrees.

The operating conditions were achieved so as to have no pressure drop in the catalytic layer, hence the pressure p_a was identical to the pressure measured at the reactor inlet and equal to P in relations (5) (6).

For our kinetic measurements we considered the chromatographic retention time as reaction time, because the length of the catalyst column was too reduced and so no difference could be made between the retention time of a reactant and that of an inert gas. On the other hand, for first order reactions, where conversions are not dependent on either the pulse concentration or on the shape of the peak, we considered as reaction time the spatial time as in the case of a continuously operated reactor.

RESULTS AND DISCUSSION

a) ESTABLISHMENT OF THE EQUILIBRIUM EQUATION

Table 1 includes the equilibrium conversions measured for a series of seven temperatures (546 – 609.5 K) and six total pressures (P = = 1.32 – 1.8).

Table 1

Equilibrium conversions (α_e) at various temperatures and pressures

Temp. K	Pressure (atm.)					
	1.32	1.40	1.50	1.60	1.70	1.80
546.0	—	0.203	0.180	0.143	0.130	0.104
558.5	0.381	0.361	0.256	0.223	0.207	0.184
567.5	0.570	0.561	0.525	0.520	0.455	0.427
576.0	0.620	0.635	0.603	0.587	0.518	0.484
583.5	0.812	0.790	0.773	0.715	0.697	—
596.0	0.950	0.903	0.874	0.842	0.839	0.825
609.5	0.972	0.974	0.950	0.948	0.938	0.913

Using the data from table 1, the $\log \frac{\alpha_e}{1 - \alpha_e} + 3 \log (P - p_{1i})$ values were calculated. Further, these values permitted to determine the constants *a* and *b* of equation (8), by employing the method of least squares.

Thus, the following equation is established for the equilibrium constant of the cyclohexane dehydrogenation reaction at a $P = 1$ atm.

$$\log K_p = 19.413 - \frac{10.751}{T} \tag{13}$$

The *a* and *b* constants were determined with a medium error of ± 3 per cent.

The resulting equation was verified by means of the thermal data found in the literature,[15 16] and of the equation established by Jarkov and Frost[4] for benzene hydrogenation:

$$\log K_p = \frac{9590}{T} - 9.9194 \log T + 0.002285\, T + 8.565 \pm 0.084 \tag{14}$$

by calculating several comparative values of the respective quantities. Thus:

The temperatures for which K_p is 1 ($\log K_p = 0$) are:

— According to equation (13) established by us 553.84
— According to the thermal data 555.13
— According to the Jarkov and Frost equation 552.02

We also calculated the log K_p values for seven temperatures of the studied range, which are listed in table 2.

Table 2

Values of the equilibrium constant (log K_p) of the cyclohexane dehydrogenation reaction calculated based on various equations

Temp. K	log. K_p		
	Based on thermal data[15,16]	Based on equation (13)	Based on the Jarkov and Frost eq. (14)
513.16	−1.6715	−1.6270	−1.5416
533.16	−0.8421	−0.7520	−0.7203
553.16	−0.0708	−0.0203	+0.0434
573.16	+0.6457	+0.6550	+0.7541
593.16	+1.3136	+1.2880	+1.4206
613.16	+1.9428	+1.8790	+2.0440
633.16	+2.5346	+2.4330	+2.6311

As illustrated, the results obtained from the relation established by us are close to the thermal data and this entitles us to deduce that our approach is suitable for the study of chemical equilibria in all the cases in which the reactant stage is gaseous and the heterogeneously catalysed reaction is rapid enough. The procedure is adequate both for

---

[15] A. P. I. National Bureau of Standards, edited by F. D. Rossini, "Selected Values of Properties of Hydrocarbons", Washington, 1947, p. 552.

its efficiency and for the satisfactory accuracy of results. We consider that the accuracy of results would be significantly improved if the instrumentation employed for the temperature control and for the measurement of the pressure in the reactor yielded better performances than the instrumentation employed by us.

The errors altering the measurement of these characteristics may bring about most significant errors in all the measurements of this kind. Analytical errors are much reduced (below 1%) if the analysis is carried out in a column that totally separates the compounds involved and under conditions in which the areas of chromatographic peaks are large enough (i.e. a high detection sensitivity and also a high rolling speed of the recording paper).

b) CALCULATION OF KINETICS OF THE STUDIED REACTION UNDER REVERSIBILITY CONDITIONS

To calculate the reaction rate and the activation energy the cyclohexane conversion to benzene was determined for three temperature values under the shown experimental conditions.

The values of α_e corresponding to the respective temperature and reaction pressures were calculated according to equation (13).

The results are shown in table 3.

Table 3

Conversions of cyclohexane to benzene (α), under conditions of reversibility

Temp. K 547.5		558.5		584.0	
t_s (sec)	α	t_s (sec)	α	t_s (sec)	α
0.184	0.1546	0.101	0.4834	0.085	0.8233
0.220	0.1736	0.124	0.5312	0.091	0.8311
0.241	0.1899	0.178	0.5759	0.111	0.8831
0.300	0.3399	0.184	0.6067	0.137	0.8913
—	—	0.210	0.6240	0.199	0.9093
—	—	0.344	0.6410	0.240	0.9213
—	—	—	—	0.271	0.9285

t_s – spatial time calculated based on equation (12).

The kinetic isotherms in fig. 2 were obtained by using equation (2) and the data above, establishing the apparent overall rate constants which are shown in table 4.

Table 4

Values of apparent rate constant (k)

Temperature k	k (cm^3 g^{-1})
547.5	0.809
558.5	0.942
584.0	1.692

Finally, using an Arrhenius plot $\log k - 10^3/T$, the activation energy was determined for reaction $E_a = 13.0$ kcal/mol which is in agreement with a large number of data in the literature.[13,17]

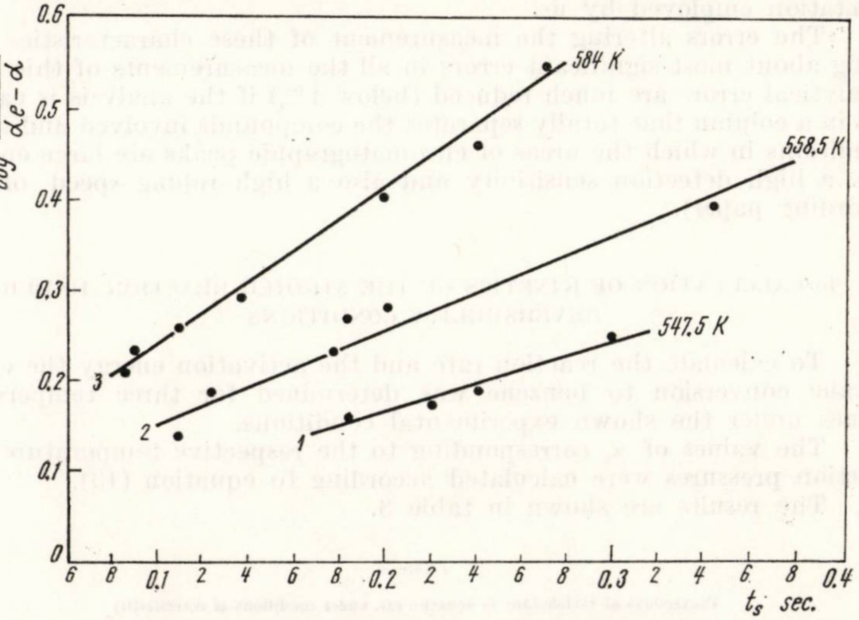

Fig. 2. — Kinetic isotherms based on equation (2):
1, dependence $\log \alpha_e/\alpha_e - \alpha$, — t_s, at 547.5 K;
2, dependence $\log \alpha_e/\alpha_e - \alpha$, — t_s, at 558.5 K;
3, dependence $\log \alpha_e/\alpha_e - \alpha$, — t_s, at 584.0 K.

SOME ASPECTS OF RADIOLYTIC OXIDATION OF PHENOL IN AQUEOUS SOLUTION

MARIA FITI

Institute of Atomic Physics, P.O. Box 35,
Bucharest — Romania

Received July 27, 1973

in the megarad range radiolysis of aqueous solution of phenol in appropriate conditions, a final solid product P_A is formed corresponding to the G (-phenol) = = 1–2 mol/100 eV. In acid solution (pH < 3) P_A is formed during irradiation and can be separated as an amorphous white yellow powder. This material is readily soluble in ethanol, acetone and water at an alkaline pH and is insoluble in water and in other nonpolar solvents at an acid pH. The dry product P_A is unstable, it gradually turns into a dark material. In neutral solution (pH = 6–8) P_A is formed as a colloid solution from which P_A can be separated by acidifying the solution, after irradiation. The alkaline solution (pH > 8) develops a brown-red colour by irradiation and does not give any solid P_A-like products. The present results showed that P_A is probably a "so-called" polymer formed by intermolecular association between phenol and its radiolytic oxidation products.

INTRODUCTION

The literature[1-3] concerning the radiolysis of aqueous phenol solution has shown that free OH radicals can hydroxylate phenol and only *ortho* and *para* dihydroxy-derivatives (catechol and quinol) and *ortho* and *para*-benzoquinone are formed.

More recent papers,[1-10] using pulse radiolysis technique reported data concerning the transient species primarily formed in the reactions of e^-_{aq}, H and OH radicals with phenol and the rate constants of these reactions.

In spite of this progress there are no results, in the literature on the radiolytic oxidative association of phenol in aqueous solution.

The present work was concerned to investigate particularly this process apparently leading to a polymeric material.

EXPERIMENTAL

Materials. All materials used for preparation of solutions and for analysis were of analytical grade purity without further purification and water was triple distilled. Deaeration of solutions, before irradiation, was carried out either in vacuum or by bubbling pure argon, through the solution of interest, for at least 30 minutes.

Iradiations were carried out in 10–20 ml solution samples contained in pirex ficels of 16 mm diameter.

As radiation source we used a 2 MeV electrons beam from a linear accelerator which gives a dose-rate of 1,5 Mrad/min and a Cobalt-60 γ-rays source at a dose-rate of 3 Krad/min. The total dose used was within 0,2 to 10 Mrad range.

Analysis of the main radiolytic products was carried out by different methods as follows.

Ultra violet spectrophotometry [1,11] was used to determine the oxidation products of phenol, as dihydroxybenzene which absorbs at λ of 288 nm ($\varepsilon = 2700\ M^{-1}\ cm^{-1}$) and benzoquinone absorbing at of 245 nm ($\varepsilon = 21500\ M^{-1}\ cm^{-1}$).

Visible spectrophotometry has been used to measure the optical absorption of coloured products in irradiated phenol solutions. This colour is attributed [12] to benzoquinone formation which has a maximum absorption at λ of 430 nm.

For phenol analysis we used the colorimetric method with *p*-nitroaniline.[13] We calculated *G*(-phenol) value corresponding to the solid product P_A formation by measuring the remaining phenol in the irradiated solution after P_A product separation.

RESULTS AND DISCUSSION

By irradiation under certain conditions, the aqueous phenol solution led to the formation of a polymer product P_A ignored in the previous work concerning the radiolysis of this system.

The results of the present work show that P_A product formation seems to be a process of both theoretical and practical importance.

Dose-effect. The solid radiolysis product of phenol is apparently formed only by irradiation of its acid aqueous solution at dose values higher than 0,1 Mrad. Even so it seems to be dose-independent because it does not require any induction period.

Dose-rate effect is also insignificant in the range of 3 Krad/min to 1,5 Mrad/min.

There is no apparent change in the nature and yield of P_A product between two samples irradiated at the same total dose but at

the extreme above values of dose-rate range. In other words the P_A product does not result from a long chain process.

Concentration effect of phenol within 10^{-4} to 5.10^{-2} M range is not significant but at concentrations higher than 5.10^{-2} M the product formed changes gradually into a brown, yellow, sticky oil-like product.

Oxygen and additives effect

The aqueous phenol solution saturated by oxygen does not give any solid product P_A, while by deaerating the solution, G(-phenol) has its maximum value of 1–2 molecules/100 eV. In normal aerated solution P_A is formed only at high dose irradiation when all oxygen is consumed. This means that the process of P_A formation does not take place in the presence of oxygen.

On the other hand, the presence of OH radicals scavengers such as ethanol leads to the decrease of P_A formation as well. This result shows that P_A precursor is mainly the intermediate entity formed by phenol reaction with OH radical.

The role of pH.

Amongst other parameters the effect of pH solution on P_A-like product formation is most important, as one can see below.

1) Acid solution (pH < 3) irradiation at doses higher than 0,2 Mrad gives during irradiation a solid product P_A which can separate as an amorphous white-yellow powder. Using NaOH aqueous solution the P_A product is readily dissolved and a yellow brownish solution is obtained. Acidifying gradually P_A alkaline solution the solid P_A product is reversibly formed.

The dry P_A powder shows a relatively poor stability turning into a dark material, but its suspension in water at an acid pH is stable. It is also easily soluble in polar solvents such as alcohols and acetone and insoluble in nonpolar solvents such as carbon tetrachloride, chloroform, benzene.

2) *Neutral solution* (pH $= 5-8$) irradiated under the same conditions turns into a yellow colloid solution which yields the solid P_A-like product at acid pH values.

The solid product formed in this case is somewhat different from that obtained in the above acid solution; it appears as a dark yellow coloured gel.

3) *Alkaline solution* (pH > 8) gets a brown-red colour by irradiation and when acidified, it turns gradually into yellow reversible colour without formation of any P_A -like solid products. This colour is attributed to the benzoquinone formed as a results of phenol oxidation.

Nature of P_A product

In order to understand the radiolytic mechanism of P_A. formation we must know the structure and the properties of this new product. As we shall see later this seems to be a "so called polymer of phenol" formed by intermolecular complex association of radiolytic oxidation products of phenol.

Infra-red spectrum of solid P_A product separated from both irradiated acid and neutral solution shows some new characteristics compared to the infra red spectrum of solid phenol.

The absorption due to the OH phenol group is considerably wider in P_A spectrum and shifted to lower frequencies. In literature[14] this fact is attributed to the OH group intermolecular association. The maximum of OH appears at 3425 cm^{-1} for pure solid phenol whereas for P_A product it appears shifted at 3390 cm^{-1} with an appreciable shoulder at 2930 cm^{-1}.

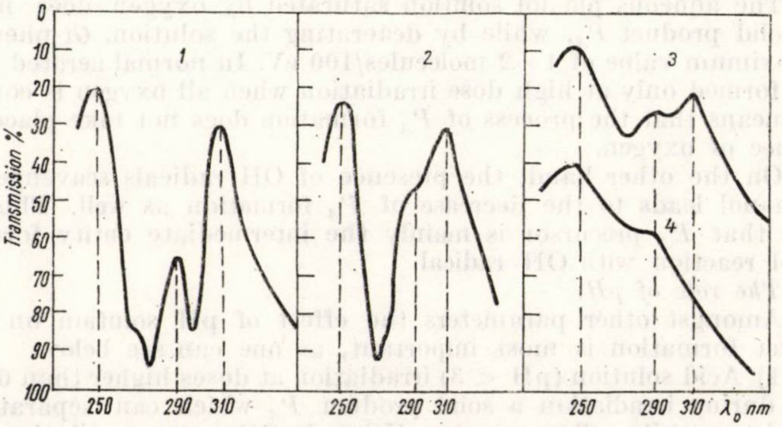

Fig. 1. — Ultra-violet spectra of 5.10^{-3}M aqueous phenol solution irradiated with 1,5 Mrad dose at different pH values but recorded at pH = 9.
1) pH ≃ 2; 2) pH ≃ 6; 3) pH ≃ 9; 4) quinhydrone aqueous solution at pH = 9.

On the other hand, the P_A product spectrum shows a new absorption at frequencies from 1650 to 1720 cm^{-1} which covers the characteristic band of benzoquinone carbonyl group.

It is known[14] that *o*-benzoquinone absorbs at 1667 cm^{-1} and *p*-benzoquinone at 1669 cm^{-1}.

This result shows that the P_A product is a complex polymer containing both phenolic and quinonoid products of phenol radiolytic oxidation. This product is probably formed by association bonds between OH group and C=O quinonoid group.

The ultra-violet spectrum of the alkaline aqueous solution of P_A essentially shows the characteristic absorptions of quinol and benzoquinone. The spectra of irradiated phenol solution at different pH values are shown in figure 1 (curves *1*, *2*, *3*). Spectrum 4 corresponds to the aqueous solution of quinhydrone. All these spectra were recorded at pH = 9.

As we can see, in spite of apparently big differences between the irradiated phenol solution 1, 2, 3, the spectra are rather similar in all cases, the maximum absorptions are at the same wavelengths of about 250, 290 and 310 nm.

---

[14] « Infrared Structural Correlation Tables », Ed. Hyden & Son. Ltd. London, 1962, table 3.

It is known from previous papers [1,11] that the 288 nm absorption is due to quionol and catechol and that of 245 nm is due to benzoquinone. The three spectra 1,2,3, differ from one another only by the absorption intensities and the relationship between them.

Using as a reference the spectrum of aqueous solution of quinhydrone, as a typical association complex of hydroquinone with benzoquinone, we can see that only the 310 nm maximum is characteristic of irradiated phenol solution but it cannot be attributed to the P_A because it appears even in the case of alkaline phenol solution (spectrum 3) where P_A is not at all formed.

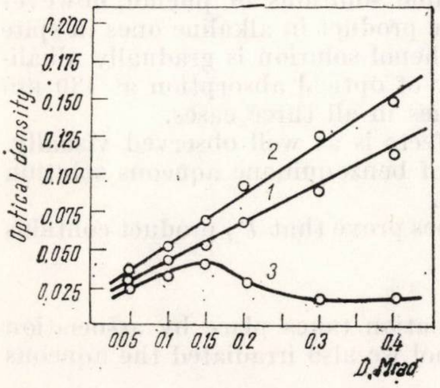

Fig. 2. — Optical absorption of 5.10^{-3}M aqueous phenol solution at $\lambda = 290$ nm as a function of irradiation dose.

1) neutral solution irradiated and measured at pH $\simeq 6$; 2) acid solution pH $\simeq 2$, measured at pH $\simeq 9$; 3) filtrate of acid solution after P_A removal, measured at pH $\simeq 9$.

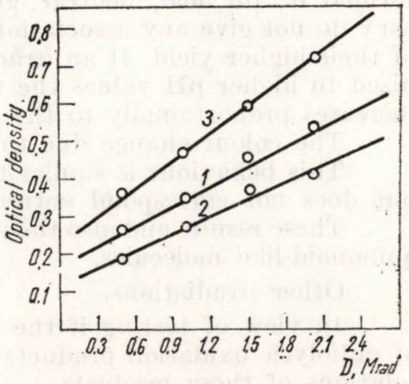

Fig. 3. — Optical absorption of 5.10^{-3} M aqueous phenol solution at $\lambda = 430$ nm recorded at pH = 9, as a function of irradiation dose.

1) acid solution pH = 2; 2) neutral solution pH = 6; 3) alkaline solution pH = 9.

Measuring optical density as a function of irradiation dose at 290 nm we obtained the results shown in figure 2.

In neutral solution we measured the optical density directly in irradiated solution (curve 1), but in acid solution we adjusted in advance the pH at about 9 in order to dissolve P_A product (curve 2). At the same time we measured the filtrate of irradiated acid solution after P_A removal and after adjusting pH to the same value (curve 3).

These results show clearly that optical absorption of 290 nm is due to the P_A product. This behaves similarly to the known radiolysis products of phenol studies before[1-10] and this fact suggests that P_A is formed from these compounds by weak intermolecular association bonds.

The visible absorption spectra of irradiated phenol solutions as above (cases 1,2,3) and of quinhydrone aqueous solution recorded at an alkaline pH are also very similar to each other. They show a broad unstructured absorption band within 360 and 640 nm which decreases gradually after 430 nm. The spectra recorded at an acid pH, in the case 3 and 4, show a maximum at 430 nm, attributed to the quinonoid like products.[1] In the case 1 and 2, because of $P_A^{\cdot}$ formation as an insoluble product at acid pH, we could measure the 430 nm optical absorption only at an alkaline pH to ensure the dissolution of the product.

Figure 3 shows the optical absorption at 430 nm as a function of irradiation dose in the three cases 1,2,3. (The measuring pH = 9). As we see from these results the quinonoid products absorbing at 430 nm are formed in all, acid, neutral and alkaline solutions of phenol, however they do not give any association P_A like product in alkaline ones in spite of their higher yield. If an irradiated phenol solution is gradually alkalinized to higher pH values the intensity of optical absorption at 430 nm increases proportionally to the pH values in all three cases.

The colour change due to this effects is as well observed visually.

This behaviour is similar to that of benzoquinone aqueous solution but does not correspond entirely to it.

These results and also the above ones prove that P_A product contains quinonoid-like molecules.

Other irradiations.

In view of testing if the P_A formation takes place by association of radiolytic oxidation products of phenol we also irradiated the aqueous solutions of these products.

The mixtures of hydroquinone, catechol with *o* and *p*-benzoquinone in aqueous solution with or without phenol, were irradiated in the same conditions as phenol solutions discussed above but no solid $P_A^{\cdot}$-like product has been obtained. This means that $P_A^{\cdot}$ is formed during radiolytic oxidation of phenol rather than from phenol radiolysis final products.

The mechanism of radiolytic association of phenol in aqueous solution.

All the results obtained in this work show that a complex radicalic association process takes place in this case. It leads to a polymer-like product of poor stability containing phenol and quinonoid molecules. The properties of P_A product show that it is not a true polymer but rather a complex association product.

The spectral data show both the similarities and differences between P_A and quinhydrone (a reference, well-known, association complex of hydroquinone and *p*-benzoquinone).

The structure of the P_A product is also more complex probably due to the fact that *o* and *p* isomers of dihidroxybenzene and benzoquinone and perhaps phenol molecules are contributing to the process.

Our analytical methods fail to establish the exact contribution of each component molecule.

By colorimetric method of *p*-nitroaniline we proved qualitatively that P_A product contains phenols with free para position (phenol and/or catechol).

In the case of high phenol concentration solutions, the phenol molecule will very likely also participate in the association because the product formed is essentially different from P_A; it is a dark yellow oil-like product.

In spite of the uncertainities connected with the real composition and structure of P_A product, our results may reveal some interesting features of this radiolytic association process.

First of all the P_A association product does not result directly by association of phenolic and quinonoid products issuing from radiolytic oxidation of phenol molecule.

As mentioned above, P_A like products do not appear by irradiating the mixtures of these compounds in their aqueous solutions.

It is very likely that P_A formation depends on some radicalic entity which appears as an intermediate of phenol radiolysis and which is subject to a pH dependent equilibrium.

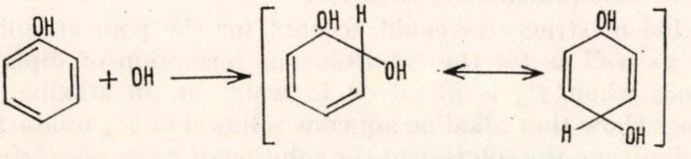
It has been shown that the final radiolytic products are essentially the same at all pH values but nevertheless the process does not occur at alkaline pH.

This fact leads to the idea that radicalic entity involved in association process at an alkaline pH takes an anionic form which does not allow the formation of association bonds.

The P_A^{-} formation appears in appropriate conditions even at small irradiation doses but it could be observed only at high dose irradiation when its concentration becomes high enough to give a precipitate.

The linear dose dependence which we obtained in both acid and alkaline solution (figure 3) supports this idea because there is no induction period for the formation of radiolytic products.

All these facts lead to the conclusion that the homolytic oxidation mechanism of phenol by radicals as studied in the previous paper [1,11,15-17] should be essentially the same for P_A product because the latter one contains the phenol oxidation product.



(1)

Hydroxylation of phenol starts with OH adduct formation in *ortho* and *para* position of aromatic ring (see scheme 1)

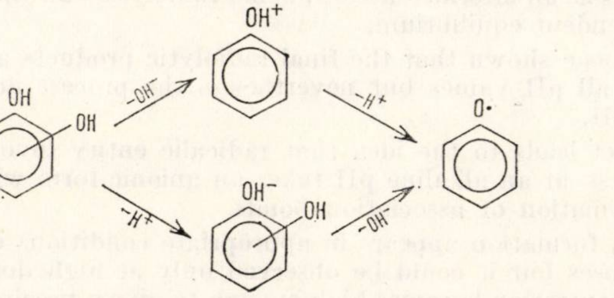
[17] N. A. Waters., « Mechanism of Oxidation of Organic Compounds », Cap. 9, Methuen Co. Ltd., London, 1964, p. 132.

OH adduct of phenol by water elimination changes into a relatively more resonance stabilized radical, fenoxyl radical (see scheme 2)

This water elimination reaction is fully reported in a pulse radiolysis work [10] as an acid-base catalysis process which could proceed, via separate OH^- and H^+ removal as follows (see scheme 3)



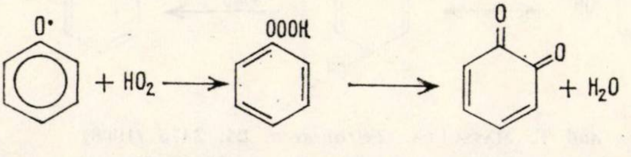
(3)

This reaction appears to be a general one for OH adducts of phenols and probably other types of aromatic compounds.[12] The issuing phenoxyl radical seems to be the radical species involved in the association process leading to the P_A-like product.

It is very difficult to know exactly what is the role of phenoxyl radical in the association process but in the absence of oxygen it is likely that phenoxyl radical reacts with the environment radicals and molecules yielding some semiquinonoid structures.

This kind of structures could account for the poor stability of the P_A product as well as for the simultaneous formation of diphenols and benzoquinones when P_A is dissolved in water at an alkaline pH. Our above findings show that alkaline aqueous solution of P_A product behaves practically similar to the solution of the solution of its unassociate phenolic and quinonoid component.

In the presence of oxygen an ozonide like structure is formed by the O_2 or HO_2 addition to the phenoxyl radical and yields directly benzoquinone as follows :



(4)

In our conditions the HO_2 radical cannot be involved in radiolytic formation of P_A product and of benzoquinone molecule which it contains. On the other hand the G(-phenol) value is too high to be explained only on the basis of OH radicals reaction. It is well known that $G_{OH} = 2{,}8$

and the phenol oxidation to benzoquinone via dihydrobenzene needs four oxidation equivalents.

This fact leads to the idea that the radiolytic formation of P_A product probably involves also another species, such as H atom radicals, H^+ ions and water molecules. The P_A^{-} product structure might result as a compromise of phenol OH group participation to both charge transfer and H bond association with $C = O$ quinonoid group.[18]

In a subsequent work we intend to make some further studies on the structure of P_A^{-}-like products because this radiolytic process seems to be of practical and theoretical importance.

POTENTIOMETRIC DETERMINATION OF DISSOCIATION CONSTANTS OF SOME AROMATIC ACETOACETAMIDES

ARJUN D. TANEJA and N. U. M. RAO

Department of Chemistry, Birla Institute of Technology and Science, PILANI (Rajasthan), India

Received July 7, 1973

Acid dissociation constants of acetoacetanilide (AAAH); acetoacet-*ortho*-toluidide (AATH); 2,4-acetoacet-xylidide (AAXH); acetoacet-*ortho*-chloroanilide (CAAAH); acetoacet-*ortho*-anisidide (OAAAH); benzoylacet-anilide (BAAH) and benzoyl-*meta*-nitroacetanilide (NBAAH) have been determined potentiometrically in 50% ethanol and at various ionic strengths. Thermodynamic dissociation constants were obtained by extrapolating to zero ionic strength. The difference in thermodynamic dissociation constants of the studied 1,3-dicarbonyl compounds has been discussed on the basis of substituent effect.

INTRODUCTION

During the last few years, studies on the complex compounds of acetoacetanilide, benzoylacetanilide and their derivatives with bivalent and trivalent metal ions have received major attention.[1–5] Harries et al. have reported the determination of ionisation constants of some acetoacetarylamides[6,7]. The present work was undertaken with a view to study the dissociation constants of acetoacetanilide (AAAH), acetoacet-*ortho*-toluidide (AATH); acetoacet-*ortho*-chloroanilide (CAAAH); 2,4-acetoacetxylidide (AAXH); acetoacet-*ortho*-anisidide (OAAAH); benzoylacetanilide (BAAH) and benzoyl-*meta*-nitroacetanilide (NBAAH) by using the Bjerrum-Calvin titration technique.[8–9]

EXPERIMENTAL

Analytical grade acetoacetanilide, benzoylacetanilide (Aldrich Chemicals, U.S.A.), acetoacet-*ortho*-toluidide, 2,4-acetoacetxylidide, acetoacet-*ortho*-chloroanilide, and benzoyl-*meta*-nitroacetanilide (Eastman Kodak, U.S.A.) and acetoacet-*ortho*-anisidide (BDH, England) were used for experiments. All compounds were recrystallized before use. All other chemicals used were of analytical or reagent grade quality. Sodium hydroxide and perchloric acid solutions were standardised by usual methods. Beckman pH meter (model H2) with a glass calomel electrode assembly was used to determine the charge in hydrogen ion concentration. Solutions of 1,3-dicarbonyl compounds were prepared in ethanol.

Method: The dissociation constants were determined by using the Bjerrum-Calvin titration technique [8,9] as adapted by Irving and Rossotti.[10,11] For reasons of solubility, dissociation constants were determined in 50% ethanol-water mixture (by volume) and sufficient amount of $NaClO_4$ was added to give a definite overall ionic strength. A number of titration were carried out at different ionic strengths viz. 0.02, 0.05, 0.10, 0.15 and 0.20. The following mixtures were titrated in small increments, with standard 1.0M NaOH and the corresponding change in pH was noted. Necessary corrections in pH for alcoholic media were applied.

Mixture 'A': 5.0 ml of 0.20M perchloric acid + 50 ml ethanol + × ml of 1.0M $NaClO_4$ (x = = volume of $NaClO_4$ required for desired ionic strength) + required volume of water to make up the volume of the mixture to 100 ml.

Mixture 'B': 5.0 ml of 0.20M perchloric acid + 40 ml of M/100 1,3-dicarbonyl compound solution in ethanol + 10 ml of ethanol + × ml of 1.0M $NaClO_4$ + required volume of water to make up the volume of the mixture to 100 ml.

All the experiments were carried out at 22.0 ± 0.1°C.

Calculations of dissociation constants: Irving and Rossotti's method was used to calculate the dissociation constants.[10] The average number of dissociable protons attached per molecule ($\bar{n}_A$) can be determined by using the following equation

$$\bar{n}_A = Y + \frac{(v' - v'')(N^\circ + E^\circ)}{(V^\circ + v')\,T_L}$$

Y = total number of dissociable protons present in the compound
T_L = total concentration of the compound
N° = NaOH concentration
E° = initial concentration of the free acid
V° = total volume of the mixture
v' = volume of alkali used for mixture 'A'
v'' = volume of alkali used for mixture 'B'

The dissociation constants were calculated by plotting $\bar{n}_A$ against pH and using the following computational methods: [10]

(i) interpolation at half $\bar{n}_A$ values (*H*)
(ii) interpolation at various $\bar{n}_A$ values (*V*)
(iii) Least square method (*L*)

The values of thermodynamic dissociation constants were obtained by determining the dissociation constants at various ionic strengths and extrapolating to zero ionic strength. The results are recorded in Table 1.

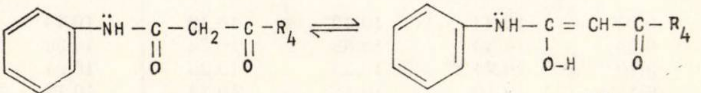
RESULTS AND DISCUSSION

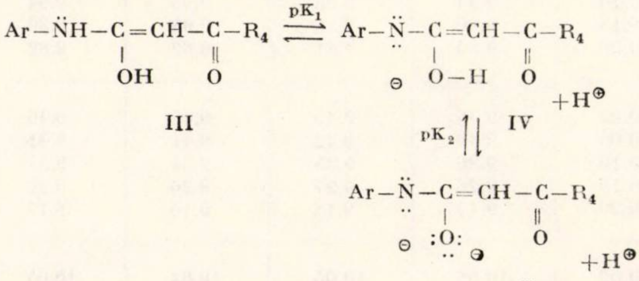
It can be seen from Table-I that the thermodynamic dissociation constants (pK_a^T) values of 1,3-dicarbonyl compounds studied decrease in the order AAAH $>$ AATH $>$ OAAAH $>$ AAXH $>$ CAAAH $>$ $>$ BAAH $>$ NBAAH. This trend can be traced to the presence ofdifferent substituents in the 1,3-dicarbonyl compounds under discussion. The enol form of these 1,3-dicarbonyl compounds may be represented by structure II.



I II

$R_n = \mathrm{H}$ except $R_4 = -\mathrm{CH_3}$ (AAAH);
R_1 and $R_4 = -\mathrm{CH_3}$ (AATH);
R_1, R_3 and $R_4 = -\mathrm{CH_3}$ (AAXH);
$R_1 = -\mathrm{Cl}$ (CAAAH) and $R_4 = -\mathrm{CH_3}$ (CAAAH);
$R_1 = -\mathrm{OCH_3}$ (OAAAH) and $R_4 = -\mathrm{CH_3}$ (OAAAH)
$R_4 = -\mathrm{C_6H_5}$ (BAAH); $R_2 = -\mathrm{NO_2}$ (NBAAH), and
$R_4 = -\mathrm{C_6H_5}$ (NBAAH)

Then the dissociation processes may be denoted as.



$$\underset{\mathrm{III}}{\mathrm{Ar{-}\ddot{N}H{-}C(OH){=}CH{-}C({=}O){-}R_4}} \xrightleftharpoons{pK_1} \underset{\mathrm{IV}}{\mathrm{Ar{-}\ddot{N}^{\ominus}{-}C(O{-}H){=}CH{-}C({=}O){-}R_4}} + \mathrm{H}^{\oplus} \xrightleftharpoons{pK_2} \underset{\mathrm{V}}{\mathrm{Ar{-}\ddot{N}^{\ominus}{-}C(\ddot{O}{:}^{\ominus}){=}CH{-}C({=}O){-}R_4}} + \mathrm{H}^{\oplus}$$

III IV V

Thus the first dissociation constant is due to the liberation of the proton from the $-\mathrm{NH}-$ group; in which case the value of pK_a should be sensitive to the nature of Ar (aryl). This is not in agreement with the results reported by Harries et al.[6,7] According to them,[6,7] the first dissociation step involves the proton of the enolic $-\mathrm{OH}$ group. If we assume this to be true, we cannot account for the large substituent effects (Table-I). They can only be accounted for if the liberation of the first proton from the $-\mathrm{NH}-$ groups is considered. It is well known that the phenyl group can act as both an electron donor and acceptor. If we assume that it acts as an acceptor in the cases of 1,3-dicarbonyl compounds studied, we see that it can accommodate the negative charge on nitrogen in the acid anion by delocalisation, thus facilitating the removal of proton from the $-\mathrm{NH}-$ group. The lower values of pK_a^T in the cases of AAXH, OAAAH and AATH are surprising as the substituents in these cases are quite strong electron donors; but here it is quite reasonable to attribute their low pK_a^T to steric factors being more significant than electronic factors. It is a common observation that substituent groups *ortho* to the acidic function in a phenyl ring have large and unexplained effects, always leading to an increase in acidity. This has been termed the '*Ortho Effect*'. Within these three compounds, however, the order of pK_a^T values is AATH > OAAAH > AAXH, which is the same as the order for the electron donor properties of the substituents in these cases. The lower pK_a^T values of CAAAH is explained on the basis of the electronic effects due to the ortho-substituted chlorine. In this case the steric effect is of little consequence. The presence of chlorine in the ortho-position makes the phenyl ring a stronger acceptor leading to the easier release of the proton from —NH—. This enhancement of acceptor properties of chlorine (in general halogen) substituted phenyl ring is supported by the fact that electrophilic substitution is faster in benzene than in halo-substituted benzene.

The low values of pK_a^T in the cases of BAAH and NBAAH are mainly due to the nature of R_4 (structure III) substituent viz. the phenyl group. The presence of this group permits extended conjugation in the whole molecule which stabilises the acid anion. The nitro-substituent in NBAAH at meta position is not expected to contribute significantly towards the raising or lowering of pK_a^T which is amply borne out by our results.

From these results it can be concluded that pK_a values depend mainly on the nature of the substituents attached to the aryl amido phenyl ring. A coarse linear correlation could be detected between experimental pK_a values and Hammett (σ) constant.[12] For the *ortho*-substituents (R_1 in formula I—II), σ values obtained for *ortho*-substituted benzoic acids.[13] This relationship is illustrated in Fig. 1.

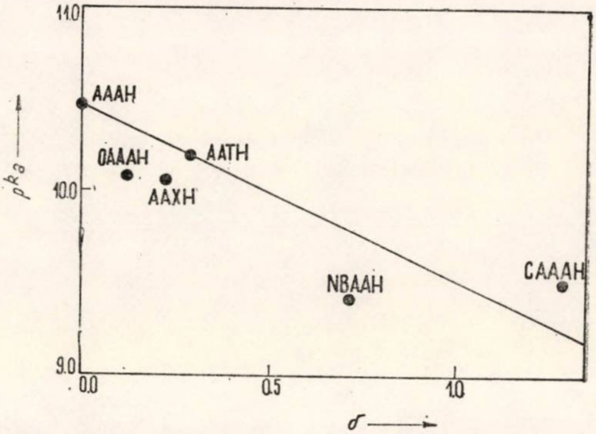


Fig. 1. — Relationship between acidity (pK_a) and Hammet substitution constants (σ) for AAAH, AATH, AAXH, CAAAH, OAAAH and NBAAH.

MICRODETERMINATION OF ORGANIC SULPHUR OR INORGANIC SULPHATE

S. W. BISHARA, M. E. ATTIA, and H. N. A. HASSAN

Microanalytical research Laboratories, National Research Center, Dokki, Cairo, Egypt

Received September 19, 1973

The use of methylthymol blue as a metallochromic indicator for barium has been applied for the indirect microdetermination of sulphate. Inorganic sulphate or sulphate produced from oxidative combustion of organic sulphur is precipitated using an excessive volume of Ba^{2+}. Without separation of the precipitate, excess of Ba^{2+} is titrated, in alkaline medium, against EDTA using methylthymol blue. A colour change from bright blue to light grey denotes the end point. A slight modification allows elimination of interference due to phosphorus or metals; halides (including fluoride) and nitrate do not interfere. For 56 determinations, whether in absence or in presence of one of the interfereing elements, the average percent error amounts to ±0.14; the standard deviation ranges between ±0.02 and ±0.28.

Trace amounts (0.01–0.20 %) of sulphur can be determined through reduction into hydrogen sulphide followed by absorption in sodium hydroxide or zinc acetate or in a mixture of both; the S^{2-} is then determined polarographically,[1] potentiometrically,[1] or titrimetrically.[2] On the other hand, determination of sulphur in amounts usually arising from combustion of sulphur-containing organic compounds depends mainly on oxidation to sulphate [3] followed by a gravimetric,[4,5] titrimetric,[6–11] spectrophotometric,[12] or polarographic [13] method of finish. Usually, an inorganic barium salt solution is reacted with the sulphate formed although salts of other metals, e.g., lead[14,15] have been proposed. This is not unexpected, however, since barium sulphate has the least solubility among sulphates of other metals (0.222 mg/100 ml of cold water).

Since evolution of the O-filled flask method of combustion,[3] the technique has been extensively used for decomposition of organosulphur compounds as evidenced from the large number of publications reported in this connection.[3,5-17] The accuracy and simplicity of the method enabled analysis of solid and liquid organic compounds of sulphur content of up, to 70%.[17] The majority of methods reported for estimation of organic sulphur depends on the fact that the sulphate formed, after fusion or absorption in an oxidising medium, can be determined gravimetrically as barium sulphate[4,5] or titrimetrically against barium ion solution.[6-11,18-21] Thorin,[6,9,10] tetrahydroxyquinone,[7] carboxyarsenazo,[8] sulphonazo III,[11,18] arsenazo III,[19] nitchromazo,[20] and chlorphosphonaze III[21] are suggested as visual indicators for barium but there seems to be some difficulty in detecting the equivalence point with most of these indicators.[11,22] Alternatively, the sulphate formed can be precipitated with Ba^{2+} and excess of the latter determined complexometrically using EDTA. Titrimetric,[3,16,17,23-25] potentiometric,[26] and amperometric[27] methods have been applied for location of the equivalence point. However, the titrimetric finish attracts much attention due to its simplicity and accuracy. Eriochrome Blact T (Erio T)[3,16,23,24] and metaphthalein[25] were applied for the microdetermination of organic sulphur after oxidation to sulphate and precipitation using an excessive volume of Ba^{2+}. However, direct chelatometric estimation of Ba^{2+} using Erio T has been criticized by Pribil[28]; even in the presence of magnesium chelatonate the method is still unsatisfactory since barium forms a somewhat weaker complex than magnesium ($\log_{MgY} K = 8.69$; $\log_{BaY} K = 7.76$).[29] Belcher, Gibbons, and West[24] determined the barium content indirectly through addition of excess of chelaton followed by back titration against magnesium chloride solution using Erio T as indicator.

In the present method, excess of barium is determined, without separation of the precipitated barium sulphate, complexometrically using methylthymol blue as the indicator. A distinct colour change, from

bright blue to light grey, denotes the end point. Nitrogen oxides and halogens (including fluoride) has no effect on the method while interferences due to phosphorus or metals could be overcome.

EXPERIMENTAL

Reagents and materials

Amberlite IR-120 (H^+) cation exchange resin.

Ammonia, aqueous conc solution.

Barium perchlorate, exactly about 0.01 M solution prepared from the A.R. grade quality and standardised against standard EDTA solution using methylthymol blue as the indicator.[28]

Ethylenediaminetetraacetic acid, 0.02 M solution standardised against standard zinc chloride solution.[30]

Hydrogen peroxide, A.R., 35% solution.

Methylthymol blue, mixed in the ratio of 1 : 100 with solid potassium nitrate.

Potassium sulphate, standard about 0.01 M solution prepared from the M.A.R. grade quality (1 ml = 0.960 mg of sulphate).

Thorium nitrate, about 0.01 M solution.

Procedures

Burn an exactly weighed amount (3–8 mg) of the organic sample as usual [3] using 250-ml conical flask charged with 5 ml of bidistilled water plus three drops of 35% hydrogen peroxide. After combustion shake for 5 minutes. Rinse the platinum gauze out and boil to remove excess of oxidant. Continue boiling till the reaction medium is 4–5 ml in volume. While the solution is still hot, introduce, dropwise with stirring, 7 ml of 0.01 M barium perchlorate solution (total volume should not exceed 11 ml).[4] After precipitation, dilute with bidistilled water till the volume is about 40 ml then add 10 ml of conc aqueous ammonia. Before titrating against 0.02 M EDTA solution, add few milligrams of methylthymol blue and continue titration till the blue colour changes to light grey.

Carry out a blank determination.

Determination of sulphur in presence of a metal. After combustion and withdrawal of the sample holder, pass the absorption solution through a 20-cm long column of Amberlite IR-120 (H^+) cation exchange resin at a rate of 2 ml/minute. Wash the resin 5 times with 10-ml portions of bidistilled water. Receive the percolate, and washings, in a conical flask. Boil to remove excess of the peroxide and continue boiling till volume is less than 5 ml. Add barium perchlorate solution and proceed as described before.

Determination of sulphur in presence of phosphorus. After combustion, boil to remove excess of hydrogen peroxide. Cool and then add 1 ml of 1 N nitric acid to attain a pH value of about 3. Introduce 2 ml of 0.01 M thorium nitrate solution. Filter to separate the precipitated thorium phosphate. Pass the filtrate through the cation exchange resin to remove excess of thorium. Wash the resin with 10-ml portions of bidistilled water (5 times). Boil the percolate, and washings, till the total volume is less than 5 ml then continue as already described.

RESULTS AND DISCUSSION

The presence of sulphur even as a minor constituent (down to 0.001% or less) in many products whether organic, e.g., petroleum, or inorganic, e.g., metals such as copper, causes some undesirable phenomenae during the different industrial processes. It is always, therefore, preferable to have alternative procedures for its accurate determination. This implies well both when sulphur constitutes a minor or a major part of the substance. The majority of synthetic organo-sulphur compounds, on the other hand, contain 5–50% by weight as sulphur. The present method has been successfully applied for determination of 0.3–2.0 mg of sulphur present in 3–8 mg samples. Nineteen compounds (aliphatic and aromatic) containing 4–42% sulphur as sulphide, disulphide, thiol, sulphoxide, sulphonic, thiourea, dithiocarbamate, or heterocyclic were analysed (Table I). Correct results were obtained with all types of sulphur linkages. For 38 determinations, the average percent error amounts to ±0.14 with a standard deviation ranging from ±0.02 to ±0.25. The method is simple and expeditive : one determination consumes less than 25 minutes including the weighing step.

Organic sulphur is transformed quantitatively into sulphate anion by combustion in an O-filled flask charged with an oxidising absorbent (aqueous hydrogen peroxide). After removal of the excess of oxidant, a measured excess of barium is used to precipitate the sulphate. The development of conditions most suitable for complete removal of sulphate as the barium salt is undoubtedly the first limiting step for any analytical method based on the interaction between sulphate and barium. Ogg,[4] after an extensive and detailed study on the gravimetric microdetermination of sulphur, recommended a reaction medium not more than 10–11 ml in volume to ensure quantitative precipitation of barium sulphate. Since the author has been interested in a gravimetric determination, he advocated digestion for 15 minutes to coagulate the precipitate. Obviously, this is no longer important when a titrimetric finish, without separation of the precipitate, is to follow.

The excess of Ba^{2+} is titrated complexometrically against EDTA solution using methylthymol blue as the indicator.[31,32] The blue-coloured barium-methylthymol blue complex changes to light grey at the end point. The change in colour is more distinct and much easier to be detected than that noticed with some other indicators, e.g., thorin. Barium (like Ca^{2+}, Sr^{2+}, and Mg^{2+}) forms with EDTA a complex of moderate stability (Log_{BaY} K = 7.76). From Bingbombs curve,[33] describing the relation between the pH value and stability constant, it is clear that the minimum pH value at which the titration of Ba^{2+} against EDTA can be conducted is slightly above 10. Aqueous ammonia or sodium hydroxide have been first proposed [31] to attain the required alkalinity but ammonia proved more advantageous.[32] The only shortcoming underlying the use of such

Different weights ranging from 3 to 10 mg of triphenylphosphine (P, % = 11.81) are mixed with the organo-sulphur compound before combustion.

a high pH value is that phosphate ion, if present, interferes leading to high results for sulphur. This could be overcome through a preliminary treatment with thorium nitrate solution. Addition of the latter to the acidified absorption solution (pH 3) precipitates the thorium phosphate quantitatively.[28] After separation of the precipitate, excess of Th^{4+} is removed by passage through a cation exchange resin. To the percolate, the known excess of Ba^{2+} is added, the solution made alkaline and then titrated normally for the sulphur figure. Correct results were obtained for sulphur in triphenylphosphine sulphide (4 determinations; Table 2). Owing to the lack of organo-sulphur compounds containing phosphorus, synthetic mixtures of triphenylphosphine with different sulphur compounds were analysed. In all cases correct sulphur figures were obtained. Up to 1.2 mg of phosphorus (found in about 10 mg of triphenylphosphine; cf. Table 2) did not interfere. It is expected that higher amounts of phosphorus can be tolerated provided the required excess of Th^{4+} is added.

Methylthymol blue forms blue-coloured chelates with a wide variety of metal cations whether in acidic (Bi, Pb, Th, Sc, La, Hg, Cd, Zn, Al, Fe, Ni, Co, In, Ga, U, V, Cr, rare-earth metals, Sn^{4+}, and Pd^{2+}) or in alkaline (Mn, Mg, Ca, Sr, and Ba) medium.[28] Consequently, many metals would interfere. However, passing the reaction solution, prior to precipitation, through a cation exchange resin eliminates the risk of possible interference by any of the metals mentioned above. As representative examples, three organo-sulphur compounds containing cadmium or zinc were analysed following this procedure. Correct results and sharp end points were obtained for sulphur with the three compounds (Table II). Sodium or potassium did not interfere even without treatment with the resin (Tables 1 and 3). This can be explained in view of the very low stability constants of these metal complexes with EDTA, e.g., $\log_{NaY} K = 1.66$.[28]

Table 3

Estimation of the sulphate ion

Ml 0.01 M K_2SO_4	Titre, ml EDTA	SO_4, mg		mg
		Calc.	Found	
—	⊙ 1.40	—	—	—
0.5	1.15	0.480	0.482	+0.002
1.0	0.91	0.960	0.944	−0.016
1.5	0.65	1.440	1.446	+0.006
2.0	0.40	1.920	1.927	+0.007
2.5	0.15	2.400	2.409	+0.009

⊙ Equivalent to 3 ml of barium perchlorate solution; a blank value of 0.04 ml is subtracted from the original titre of 1.44 ml.

Perchlorate, chloride, bromide, and iodide have no effect on the method; addition of up to 40 mg of chloride ion were found harmless. Since the H^+ increases the solubility of barium sulphate,[34] Cl^- was introduced as sodium chloride. Fluoride, also, did not interfere. Mixing cystine with about 8 mg of fluorobenzoic acid (1.25 mg F^-) gave accurate results for sulphur. This is not unexpected, however, since the solubility of barium fluoride is 120 mg/100 ml of cold water. Some of the compounds analysed in Table I contain nitrogen whether in the partially or fully oxidised form. However, the amount of nitrogen oxides produced after oxidative combustion of such class of compounds did not affect the sulphur figure. Furthermore, addition of as much as 50 mg of NO_3^-, added as potassium nitrate, still proved tolerable. That such high nitrate concentrations exert no influence on the result for sulphur suggests suitability of the proposed method for estimation of sulphur in nitrate explosives.

The present method hasbeen successfully applied for determination of inorganic sulphate. Obviously, the same procedure is adequate after elimination of the oxidative combustion step. Results obtained using standard potassium sulphate solution are given in Table 3.

SEPARATION OF CREATININE FROM LEUCINE IN A PROTEIC HYDROLYSATE BY PAPER CHROMATOGRAPHY WITH A COMBINED TEMPERATURE AND STATIONARY PHASE SECTION GRADIENT*

A. CONSTANTINESCU and C. LITEANU

"Babeş-Bolyai" University, str. Arany Ianoş 11, Cluj, Romania

Received October 12, 1973

The chromatographic resolution has been largely increased by associating a temperature gradient with a complex gradient of stationary phase section, enabling thus the separation of a creatinine and a leucine mixture. The possibility of an interaction between creatinine chromatographic spots and some amino acids having close R_f values is discussed. In order to reveal the effect of the change in the stationary phase section (baffles) in the separation process, the growth effect of the chromatographic column length was calculated for the creatinine + leucine mixture.

In addition to essential amino acids, proteic hydrolysates may also include unessential amino acids, such as creatine and its internal anhydride, creatinine. Although these do not play a major part with regard to the quality of the proteic hydrolysate, their separation from complex mixtures with other amino acids of the hydrolysate raises a series of analytical difficulties, particularly due to the presence of other amino acids in significant proportions, such as leucine and isoleucine. The aim of this paper has been to solve this difficulty in the case in which leucine is present in the creatine and creatinine mixture.

WORKING PROCEDURE

The technique of isothermal ascending chromatography on Whatman No. 1 paper was first used with an *n*-butanol + acetic acid + water 4 : 1 : 5 v/v mixture as an eluent.

Samples were also chromatographed in a temperature gradient, making use of a suitable chromatographic chamber for this purpose.[1]

---

* Paper presented at the Symposium "Gradient chromatography", Cluj, September 1972

[1] C. LITEANU and S. GOCAN, *Bull. Soc. chim. France*, **1969**, 1416.

Creatine and creatinine, their mixture, a leucine + isoleucine + creatine + creatinine mixture were chromatographed in parallel, as well as the proteic hydrolysate, both on baffle-free columns and on baffled chromatograms, first isothermally and then in a temperature gradient, with similar chromatographic times. As a support of chromatographic migration, we used, under the same conditions, in addition to continuous strips (the classical form of chromatogram), also baffle-punched paper chromatograms employed in a previous work.[2]

Data obtained for samples containing only creatinine and only leucine and creatine, respectively, are listed in table 1.

Table 1

Separation of creatinine from leucine

Time (h)	t_1	t_2	t. grad (°/cm)	R_f					
				Creatinine		Leucine		Creatine	
				with baffles	baffle-free	with baffles	baffle-free	with baffles	baffle-free
1.5	25	25	0	0.80	0.66	0.78	0.62	0.54	0.48
1.5	25	55	4.3	0.91	0.80	0.83	0.67	0.62	0.56

RESULTS AND DISCUSSION

R_f 0.48 and 0.60, respectively, resulted in the case of creatine and creatinine separated and identified from proteic hydrolysate under isothermal conditions and on a baffle-free band.

The deviation of the R_f value reported in the case of creatinine ($R_f = 0.60$) versus that found in the reference sample ($R_f = 0.66$) may be explained on the basis of the interaction between the creatinine spot and amino acid spots having close R_f values, concomitantly separated from proteic hydrolysate on the same chromatographic support, filter paper. Similar interactions are in fact reported in other papers as well.[3,4]

The amino acids leucine and isoleucine, phenyl alanine, methionine and valine are present in the proteic hydrolysate with R_f values which are close to creatine and creatinine. Consequently, the interaction between creatine and creatinine spots may be discussed only in relation to these amino acids.

Although the creatine spot ($R_f = 0.48$) is located on the chromatogram between the phenyl alanine spot ($R_f = 0.52$) and the valine-methionine spot ($R_f = 0.40$), it fails to interact with the latter ones, keeping its R_f value unchanged.

We explain this finding by means of data obtained by us on the chemical composition of proteic hydrolysate.[5] Measurements of areas delimiting the chromatographic spots of essential amino acids separated from hydrolysate result in a 1.9% composition of phenyl alanine. This reduced phenyl alanine content as well as the value $\Delta R_f = 0.04$ (phenylalanine-creatine) rules out the possibility of an interaction between creatine and phenyl alanine spots.

Although valine content is higher (6.2%), an interaction of the creatine spot with valine spot is unlikely in this case too, due to a difference $\Delta R_f = 0.08$, sufficient for a good delimitation of the two spots on the chromatogram.

Although $\bar{\Delta} R_f > 0.05$ (creatinine-leucine (isoleucine)), the interaction of the leucine-isoleucine spot with the creatinine one becomes possible considering the higher leucine + isoleucine content (16.8%) in the hydrolysate.

The assumed interaction was verified by further cromatographing, under the same working conditions, 0.01 ml of an aqueous solution of an artificial mixture containing 0.1% leucine + 0.1% isoleucine and 0.1% creatine + 0.1% creatinine in equal volumes, compared to the same pure reference amino acids. It has been found that while the R_f value of creatine in the mixture practically remains the same as in the case of pure creatine, the R_f of the creatinine in the mixture decreases to 0.60 against 0.66 obtained for the pure reference substance. These data may contribute to the verifying of the above-mentioned hypothesis on the spot interaction.

In view of reducing this effect which hinders separation, all the samples were also chromatographed in a temperature gradient. For $\Delta t = 30°$ ($t_1 = 25°$; $t_2 = 55°$) the distance between the site of the chromatographic spot corresponding to creatinine and that corresponding to leucine exceeds 3 cm, so that the separation of creatinine from leucine in an artificial mixture becomes evident in the temperature gradient. The chromatogram of the proteic hydrolysate also reflected two clearly delimited spots at the migration distances of pure creatinine and leucine. The chromatographic separation of creatine from leucine, hindered by the big difference of their concentrations in the composition of the proteic hydrolysate, is therefore possible in a temperature gradient.

The R_f values obtained in a temperature gradient for creatinine (0.80), leucine (0.67) and creatine (0.56), both in the case of hydrolysate and of the artificial mixture containing leucine + isoleucine + creatine + + creatinine, were similar.

To reveal the effect of the modification of the stationary phase section (baffles) on the separation process, we may calculate the growth effect of the chromatographic column length, for instance for a creatinine + leucine mixture.

The separating effect of the temperature gradient may be calculated by means of Liteanu and Gocan relations[6] :

$$\Delta(R_f)_{\text{t.grad}} = \Delta(R_f)_{\text{isot.}} \cdot \frac{V + \Delta V}{V} \tag{1}$$

---

[6] C. Liteanu and S. Gocan, *Bull. Soc. chim. France*, **1969**, 1416.

where V is the volume of the mobile phase and ΔV is the additional eluent volume leaving the chromatographic column through evaporation due to atmospheric nonsaturation and to its condensation on the surface of the eluent in the vessel.

By replacing the data from table 1 in relation (1), we obtain for the baffled paper chromatogram:

$$0.91-0.83 = 0.02\,\frac{V + \Delta V}{V}$$

respectively $V = 3\ V$.

Since $V = lA_M$ for $l = 7$ cm (after 1.5 h) (l is the height reached by the solvent front) and A_M^- is the mobile phase section, we obtain:

$$\Delta V = \Delta l A_M$$

that is:

$$3lA_M = \Delta l A_M$$

$$\Delta l = \frac{3l\,A_M}{A_M} = 3 \times 7 = 21\text{cm}$$

Similarly, we may also calculate the "chromatographic column stretching" in a temperature gradient for the continuous strip chromatogram:

$$0.80 - 0.67 = 0.04 \times \frac{V + \Delta V}{V}$$

$$0.13 = 0.04 \times \frac{V + \Delta V}{V}$$

$$0.13\ V = 0.04\ V - 0.04\,\Delta V$$

$$0.09\ V = 0.04\,\Delta V$$

$$\Delta V = 2.25\ V$$

$$0.25\ V = \Delta l A_M$$

$$\Delta l = 2.25\ \times 7 = 15.75\ \text{cm}.$$

Therefore, the baffle-punched paper chromatogram increases even more the separating effect of the temperature gradient, favouring separation which does not actually take place under the conditions of an isothermal chromatography. As the size of the stationary phase surface A_s changes due to the new form of the chromatogram, an increase in the flow rate of the stationary phase will occur in the area of baffles.

Fig. 1 illustrates the complex gradient of the stationary phase section associated with a complex gradient of the eluent flow rate.

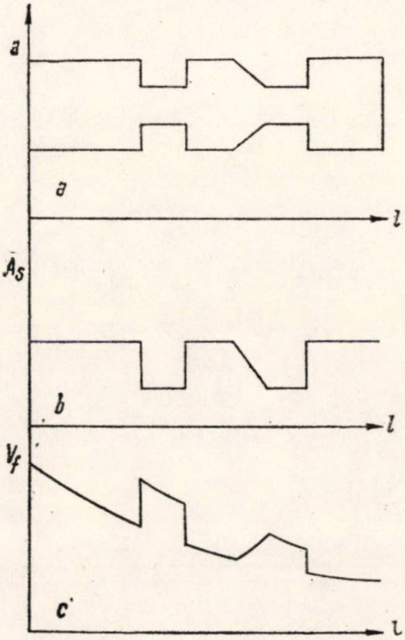

Fig. 1. Combined temperature and stationary phase section gradient: *a*, shape of chromatographic paper; *b*, variation of he support section; *c*, variation of the eluent flow rate.

CONCLUSIONS

The association of a temperature gradient with a complex gradient of the stationary phase section largely increases the chromatographic resolution, enabling thus the separation of the creatinine and leucine mixture.

Revue Roumaine de Chimie, **19**, *6*, 1113–1119 (1974)

COMPTES RENDUS

MARIA FITI, "Dozimetria chimică a radiaţiilor ionizante" (Chemical dosimetry of ionizing radiations), Ed. Academiei, Bucharest, 1973, 240 p.

The past half century has witnessed an explosive growth of interest in the radiation sources field and a significant increase of the number of physical and chemical methods of radiation dosimetry. This is due, in part, to the development of radiation physics and chemistry and, in part, to the imperative necessity of determining the radiation dose in various cases of radiation sources applications.

A monograph dealing almost exclusively with dosimetry may be justified because today the progress of nuclear techniques is closely related to the methods of measuring the radiative energy and its physical, chemical and biological effects. In this field chemical dosimetry is a preferable method because of its simplicity and this monograph intends to provide an outline of the main methods available for it. The material is organized to cover both aspects of chemical dosimetry : the fundamental principles of radiation chemistry, dosimetry and the practical applications. The first two chapters deal with general problems in radiation dosimetry and with fundamental principles of radiation chemistry. The subsequent four chapters treat the gas-phase, aqueous solution, organic liquids and solid-state chemical dosimeters with details on their preparation and on the chemical analysis methods involved. The last one gives some applications of chemical dosimetry for special problems, such as high dose-rate electron beams dosimetry, mixed radiation field dosimetry, and medical and biological dosimetry.

The monograph is distinguished by the following features :

I) it indicates the main directions towards which the subject is now moving,

2) it gives an insight into the recent literature in this field and makes references mainly to recent papers,

3) the book will be particularly suitable for chemists, physicists, radiobiologists, and physicians.

Popa Gabriela

MARIUS PROTOPOPESCU. "Teoria electronică a metalelor" (Electronic theory of metals) Ed. Academiei, Bucharest, 1973, 365 p.

The book undertakes to present a coherent way of explaining a series of physico-chemical properties of solids, with a particular emphasis on metals.

To approach this work some knowledge of classical theoretical mechanics is necessary, but to approach the quantum mechanics concepts, sufficient data are included in the book.

It begins defining, from a quantic viewpoint, the laws of electrons behaviour as microparticles in potential fields, after the notions of oprator in quantum mechanics and Schrödinger equation have been presented. The movement of free electrons, the movement of electrons in a constant potential field, the tunnel effect, potential barrier and the electron in a potential hole are treated. Then, we pass to the treatment of the hydrogen atom, analysing the problem of the electrons in a spherical symmetry potential field. Parameters *M* and *L* whose important physical significance is further explained are introduced in resolving Schrödinger equation.

Further on an approximation is presented for obtaining Schrödinger equation solutions, in the case of multielectron atoms : some physico-mathematical models of electrons behaviour in atoms are briefly presented, such as : the self-consistent field method (Hartree-Fock), variational calculus (Hylleraas), models based on perturbation theory, matricial model (Slater) and statistical model (Fermi-Dirac) and also some periodical atomic properties, among which most important are the paragraphs dealing with the electronic stucture of the atoms in relation with the Mendeleyeff's system, electronegativity (special attention is paid to Pauling's way of defining this concept) and atomic and ionic radii.

The nature of interatomic bonds is presented by a discussion of Stark effect and Zeeman effect ; then Van der Waals type bonds, quantic forces (Heitler— London method, molecular orbitals method and types of hybridization included), ionic bonds (cohesive energy of the lattice is calculated and comparison is made between theoretically and experimentally determined values) and metallic bond are presented.

The work includes an important chapter dealing with the crystalline state, providing the reader with a modern and complete description of the crystal symmetry question, using the group theory and representation theory.

The state of electrons in crystals is described according to the perfect electronic gas model (Drude-Lorentz) on grounds of the Boltzmann statistics, whose inconsistency is shown, then the quantum statistics, theory (Fermi) is described.

Zone theory comes next : plane wave functions modulated by the periodic field of the lattice are defined (Bloch functions) and zonal structure of energetic spectrum of electrons moving in periodic fields is deduced. Bidimensional and tridimensional model of zones are described and examples are given : determination of Brillouin zones for cubic and hexagonal compact networks. The interrelation between Brillouin zones shape and X-ray diffraction patterns is shown.

The connexion between metals, semiconductors and dielectrics is also briefly described, then quasifree electron theory and quasibound electron theory are described and Fermi surface is defined.

The last chapter of this work is devoted to the calculus of energetical zones structure ; the calculus methods described are cellular method (Wigner-Seitz), LCAO method (Linear Combination of Atomic Orbitals) (Bloch 1928) and OPW method (Orthogonalized Plane Wawe (Herring 1940) developed by pseudopotentials method (Harrison 1966). The physical essence of electric resistivity of metals is shown, as being the scattering of electronic waves in metals because of thermal vibrations and lattice defects.

The work is concluded by an exposition of some methods for determining Ferm surfaces ; the relative weight of the chapter, important enough, is explained by the fact that actually all electronic properties of metals are determined by the density of energetical states at the Fermi surface.

Remarkable is the very concise and clear exposition, covering a wide range of subjects in a resctricted volume.

Throughout the whole book the effort for assigning a physical meaning to mathematical concepts used is obvious ; in important cases, the calculated data are correlated with the experimentally determined ones, and the inconsistencies of the theory are shown.

The book would have been more profitable for those who need further information about the subject, if more precise references had been made.

The work does not contain a discussion of superconductivity.

V. Stancovski

"Topics in Current Chemistry" (Fortschritte der chemischen Forschung), **41**, New Concepts I, Springer-Verlag, Berlin, Heidelberg, New York, 1973

B. M. TROST, "Sulfuranes in Organic Reactions and Synthesis", p. 1—29. Trost's review covers the most recent area on sulfurane chemistry. The two classes of sulfuranes, π- and σ-sulfuranes, are today widely applied in the new organic synthesis.

After an introductory chapter, two chapters refer to π-sulfurane addition and elimination reactions and another one to σ-sulfuranes. Many examples are given in which the sulfuranes are intermediates.

The use of diphenylsulfoniumallilyde and diphenylsulfoniumcyclopropyilide in addition reactions is largely illustrated. The new synthesis of oxaspiropentanes and the subsequent one step cyclobutanone synthesis using diphenylsulfoniumcyclopropylide are exemplified. The ready availability of butyrolactones as well as of 5-mono and 5,5-disubstituted-γ-butyrolactones from the parent carbonyl compounds is described.

The paper illustrates the role σ-sulfuranes play in the reactions generating new carbon-carbon bonds such as formation of biaryls or allylaryls. The reaction of phenyllithium and vinyllithium with S-phenyldibenzothiophenium fluoroborate is a significant example. The only mechanism that is consistent with the reaction products is that by a sulfurane intermediate. Other types of reactions which find an interesting interpretation in the new concept of sulfurane chemistry are stereospecific desulfurizations and fragmentations of alicyclic three-, four-, and fivemembered ring sulfuranes.

The organic chemist will find in Trost's review a fascinating domain and an attractive tool for manipulating organic synthesis.

W. KUTZELNIGG, "Electron Correlation and Electron Pair Theories", p. 31—73. Kutzelnigg's original paper surveys the role of electron correlation energy in quantum chemical processes and develops some outstanding methods for calculating correlation energy related to electron pair theories. 70 references are cited therein.

The correlation energy is defined as the difference between the "true" Hartree-Fock energy and the "true" non-relativistic energy. Considerations are made mainly upon closed-shell states. Methods for estimating the correlation energy are discussed. The author emphasizes in particular the comparison between "experimental" and "computed" correlation energies for known molecules in order to check the reliability of the correlation energies predicted for unknown molecules. An example is given where the importance of correlation energy for quantum chemical predictions is outlined. The relationship between correlation energy and some physical quantities is shown. Correlation energy is analysed in terms of electron density and pair density. The concept of probability theory is applied to electron correlation considering statistically independent and correlated distributions. The main causes of electron correlation in space are discussed : the Pauli principle, spin and spatial symmetry requirement of the electron state and the Coulomb repulsion between the electrons. The correlation of the electrons in space for the ground state of the H_2 molecule is further examined. The method for calculating the electron correlation energy by independent electron-pair approximation (IEPA) is developed. The advantages of both pseudo-natural-orbital configuration-interaction (PNO—CI) method and coupled-electron-pair approximation (CEPA) method are demonstrated. The author also mentions some other methods for calculating electron correlation energy based on the idea of electron pairs, for instance those using antisymmetrized geminal power (AGP) or n-projected BCS function or pure perturbation theoretical methods. The use of calculated electron correlation energy values in the general methods of quantum chemistry as well as in the modern interpretation of chemical structure is outlined.

The theoretical chemist finds in Kutzelnigg's paper an excellent treatment of the most recent advances in electron correlation energy calculation.

R. G. PEARSON, "Orbital Symmetry Rules for Inorganic Reactions from Perturbation Theory", p. 75—112. Pearson's paper on symmetry rules is a new interesting treatment of this subject in which the author is responsible for a great number of achievements. The paper deals with some of the most up to date aspects of modern chemistry viewed by orbital molecular theory.

After an introductory description of basic principles of symmetry the author develops widely the concept of bond symmetry rule. Using the orbital symmetry properties of the bonds to be broken and the bonds to be made the bond symmetry rule defines an allowed reaction as a reaction in which the symmetry of the bonds that are made is the same as the symmetry of the bonds that are broken. The rule is applied to reactions of any molecularity.

Examples of the symmetry rule are given in the paper. Possible reactions of diatomic molecules with each other are first considered. This concept is extended to addition reactions to carbon-carbon double bond and to some other addition reactions.

The symmetry of possible reaction coordinates is analysed for a wide range of reactions : the unimolecular decomposition of water, the ring opening reactions of organic molecules in disrotatory and conrotatory ways and the olefin disproportionation (metathesis) reaction catalysed by transition metal complexes. The case when no elements of symmetry exist in molecules or no elements of symmetry are conserved during the reaction is analogous to forbidden transitions in electronic spectroscopy. In this case a reduction in symmetry can make a forbbiden reaction partly allowed but it still has a high activation energy. The phenomenon of partial forbiddness or allowness is explained by means of wave function properties. The allowness and forbiddness of a reaction is generalized beyond the symmetry properties. The mechanism of some important reactions of transition metal organometallic compounds (ligand migration or insertion reaction, oxidative-addition reaction and oxidative-cyclization reaction) are detailed in the terms of the general concept of the reaction path.

Pearson's paper is very useful for both theoretical and experimental chemists interested in the recent progress on symmetry subject.

H. GELERNTER, N. S. SRIDHARAN, A. J. HART, S.-C. YEN, F. W. FOWLER, H.-J. SHUE "The Discovery of Organic Synthetic Routes by Computer", p. 113—150. This paper deals with one of the most fascinating problems of up to date chemistry, the discovery of multistep organic syntheses for relatively complex structures with the aid of computer. The paper describes a computer programme written for the IBM System 360/67 called Synchem. The algorithm that governs Synchem is then discussed. Using a limited library containing information about organic reactions and reaction mechanisms, provided initially in a tabular form to the computer, a correct synthesis for some dozens structures was developed without the chemist's intervention. The particularly interesting synthesis of the polycyclic molecule of twistanone was chosen by these authors as an illustration of the way the programme works. Another example discussed is the synthesis of Vitamin A. The results obtained by means of computer are vizualized as a promising future in discovering novel and useful synthetic routes in organic chemistry.

Valerian Drăguțan

Structure and bonding. 13. Springer Verlag, Heidelberg, New York, 1973, 273 p.

The term rare earths is commonly assigned to the 14 lanthanides, representing the 4 f transition elements. The present compendium includes under the name rare earths also the 5 f transition elements (the actinides). Both series 4 f and 5 f are object of growing interest from theoretical as well as from practical point of view.

The first article deals with structural systematics in actinide fluoride complexes. R.A. Penneman and R.R. Ryan show in this survey that the 5 f electrons have little directional effects in determining actinide fluoride complex structures. Radius and charge play a predominant role in the determination of structure and coordination type. The authors note amongst the principal trends, the multiplicity of valences displayed by these elements, as well as fixed valences for upwards a dozen of consecutive elements, the large cation size and its reduction with increasing atomic number, for the tri- and tetravalent ions. Comparing actinide and lanthanide fluorides, it can be seen that these obviously large ions of both series, preclude lower than six coordination with F^- and make six coordination a rarity. But as the size diminishes with atomic number, changes are apparent (diminution of coordination number and recurrence of structures previously observed for the smaller d-transition elements).

The article is a survey of the structural characteristics displayed by the actinide fluoride complexes. The data based on powder X ray diffraction and neutron diffraction by single crystal technique were reported on coordination numbers from 6 to 9.

The next 3 articles concern the lanthanides. The shrinkage of the atomic volume as the 4 f subshell is filled, commonly referred to as "the lanthanide contraction" is due to an especially imperfect shielding from the nuclear charge of one f electron by another f electron. Unlike the d transition elements, the lanthanides show a gradual, monotonic variation in the ionic radius amounting to 20% from La^{3+} (1.06 Å) to Lu^{3+} (0.85 Å) for sixfold coordination. The influence of this varying ionic size on coordination number and coordination geometry is a unifying concept in chemistry.

In the 2nd article concerning the spectra and energy transfer of rare earths in inorganic glasses, Renata Reisfeld shows a remarkable similarity between the above mentioned phenomena in glasses and in crystals. Despite the absence of both long range and cellular disorder, the author considers that the immediate vicinity of all rare earth ions does not significantly vary from one site to another and all sites have a definite microsymmetry. Hence the optical properties of rare earths in glasses are analysed in a manner similar to that of impurities in crystals, the principal difference being that the disorder will introduce perturbative effects of these properties. The conclusions are drawn, based on a large number of experimental data.

The 3rd article, written by J. Felsche, is devoted to the crystal chemistry of the rare earths silicates. The above mentioned compounds form a chapter in the chemistry of large-cation silicates. The RE^{3+} ionic radii are ranging from 0.85 to 1.28 Å, the crystal structures consist of isolated (SiO_4) tetrahedra or groups of (Si_2O_7) or $(Si_3O_{10})$and oxygen-coordination reaches six to tenfold values.

A detailed structural description of rare-earth silicates no more complex than ternary compounds, is presented; compounds containing OH groups or molecular H_2O are not included. The data are correlated in order to show periodicity or discontinuities along the rare-earth series.

In the last article, C. K. Jørgensen discusses the inner mechanism of rare earths elucidated by photo-electron spectra. According to the arguments drawn from the refined spin-pairing energy theory, applied to the spectra of solutions and crystals and the data of photo-electron spectrometry, the writer concludes that the value $1 = 3$ certainly contributes to the specific properties (ionization energy, average radius contributing to the relatively strong photo-electron signals and to the almost monoatomic character of the $4f^9$ J-levels in compounds) of the 4 f group.

The compendium is written with the cooperation of outstanding specialists, each article ending with a minute bibliography, making the whole work very useful to specialists in the matter.

Florica Popea

Structure and bonding. 14. Springer Verlag, Berlin, Heidelberg, New York, 1973, 170 p.

This volume of the series is intended to offer informations on main topics of general interest in inorganic chemistry.

The first article is a survey of the studies concerning the structural chemistry of polynuclear transition metals. The deep colors of some members of this class of compounds has always been an attraction for the chemists. These inorganic polymers display a rich variation in their stoichiometrics and therefore in their properties. The broad range of compounds having the general composition $M_K^A\,[M^B(CN)m]_1 \times H_2O$ is due to the large number of possible combinations of transition metals M^A and M^B and particularly by considering the possible oxidation states.

The authors, Andreas Ludi and Hans Ulrich Güdel, restrict the discussion only to structural properties of crystalline cyano compounds containing $M^B(CN)_6$ groups, with the characteristic construction element, the four atomic sequence $M^A - N - C - M^B$. M^B is a transition metal, M^A a transition metal, or a metal of class B or hydrogen.

The first recorded synthetic coordination compound, Prussian blue, $Fe_4[Fe(CN)_6]_3 \times \times H_2O$ is the prototype of the polymeric cyanides. Altough a wide variety of physical methods has been used to elucidate its structure and its analogs, the characterization of their crystal structure has been accomplished only recently when suitable single crystals could be prepared.

The electronic spectra drawn from diffuse reflectance measurements of fine powders, represent in many cases a simple superposition of two isolated chromophores. The further improvement of growth of single crystals is expected to permit precise spectroscopic studies leading to a more detailed picture of the electronic structure of these compounds.

In the second article, the authors, A. Müller, E. Dieman and C. K. Jørgensen discuss the electronic spectra of tetrahedral oxo, thio and seleno complexes formed by elements of the beginning of the transition groups. The topics enclosed are : a comparison with halide complexes, molecular orbitals in tetrahedral complexes, mixed complexes with three oxide and a fourth ligand, spectra of complexes with four chalkogenide ligands, chalkogen binding ligands and photo-electron spectra.

The third article, written by B. J. Hathaway deals with the evidence for "out-of-the-plane" bonding in axial complexes of the copper (II) ion. With the continuous increasing number of axial copper (II) complexes of known crystal structure, the "effective" coordination number of the local copper (II) ion environment is becoming less certain. The stereochemistry of the copper(II) ion is commonly described as being dominated by the four coordinate square coplanar stereochemistry, involving four relatively short in plane bonds of ca. 0.2 Å. The presence of further ligands along the axial directions, at appreciably longer bond-lenghts is recognized and described by such expressions as 4+2 coordination (elongated tetragonal octahedral) or 4+1 coordination (square piramidal). However, it is not clearly expressed whether or not these fifth and sixth axial ligands are actually involved in coordination along these axial directions or simply present due to the packing of the complex in the crystal lattice. The author, B. J. Hathaway, collects together the different types of evidence for out-of-the-plane bonding in axial copper (II) complexes and assesses the different methods available for satisfying the out-of-the-plane bonding potential of a strilcty square coplanar CuL_4 chromophore.

The fourth article concerns two symmetry parametrization of the angular-overlap model of the ligand-field. Relation to the crystal-field model.

Ligand-field models have been successfully applied for parametrizing experimental results. In this paper, C. E. Schäffer treats the reparametrization of the angular-overlap model (AOM) for the case when the central ion to ligand bonds have a linear symmetry and makes a comparison with the conventional perturbation model. The author shows that an electrostatic contribution to the semiempirical parameters can never be evaluated from experiments determining parameters and discusses some of the problems associated with the zero points for the energy.

The fifth article is devoted to saltebullioscopy. B. Magyar presents the theory and some experimental results obtained with the method. He underlines its usefulness in cases when the usual ebullioscopy and cryoscopy fail to give reliable results.

The last article treats the structural chemistry and bonding in azides. Ulrich Müller considers the interatomic distances between the nitrogen atoms and other atoms of the compound, as the main criteria for the assignement of an azide to one of the three groups : ionic, coordinative or molecular azides. In this article, the author presents the structure data for the principal members of the three classes of azides mentioned above.

Each article ends with an up-to-date bibliography so that the whole work presents attraction for the specialists in the domain.

NOTE POUR LES AUTEURS

La *Revue Roumaine de Chimie* publie des articles en anglais, français, russe, allemand ou espagnol. Les auteurs sont priés d'envoyer des articles, notes, communications et comptes rendus inédits.

Les manuscrits seront dactylographiés à deux intervalles. Les tableaux seront dactylographiés sur feuilles séparées, de même que la légende des figures. Les diagrammes seront tracés à l'encre de Chine sur papier calque. Les tableaux et les figures seront numérotés par des chiffres arabes, en nombre strictement nécessaire. Prière de ne pas inscrire les mêmes données dans les tableaux et les figures. Les formules chimiques seront incluses dans le texte; en outre, elles seront transcrites sur des feuilles séparées. Les auteurs sont priés d'indiquer les caractères italiques (en soulignant les lettres au crayon), ainsi que tout autre caractère spécial. L'ordre des références bibliographiques sera celui de leur mention dans le texte; le nom de l'auteur sera précédé de l'initiale du prénom; les publications périodiques seront présentées suivant les prescriptions internationales. Les références seront ajoutées à la fin de l'article; elles paraîtront comme des notes, au bas de la page. Le texte sera précédé d'un résumé, comprenant 15 lignes au maximum.

L'entière responsabilité du contenu des articles appartient aux auteurs. On publie des articles dus aux collaborateurs roumains ou étrangers. Les auteurs recevront 50 tirés à part.

THE SECOND INTERACTION VIRIAL COEFFICIENT OF GAS MIXTURES. I

THE NITROGEN + HYDROGEN MIXTURE

RODICA VÎLCU and I. GĂINAR
University of Bucharest, Laboratory of Chemical Thermodynamics

Received June 14, 1973

The construction and operation of an original installation for the measurement of pressure variations when mixing two real gases, are described. The apparatus is used for estimating the excess volumes and the second interaction virial coefficient of the $N_2 + H_2$ mixture at the standard temperature and at pressures ranging from 10 to 80 atm. Experimental data are compared with values calculated by the authors using the equations of state as well as other experimental data from the literature.

INTRODUCTION

Large number of equations of state have been proposed in order to correlate the variables $P-V-T$ for real gases. However, most of them have a purely phenomenological nature and their parameters can hardly be correlated to the molecular parameters of the systems. The only equation with a sound theoretical foundation is the equation with virial coefficients set forth by Kamerlingh Onnes,[1] that may be written as a sequence of powers, after the gas density ρ, as follows

$$\frac{PV}{RT} = 1 + B\rho + C\rho^2 + D\rho^3 + \cdots \qquad (1)$$

where B, C, D, etc. are the 2nd, 3rd, 4th, etc. ... virial coefficients.

The convergence of the series is very good for low pressure; the higher terms may be omitted since they are negligible. However, at higher pressures one should include a large number of terms in order to obtain a satisfactory agreement with the virial coefficients to be determined from experiment.

Only the second virial coefficient, B, may be obtained with fairly good accuracy; the values of C, from $P-V-T$ data, are less accurate, and the coefficient D cannot be experimentally [2] determined. Even the sign of D is uncertain, although theoretical considerations favour a positive value, except for low temperatures.

---

[1] H. Kamerlingh Onnes, *Comm. Phys. Lab. Leiden*, **71**, 74 (1901).

In the case of a gas mixture, the virial coefficients of that mixture have to be defined. For a binary system, the second virial coefficient of the mixture, B_m, is written as :

$$B_m = x_1^2 B_{11} + 2x_1 x_2 B_{12} + x_2^2 B_{22} \tag{2}$$

where B_{11} and B_{22} represent the second virial coefficient of the pure components, while B_{12} is the interaction virial coefficient, defined by the relation

$$B_{12} = 2\pi N \int_0^\infty [1 - e^{-\varphi(r_{12})/kT}]\, r_{12}^2 \, dr_{12} \tag{3}$$

where $\varphi(r_{12})$ is the interaction potential and the universal constants N, k have the well-known physical significance.

We see therefore that the second interaction virial coefficient is expressed in terms of the interaction potential $\varphi_{12}(r)$, between two neighbouring molecules belonging to different chemical species.

The interaction virial coefficient B_{12} may be theoretically calculated from rel. (3), if we know the potential $\varphi_{12}(r)$ describing the interaction between the molecules 1 and 2.

To this purpose, we make use of the empirical potentials (Lennard-Jones 6 — 12, Buckingham, Kihara, Stockmayer).

The choice of the potential function depends, of course, on the specific properties (geometrical shape, electrical magnetical properties, etc.) of the interacting molecules.

To obtain the potential parameters of the mixture, combinational rules are used, which enable us to calculate these parameters from the corresponding values of the pure components (provided that both the pure components and the mixture involve a potential of identical form).

Except for some very simple cases, these combinational rules have no theoretical foundations.

A very precise determination of the second interaction virial coefficient might serve for establishing some criteria allowing to remove the empirical character of the choice of potential functions.

In order to obtain thermodynamical excess functions and interaction virial coefficients in binary systems, we have initiated a systematic study of the thermodynamical properties of gas mixtures at high pressures.

In our experiments, we used the method advanced by Edwards and Roseveare, [3] i.e. the variant used by a group of physicists of the Kamerlingh Onnes laboratory in Leyden. [4]

[4] P. ZANDBERGEN and J. J. M. BEENAKKER, *Physica*, **33**, 343 (1967).

The method has extensively been applied at low pressures, [5-8] while for high pressures there was only one experiment, [4] where measurements have been extended up to about 100 atm.

Generally, the technique of low pressure measurements has been very much refined in the last years, with the aid of modern electronics. Nevertheless, at high pressures there are still only few contributions which describe particularly accurate techniques for estimating pressures, because of the difficulties in the operation of working devices.

If such difficulties are however overcome, the results can provide particularly rich information on the deviations of the real gases from the ideal behaviour.

PRINCIPLE OF THE METHOD

If two molecular gaseous species 1 and 2, in two containers A and B, connected to a third one C, which serves as reference vessel (with identical input pressures), are mixed under isothermal conditions, we always note the appearance of a pressure variation whose value depends, for a given pressure and temperature, on the gas nature.

Within the variant used by Edwards and Roseveare, [3] the volume variation accompanying the mixing phenomenon is measured while keeping constant the working pressure.

At high pressures the isochore conditions are preferred since it is much more convenient to measure the pressure variation by a suitable pressure gauge (manometer). To this end one may successfully use U-shaped, differential manometers, simple and highly sensitive to small pressure variations. [4] To reach the particularly high pressure required by the method (minimum $1/10^4$ from the value of the static pressure) we have used a manometer of own design, operating as a baroresistive transducer, described in this paper.

Since the dead space of the gauge is a pressure function, a small amount of gas has to be removed from the mixture so that the pressure should recover the gas filling value of the apparatus. The number of gas moles removed from the system may be found by letting the gas into a container of known volume, previously emptied, perfectly thermostated and sufficiently large to enable the application of the law of ideal gases on calculating.

CALCULATION OF THE EXCESS VOLUME WITHIN THE PROPOSED METHOD [4]

To obtain the excess volume we shall proceed as follows : consider that, prior to mixing, in container A there are n_1 moles of gas 1, and in container B, n_2 moles of gas 2, at the same pressure P and temperature T.

[8] C. M. Knobler, J. J. M. Beenakker and H. F. P. Knaap, *Physica*, **25**, 909 (1959).

If we denote the volumes of both vessels by V_A and V_B, we may write

$$V_A + V_B = n_1 V_1^0 + n_2 V_2^0 \tag{4}$$

where V_1^0 and V_2^0 are the molar volumes of pure components. Subsequent to mixing and the recovery of the initial pressure, by removing Δn moles from the system, we get

$$V_A + V_B = (n_1 + n_2 - \Delta n) \cdot V^M = n_1 V_1^0 + n_2 V_2^0 \tag{5}$$

where V^M is the molar volume of the mixture. By introducing the molar fractions x_1 and x_2, we obtain

$$\frac{\Delta n}{n_1 + n_2} = \frac{V^M - (x_1 V_1^0 + x_2 V_2^0)}{V^M} = \frac{V^E}{V^M} \tag{6}$$

where V^E is the excess volume defined by the well-known rel.

$$V^E = V^M - V^{M,id}\ ; \quad V^E = V^M - (x_1 V_1^0 + x_2 V_2^0) \tag{7}$$

The combination of the last two relations allows to remove V^M so that

$$V^E = \frac{\Delta n}{(n_1 + n_2) - \Delta n} (x_1 V_1^0 + x_2 V_2^0) \tag{8}$$

To obtain the excess volume by eq. (8), one should determine the molar volumes of pure components V_1^0 and V_2^0, the numbers of moles n_1 and n_2 contained in the two vessels A and B under certain pressure and temperature conditions, the corresponding molar fractions x_1, x_2 as well as magnitude Δn. The first six magnitudes may be obtained by equations of state chosen so that they should describe most accurately the behaviour of gases at high pressures. In our calculations we used the Beattie-Bridgemann equation. The estimation of Δn resulted from intricate and tedious experimental measurements, as described in the next section.

If we admit the effect of high order virial coefficients as being negligible, then the virial equations for gas 1, gas 2 and the mixture assume the simple form of

$$\frac{PV_1}{n_1} = RT + B_{11}P\ ; \quad \frac{PV_2}{n_2} = RT + B_{22}P\ ; \quad \frac{PV^M}{n_1 + n_2} = RT + BmP \tag{9}$$

If we consider the reference rel. (7), we get

$$V^E = B_m - x_1 B_{11} - x_2 B_{22} \tag{10}$$

Combining this equation with eq. (2) deduced by Lennard-Jones and Cook, for molecules obeying a potential with spherical symmetry, we get

$$\frac{V^E}{x_1x_2} = 2B_{12} - (B_{11} + B_{22}) \tag{11}$$

If one assumes that the real gas mixture has an ideal behaviour, then

$$B_{12} = \frac{1}{2}(B_{11} + B_{22})$$

which is similar with the lack of volume and pressure variations on mixing.

For the real gas mixtures this relation does not work and therefore the magnitude of the deviation is expressed by the excess virial coefficient E:

$$E = B_{12} - \frac{1}{2}(B_{11} + B_{22}) \tag{12}$$

The measurements have shown that for low pressures, the excess virial coefficient, E, is always positive and does not depend on the mixture composition.

Relations (11) and (12) lead to a very simple expression that stands for the dependence of the excess virial coefficient E on the excess volume V^E :

$$V^E = 2x_1x_2E \tag{13}$$

Thus, the interaction virial coefficient B_{12} is obtained due to an indirect calculation involving many stages. Assuming that x_1 and x_2 are determined with negligible error as compared to the error affecting the magnitudes B_{11}, B_{22} and V^E, the value of B_{12} is obtained with an uncertainty degree increased after each calculation stage.

We shall present our results concerning the $N_2 + H_2$ system. The choice of this system has been made from practical considerations :

1. Pure gases are easily available and cheap. The thermodynamical behaviour of the $N_2 + H_2$ mixture has also applicative significance, related to the manufacturing process of ammonia.

2. This mixture ranges among the few systems investigated at high pressures, a fact allowing to draw some conclusions referring to the operation and the accuracy of data provided by our experimental, wholly original apparatus.

The experimental apparatus (figure 1) is made up of the following parts :

1. Filling system with compressed gas
2. Gauging system for pressure inspection and measurement
3. Working device
4. Mixing system
5. Thermostating system

Fig. 1. — General scheme of the installation for the measurement of pressure variations on mixing two gases.
I, Charging system; T_1, T_2, pressure trasducers; II, Mixing vessel; *M*, Hg manometer; *P*, Hg pump; *C*, thermostatic glass reservoir.

1. *The filling system* (see fig. 1) has two autoclaves, V_1 and V_2, of approximately 2 liters each, made of stainless steel with metal disc packing ; the autoclaves have inspection manometers and special input and output pressure valves.

The connection with the gas source — either compressed gas pipes, S_1 and S_2, or a compressor delivered by the firm "Andreas Hoffer" — is performed with pipes of $\varnothing_{\text{int}} = 1$ mm and $\varnothing_{\text{ext}} = 2$ mm.

Since gases are of high purity (beyond 99.8 %) no additional purification has been necessary . Gases have been, however, passed, prior to their admission into V_1 and V_2, through a cylindrical container each, of about 1 liter in volume and charged with heat-activated molecular sieves, in view of removing any water traces.

2. *The gauging system* is made up of usual manometers, with Bourdon tubes, M_1 and M_2, and of special manometers, T_1, T_2 and M. The use of the latter is required by the fact that even the finest classical manometer, with elastical element, does not allow the filling with gas pressure, with an accuracy that should go beyond a few cm Hg, at some tens of atm.

This shortcoming is removed by using special manometers, which increase the filling accuracy of two enclosures, in a differential system, up to a limit located below 0.1 mm Hg for statical pressures over 100 atm.

The fine adjustment of pressure occurs in two stages :

In a first stage we used a manometer, T_1, with a dislevelment capacity of 1.5 atm. Construction and operation : a U-shaped stainless-steel pipe is filled with a known amount of Hg, purified by successive distillations. At one of its tips a piece is axially connected with the body, where a glass rod, approximately of 1.5 m in length , is mounted. On this Hg-immersed rod is widely coiled a thin wolfram wire ($\varnothing = 0.02$ mm) with a total resistance of some hundreds ohms. The Hg level in equilibrium determines a fixed and constant value of the resistance ; the shift of the Hg level is accompanied by a decrease or an increase in the ohmic resistance.

The change in the intensity of the signal generated by a multivibrator which is applied to a resistance bridge made up of a wolfram resistance, is due to the shift of the mercury level with respect to the pressure variations.

The moment a pressure variation is recorded by the manometer, the bridge loses its balance and a signal appears that is amplified and reproduced by a loud speaker.

To cancel the signal — a situation corresponding to pressure leveling at the two arms of the manometer — one operates the input valves by introducing or removing from one of the vessels a certain amount of gas. This system allows the supply in a differential system, irrespective of the value of the static pressure, with an accuracy of ± 10 mm Hg.

The second stage which ensures the adjustment of the supply in a differential system with a ± 0.02 mm Hg accuracy is required by the characters of the method : the pressure variations, a result of the gas mixing , show values ranging from $1/10^5$ to $1/10^4$ from the static filling pressure.

The achievement of such a high accuracy is based on the use of the resistive transducer T_2 already mentioned, of original construction, where the very small pressure variations are read by means of a galvanometer with a 1×10^{-9} A/mm sensitivity.

This manometer is based on the variation of the ohmic resistance of a thin-film, metallic deposition on glass, immersed in Hg, owing to the pressure variations. The device plays the part of a null instrument in terms of pressure. Construction details and operation may be found in a distinct work. [9]

3. *The proper working apparatus* is made up of a massive stainless steel cylinder (see details in fig. 2) where three holes were applied which by their closing resulted in the two working vessels A and B and the reference vessel C. According to their construction all the

---

[9] R. Vîlcu and I. Găinar, *Rev. Roumaine Chim.* (in press).

three enclosures have the same volume (477.26 ccm). A stainless steel piece of special construction, D, with a built-in valve, E, with needle closing, ensures the sealing-off of containers A and B, enabling at the same time—due to the furrow grooves — the discharging, filing, mixing and emptying.

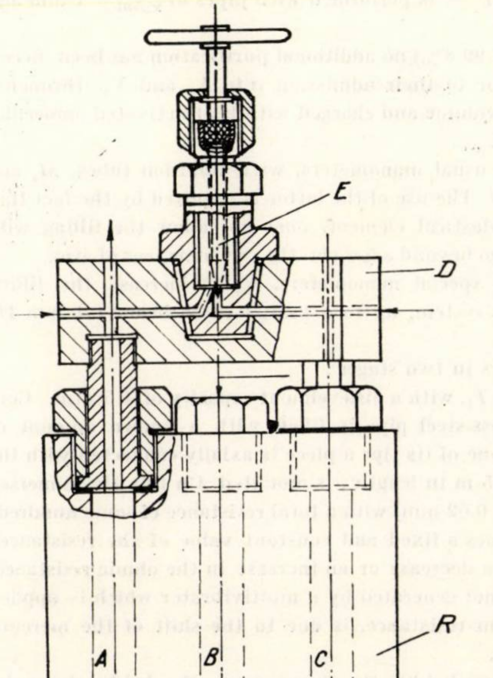

Fig. 2. — Mixing vessel (details).

A, B, Mixing cells; C, Reference cell; D, Coupling piece between the mixing vessel and charging system; E, stainless steel valve; R, massive stainless steel cylinder.

In order to obtain variations with the composition of the thermodynamical magnitudes of the mixture, use has been made of two additional pressure vessels (both with a 400 ccm volume) which may be in series connected with the main vessels by means of a metallic capillary.

The great number of connecting pipes as well as the existing valves, denoted by figures, have been a source of difficulties until we obtained a high degree of tightness. To this end we have used needle closing systems and original valves with steel ball tightening.

4. *Mixing system.* The gas mixing is carried out with a mercury pump P of own design. The electro-mechanically operated piston has an efficient volume of about 300 ccm that is enough to obtain perfect mixing after 80—100 expansions and compressions.

5. *Thermostating system.* The accuracy of the measurements depends to a considerable extent on the achievement of a best possible thermostating. To this end, the working vessel R and the additional containers (not represented in our design) are immersed in a thermostating 40 — 1 bath, Q, with paraffin oil and provided with a mighty stirrer.

Since at the measurement transducer, T_2, the dislevelment is followed on a single arm, its thermostating is required so that no fluctuations greater than ± 0.01° should be allowed. This is achieved by means of an electronic thermoregulating device with proportional action that uses, as temperature transducer, a 150-ohm Philips thermistor.

The mercury manometer, M, serves for the control of vacuum in the installation to be operated and of the small pressures in vessel C, determined by the procedure that has been chosen, as it will be seen in the next section.

PROCEDURE

The thermostating systems are actuated; on reaching the desired working temperature we start the gas filling. While all the valves are open we proceed to the connection with the vacuum installation and the vacuum is followed at the Hg manometer. After reaching a vacuum of the order of 10^{-2} mm Hg, valves 13, 15, 16 and 17 are closed; the valves at the containers with compressed gas are opened and the gas is let in carefully under permanent control by means of manometers M_1 and M_2, mounted on autoclaves.

When both manometers show the same pressure, valves 1 and 2 are shut and the fine adjustment occurs by means of baroresistive transducers T_1 and T_2. When the differential control system points out a pressure difference between the two containers of at most 0.1 mm Hg, valves 3, 4, 5, 6, 7, 8, 9 ,10, 11 and 12 are closed and valves 15 and 16 are opened.

The determination of accurate pressure variation on mixing is related particularly to a best possible mixing of the two gases. This requirement is carried out performing a great number of expansions and compressions with the mercury pump, *P*. If Zandbergen and Beenakker [4] considered only a number of 10—20 mixings, in our experiments, when the volume of the vessels is 10—15 times greater, a number of 80—100 mixings are required so that two consecutive measurements should not lead to pressure variations beyond 0.01—0.02 mm Hg.

The pressure variation is measured after completion of the mixing process. To this end we open valve 11 and the deviation from balance, prior to mixing, is read at the galvanometer mounted in the circuit of transducer T_2 and it is converted into pressure units (mm Hg) with the help of the calibration graph. The previously thermostated vessel *C* is emptied; then valves 12 and 17 are consecutively opened. Valve 17 with micrometric screw allows the finest possible removal of the gas excess into vessel *C* until the light spot of the galvanometer recovers the balance prior to mixing. With a precision cathetometer (± 0.005 mm Hg) we read on manometer *M*, the pressure in vessel *C*.

Knowing the volume ($\sim$ 2 000 cm^3) and the temperature, we calculate the number of gas moles Δn, which must be removed from the system, so that the pressure should come back to the original value.

RESULTS AND DISCUSSIONS

Besides the use of the experimental data for the evaluation of excess volumes, the calculation of the excess volumes was reconsidered for a great number of compositions and pressures, performed according to the procedure, as described in an earlier paper. [10] To this purpose a programme for a digital computer IBM 360 was used.

A set of calculated values for V^E which integrate within the pressure domain experimentally studied, are shown in table 1. These data are worth being plotted (see figure 3) in order to emphasize the perfect symmetry of the parabolas representing the V^E dependence — composition and the almost insignificant change of the excess volume with pressure. The experimental values for the excess volume given in table 2, differing somewhat from the calculated ones, show the same behaviour against pressure. Table 3 gives comparatively the values of excess volume, as obtained by us at 25°, at pressures comprised between 10 and 80 atm and variable

compositions, and the Zandbergen and Beenakker's [4] values in the same pressure interval but extrapolated to the molar ratio 0.5.

A brief examination of the presented values leads to an excellent agreement between our values and the values of the mentioned authors, [4] with the single observation that, in full concordance with the theory, our values are somewhat smaller, due to the difference of about 6° between our working temperature and that of the mentioned authors.

Besides the values of excess volumes V^E and the mole number which must be removed from the system such that the pressure reach the original value (charging value), table 2 contains also the changes of the mixing pressure ΔP as well as the changes of the pressure attained in the vessel C after the removal of Δn moles of gas.

We have considered this pressure as an excess quantity (denoted by P^E), in as much its value expresses the deviation degree from the ideality of the gas mixture. Figure 4 gives graphically the curves expressing the variation of ΔP and P^E, respectively, with pressure. Both curves have the same feature ; up to approximately 25 atm ΔP and P^E obey a curve, but a linear dependence is afterwards observed for both quantities.

If the excess volume is extrapolated at $P = 0$, one obtains an experimental value $V^E = 3.31$ cm³/mol. With this value and the virial coefficients for pure gases (table 4), a value for B_{12} of 11.1 cm³/mol is obtained, in full agreement with that reported by Michels and Wassenaar [11] (see table 5) from P, V, T data at 298.16°K, considered as the best available value for B_{12}.

To calculate $B_{12}(T)$ theoretically, the Lennard-Jones potential (6, 12)

$$\varphi(r) = -4\,\varepsilon_{12}\left[\left(\frac{\sigma_{12}}{r}\right)^{6} - \left(\frac{\sigma_{12}}{r}\right)^{12}\right] \tag{14}$$

as well as the mixing rules

$$\varepsilon_{12} = (\varepsilon_{11} \cdot \varepsilon_{22})^{1/2} \tag{15}$$

$$\sigma_{12} = (\sigma_1 + \sigma_2)/2$$

were used.

[c] This paper.

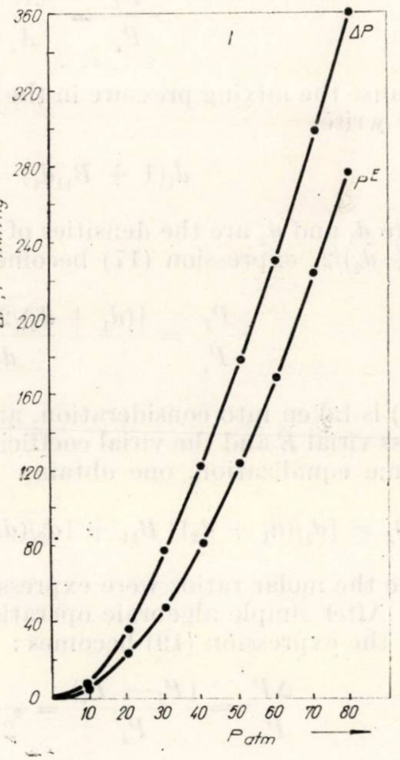

Fig. 4. — Variation of ΔP and PE with the pressure of the mixture $N_2 + H_2$, at the standard temperature.

Since the equation (3) cannot be exactly integrated, the values given in the Tables I – B from "Molecular Theory of Gases and Liquids" [12] were used.

If the values of potential parameters for hydrogen and nitrogen are used, as reported in the above-mentioned paper, [12] a theoretical value for B_{12} at 298,16° K equal to 11.5 $\mathrm{cm^3/mol}$ is obtained, in good agreement with that experimentally found.

In order to get information concerning the pressure influence on the excess virial coefficient – and hence implicitly on the interaction virial coefficient B_{12} – the experimental measurements concerning the pressure changes ΔP which occurred during the mixing of the two gases were taken into account (see table 2).

The calculation scheme (reported in ref. 8) is the following : the gas pressure at constant temperature may be expressed as a function of density and the second virial coefficient, according to the expression

$$P = A \cdot d\,(1 + Bd) \tag{16}$$

The ratio between the initial and final (after mixing) pressures could be in this case written as follows :

$$\frac{P_f}{P_i} = \frac{A_f \cdot d_f\,(1 + B_f \cdot d_f)}{A_i \cdot d_i\,(1 + B_i \cdot d_i)} \tag{17}$$

Because the mixing pressure in the two working reservoirs is the same, we may write

$$d_1(1 + B_{11}d_1) = d_2(1 + B_{22} \cdot d_2) \tag{18}$$

where d_1 and d_2 are the densities of the two gases before mixing ; if $d_f = (d_1 + d_2)/2$, expression (17) becomes

$$\frac{P_f}{P_i} = \frac{[(d_1 + d_2)/2]\ [1 + B_f\,(d_1 + d_2)/2]}{d_1\,[1 + B_{11}d_1]} \tag{19}$$

If (2) is taken into consideration, and B_{12} is expressed by means of the excess virial E and the virial coefficients for the pure gases, according to the volume equalization, one obtains

$$B_f = [d_1/(d_1 + d_2)]\,B_{11} + [d_2/(d_1 + d_2)]\,B_{22} + 2d_1\,d_2E/(d_1 + d_2)^2 \quad (2\,0$$

where the molar ratios were expressed in terms of density.

After simple algebraic operations and taking into account the result (2 0), the expression (19) becomes :

$$\frac{\Delta P}{P_i} = \frac{(P_f - P_i)}{P_i} = \frac{d_2E}{2\,(1 + B_{11}\,d_1)} + \frac{(d_2 - d_1)^2}{4\,d_1\,d_2} \tag{21}$$

---

[12] J. O. Hirschfelder, C. F. Curtiss and R. B. Bird, "Molecular Theory of Gases and Liquids", J. Wiley & Sons, Inc., N Y., 1967, p. 1114.

which may be well extended by introducing the third virial coefficients C_{111} and C_{222} as well as the third excess virial coefficient

$$E = 2\left[\frac{\Delta P}{P} - \frac{(d_1 + d_2)^2}{4\, d_1 d_2}\right]\frac{P}{RT\, d_1 d_2} + \frac{(d_1^2 - d_2^2)(C_{111} - C_{222}\, d_2)}{4\, d_1 d_2} -$$

$$- 3/4\ (d_1 F_1 + d_2 F_2) \tag{22}$$

where F_1 and F_2 represent the 3rd excess virial coefficient defined according to the following expression :

$$F_i = C_{iij} - \frac{1}{3}(2C_{iii} + C_{jjj}) \tag{23}$$

Equation (22) may be written in a more suitable form as a result of the substitution

$$d_i = P/RT - B_{ii}\left(\frac{P}{RT}\right)^2 + (2B_{ii} - C_{iii})\left(\frac{P}{RT}\right)^3 + \dots \tag{24}$$

performed for both components.
One finally obtains

$$E = \frac{2\ RT\Delta P}{P^2} - 2[(B_{11} - B_{22})^2/4 - E(B_{11} + B_{22})/2 + 3\ (F_1 +$$

$$+ F_2)/8]\frac{P}{RT} - 2\Big\{3/4\ (B_{11} - B_{22}) \times [(C_{111} - B_{11})^2 - (C_{222} - B_{22})^2] +$$

$$+ \frac{E}{2}(2B_{11} + B_{11}B_{22} + 2B_{22} - C_{111} - C_{222}) - 3[F_1(2B_{11} + B_{22}) +$$

$$+ F_2(B_{11} + 2B_{22})]\Big\} \times \left(\frac{P}{RT}\right)^2 + \cdots \tag{25}$$

If only the first two terms in the expansion are retained and neglecting the upper terms (of negligible values), after all the necessary substitutions, the following relationship is obtained for the system $N_2 + H_2$ at $T = 298.16°K$:

$$E = 0.6438 \cdot \frac{\Delta P}{n^2} - 2\left[84.732 - \frac{9E}{2}\right] . 4.08 \cdot 10^{-4}\, n \tag{26}$$

where $n = P \cdot 10^{-1}$ atm.

Table 6 summarizes the results obtained. As may be seen in this table a marked increase takes place with pressure values of the inter-reactions in pure gases compared with the mixture, such that the virial coefficients of the interaction diminish with the pressure increase.

Table 6

The dependence of the excess virial coefficient on pressure

P	10	20	30	40	50	60	70	80
E	6.21	5.96	5.52	4.86	4.58	4.11	3.80	3.61

As a final remark, one may state that only few studies have been hitherto devoted to the domain of intermolecular interactions in the binary mixtures of real gases at high pressures.

The present paper may be quoted in the line of the most recent existing researches in this field and the authors hope that the importance of the mentioned subject justifies the effort to design an original experimental equipment able to fulfil the exigency required by the exact measurements accomplished under the conditions of moderate or high pressures.

SIMULTANEOUS VIBRATIONAL TRANSITIONS. III*

COLLISION COMPLEXES OF CHLOROFORM IN NONPOLAR SOLVENTS

SIMONA BĂDILESCU

Petrochemical Works Pitești, Romania

Received June 26, 1973

The frequencies and half-widths of the (C–H)-stretching band of chloroform in mixtures of carbon disulphide and carbon tetrachloride were determined. The formation of short-lived aggregates — collision complexes — was demonstrated and the spectral parameters of the complexes were studied.

INTRODUCTION

The conditions for the applicability of solvent shift theories based on the reaction field model have been considered, and the mechanisms of the various types of the solvation processes have been discussed by Horák et al. [1–6] The simple Kirkwood – Bauer – Magat (KBM) relation has been experimentally extensively tested and it was found to agree statisfactorily with the observed shifts in some nonpolar solvents and solvent mixtures.

In this work we wish to report the results of the study on the behaviour of C–H stretching vibration of chloroform in mixtures of two nonpolar solvents and to correlate the data thus obtained, with the general picture of the simultaneous vibrational transitions (ST) in these mixtures. [7,8]

The ability of the chloroform proton to form hydrogen bonding with various solvents is well established [9–12] and, as already known, in nonpolar

solvents chloroform exhibits a single, sharp (C—H)-stretching band, in the 3 000 cm^{-1} region, which is assigned to the ν_{C-H} stretching vibration. However, we ascribe this band to the primary collision complex "chloroform — nonpolar solvent", which is solvated by further molecules of the nonpolar solvent in the secondary solvation shell. When the solvent is a mixture of two nonpolar compounds, chloroform might afford collision complexes with both solvents and thus the ν_{C-H} band is in fact a double unresolved band which appears near 3 000 cm^{-1} as a broad band, owing to the presence of two kinds of complexes.

EXPERIMENTAL

The materials used were of adequate purity and were dried on molecular sieves, before use.

The infrared spectral measurements were accomplished on a Perkin — Elmer (Model 621) spectrophotometer, in the 3 000 cm^{-1} region and with a Carl Zeiss — Jena (Model UR—10) spectrophotometer (LiF optics), in the 4500 cm^{-1} region.

The wavenumber scale was rechecked before and after each measurement, by scanning the (C—H)-band of chloroform in carbon tetrachloride, at 3015 cm^{-1}. The wavenumber reproducibility was about ± 1 cm^{-1} for the sharp bands and about ± 2 cm^{-1} in the case of the broad bands.

The cells used were of 1 mm thickness (KBr windows) and the concentration of the chloroform was kept at about 0.2 mole$\cdot$l^{-1} in each mixture. The ST-bands in carbon disulphide — chloroform mixtures were measured as reported, [7,8] using a 10 mm special cell.

The binary solvent mixtures were obtained by mixing appropriate volumes of solvent, measured with a precision of $\pm$ 0.01 ml at the same temperature as in measurements.

The ε values of the solvent mixtures were calculated by means of the procedure used by Horák et al.[4] It was assumed that v_1 and v_2 are the concentrations of the two components (in volumes) and ε_1 and ε_2 — the dielectric constants of the pure components.

The relative concentrations of the collision complexes in binary solvent mixtures were estimated from the absorptivities measured in each nonpolar solvent.

RESULTS AND DISCUSSIONS

The frequency values and the half-widths of (C—H)-stretching band of chloroform, in eleven mixtures with various CS_2 — CCl_4 ratios, were measured and the results are listed in table 1. The ν_{C-H} dependence on the dielectric constant factor is approximately linear, thus confirming the validity of the KBM relation for the secondary solvation shell in which the collision complexes are clustered (fig. 1). The extrapolation to "zero field effects" ($f(\varepsilon)=0$) would bring an evidence about the properties of the complex molecule not affected by external forces. However, such an extrapolation failed, the determination of ν_0 involving a fairly long extrapolation which limits the accuracy of the values thus obtained; the case is similar with the one encountered by Horák et al. [4] in one instance.

The ST-band frequency of CS_2 — $CHCl_3$ collision complex in mixture of CS_2 and CCl_4 correlates also well with the dielectric constant of the solvent mixture (fig. 1).

It is seen that the difference between the ST-band frequency of collision complex and the value of the ν_{C-H} band in solvated complex is roughly of the same magnitude and the value is the same as that of the

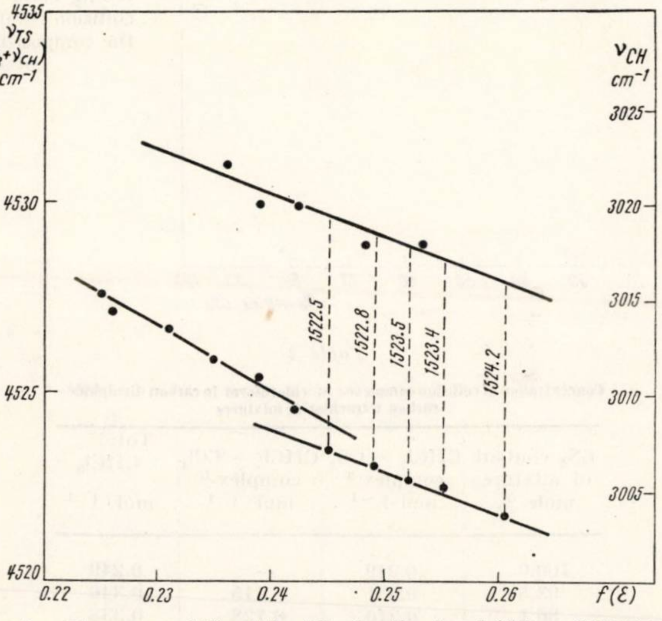

Fig. 1. —Frequency shifts of the ST-vibration band (CS_2 — $CHCl_3$) in CS_2 — CCl_4 mixtures.

asymmetrical frequency of CS_2 molecule — the partner in ST-band. This is a strong evidence for the existence of a distinct primary collision complex which is solvated by the solvent molecules in the secondary shell. The ν_{C-H} band of the individual collision complexes, and also the ST-band, shift along with the change of the composition of the secondary solvation shell according to the simple KBM relation.

Horák reported that the existence of collision complexes is in line with the lattice theories of the liquid states. [2] It is obvious that for an effective collision, the solvent molecule should reach the near vicinity of the active group in solute molecule. The distance of approach will be larger than that in case of a stable, donor—acceptor type complex. In the preceding paper of this series,[13] it was shown that the $CS_2 - CHCl_3$ collision complex possesses a certain degree of geometric orientation.

The curve in figure 2 shows that the greatest value of the chloroform ν_{C-H} half band-width, in the collision complex, was found in case of a solvent mixture containing 50—60% moles carbon disulphide.

---

[13] S. Bădilescu, *Rev. Roumaine Chim.*, **16**, 9 (1971).

An estimation of the relative concentration of the chloroform in CS_2-CHCl_3 and CCl_4-CHCl_3 collision complexes in the solvent mixtures has been made assuming that both absorptivities and half-widths of the component bands are approximately constant (table 2). The results show that the assumption of a constant half-width may be only a first approximation, valid in a rather narrow range of solvent properties (mixtures 8 $\div$ 11, table 2). Nevertheless, the average deviation of the sum of the estimated concentration from the total quantity of chloroform used is 10–15%.

CONCLUSIONS

The behaviour of the chloroform ν_{C-H} spectral parameters in mixtures of nonpolar solvents afforded strong evidence for the existence of short-lived aggregates, formed by collisions between one molecule of a solute and, probably, one molecule of a nonpolar solvent. The aggregates of this kind — collision complexes — are distinct spectroscopic species, with characteristic ST-band frequencies, which are solvated in the secondary shell by a mixture of the molecules of the two solvents.

SIMULTANEOUS VIBRATIONAL TRANSITIONS. IV[1]

SHAPE OF SOME BANDS OF CARBON DISULPHIDE AND CHLOROFORM, AND RELAXATION MECHANISMS IN SOLUTIONS

SIMONA BĂDILESCU

Petrochemical Works Pitești, Romania

Received August 9, 1973

The half band-width of ν_1 vibration of chloroform molecule in a carbon disulphide environment and also of carbon disulphide ν_3 vibration in a chloroform environment have been experimentally determined and various vibrational relaxation mechanisms have been discussed. The half band-width of the simultaneous vibrational transition (ST) corresponding to the collision complexes have been determined and the relationship between the lifetime of the complex and the relaxation times of the concurrent vibrations have been discussed.

INTRODUCTION

It is well known that apart from the vibration frequency of the IR absorption bands, the molecular interactions in liquids and in solutions are also identified by their width. [2-9] Rossi et al. [10] reported the results of the frequency and half band-width determinations of the ν_{C-H} vibration mode of haloforms in carbon disulphide and carbon tetrachloride solutions and pointed out the perturbing influence of carbon disulphide in the reorientation movements of haloforms. This influence is attributed to the shape of the carbon disulphide molecule, but the results differ from Rakov's theory. [11] Indeed, according to the latter theory, molecular reorientations should take place much easier in carbon disulphide than in carbon tetrachloride, since the reorientation barrier in carbon disulphide is much smaller ($U_{or} =$

$=1.2$ kcal/mole, *versus* 2.6 kcal/mole for carbon tetrachloride). Rossi's et al. experimental data might be interpreted as a result of the inhibition of reorientation movements of haloforms subsequently to the formation of their collision complexes with solvent molecules.[12,13]

The results of the study of half band-widths ν_{C-H}(ν_{C-D}) of haloforms ($CHCl_3$, $CHBr_3$, CHI_3 and $CDCl_3$) in carbon disulphide solutions and of the corresponding simultaneous vibrational transition (ST) bands, $\nu_{TS} = \nu_3 + \nu_1(CHX_3)$ are presented below.

EXPERIMENTAL

The half band-widths of fundamental and TS vibration bands were determined using a Carl Zeiss – Jena spectrophotometer (Model UR – 10). Accurate measurements of the geometric slit were performed at all wave numbers and the spectral slit was calculated by the following relation :

$$s = \overline{A}s' + F(s)\overline{B}$$

where $\overline{A}$ and $\overline{B}$ are constants of the spectrophotometer, $F(s) = 0.5$, and s' is the value of the geometric slit. The results of the slit measurements at the wave numbers corresponding to the fundamental bands and to ST bands are presented in table 1.

Table 1

Values of spectral slits on a Carl Zeiss – Jena (UR – 10) spectrophotometer

$\overline{\nu}$, cm^{-1}	$\overline{A}$(cm^{-1}/mm)	$\overline{B}$ (cm^{-1})	s' (mm)	s, cm^{-1}
1515	23.5	2.21	0.261	7.23
1730	35.5	2.96	0.206	8.79
1827	41.5	3.30	0.178	9.04
1970	51.0	3.80	0.128	8.43
3020	19.6	0.945	0.1562	3.53
4530	63.0	2.09	0.0954	7.00

The ν_{C-H} half band-width of chloroform in carbon disulphide was also determined by means of a Perkin-Elmer (Model 621) spectrophotometer with an automatic slit programme (1.22 cm^{-1} at 3 000 cm^{-1}), the spectral slit being determined by the relation :

$$s(cm^{-1}) = C + BW$$

in which the constants have the following values : $C = 0.141$, $B = 0.00794$ and $W = 136$.

The fundamental half band-widths were determined by the Vincent-Geisse[14] procedure, suitable for intense bands. Determinations were performed within $0.1-3.10^{-3}$ moles/cm^3 concentration ranges (thicknesses comprised between 1 and $10 \cdot 10^{-2}$ cm). The $s/\Delta\nu$ ratios varied between 0.1 and 0.15 and the half band-widths were corrected according to Ramsay tables.[15]

[15] D. A. Ramsay, *J. Amer. Chem. Soc*, **74**, 72 (1952).

The dependence of the ν_1 half band-width ($CHCl_3$) on chloroform concentration in carbon disulphide was tested by making determinations in solutions containing between 20 and 80% chloroform.

Since the spectral slit in the 1500 cm^{-1} region is 7cm^{-1}, the half band-width ν_3 (CS_2) at 1515cm^{-1} may present extremely large errors and therefore these values were not taken into consideration.

The ST half band-widths were determined by the method of extrapolation using cells with thicknesses between 6 and 30 mm. The ST half band-widths were determined in mixtures with various proportions of carbon disulphide and chloroform and the values obtained did not require corrections. The half band-widths were also determined in the presence of variable amounts of carbon tetrachloride.

RESULTS AND DISCUSSION

The results of measurements of the half band-width of ν_1 vibration are given in table 2, and those of the ST bands are listed in table 3. Fig.1 illustrates (*a*) the variation of the ST half band-width (CS_2 + $CHCl_3$) with the mixing ratio $\left(\text{m.r.} = \dfrac{\text{ml.}CHCl_3}{\text{ml.}CHCl_3 + \text{ml. }CS_2}\right)$, and curve *b* represents the same value in the presence of carbon tetrachloride ($CS_2 + CHCl_3 + CCl_4$).

Table 2

Half band-width of $\nu_1(CHCl_3)$ and $\nu_3(CS_2)$ vibrations in various molecular environments

Compound	Vibration	Solvent	Frequency cm^{-1}	$\Delta\nu_{1/2}$ cm^{-1}
Chloroform	$\nu_1(C-H)$	CCl_4	3015	16.5
Chloroform	$\nu_1(C-H)$	CS_2	3003	12*, 14
Bromoform	$\nu_1(C-H)$	CS_2	3022	12.4
Iodoform	$\nu_1(C-H)$	CS_2	3003	12.7
Carbon disulphide	$\nu_3(CS_2)$	$CHCl_3$	1515	13.4

* The value has been determined on a Perkin-Elmer (Model 621) spectrophotometer.

The results show that $\Delta\nu_{1/2}$ is practically independent of the concentration of the solution, which proves that the relaxation of this vibration in a carbon disulphide medium is of a reorientational type. The results are quite close to other experimental data[10,16,17] and also to the results of the determination of the vibrational relaxation time from dielectric relaxation measurements.[18]

Table 3

Half band-width of ST vibration

Collision complex	ν_{ST} cm^{-1}	$\Delta\nu_{1/2\,ST}$ cm^{-1}
$\nu_3(CS_2) + \nu_1(CHCl_3)$	4533	56
$\nu_3(CS_2) + \nu_1(CHBr_3)$	4538	40
$\nu_3(CS_2) + \nu_1(CHI_3)$	4517	38
$\nu_3(CS_2) + \nu_1(CDCl_3)$	3760	33
$\nu_3(CS_2) + \nu_2(CCl_4)$	1734	32
$\nu_3(CS_2) + \nu_4(CCl_4)$	1828	38
$\nu_3(CS_2) + \nu_1(CCl_4)$	1927	43

According to Rakov's theory, [11] the relaxation time gives the time during which the molecule maintains a given orientation and is related to the half band-width value by the relation :

$$\Delta\nu_{1/2} = \frac{1}{c\pi\tau} \qquad (1)$$

By calculating the relaxation times of ν_1 vibration of the chloroform we find $\tau = 0.64 \cdot 10^{-12}$ sec. in carbon tetrachloride and $\tau = 0.88 \cdot 10^{-12}$ sec. in carbon disulphide ; these values attest a hindrance of the reorientation in carbon disulphide. The relaxation time (the hindrance) is longer in CS_2 than in CCl_4 (inert solvent) but it is significantly more reduced than in the case in which complexes are formed by hydrogen bonds (for instance in benzene) where the relaxation times range within 1.5 and $2 \cdot 10^{-12}$ sec. [19]

With regard to vibration ν_3 (CS_2) in a chloroform environment some authors interpreted this half band-width in terms of a reorientational relaxation. [3] However, some recent data [20] provided evidence in support of a relaxation mechanism in which the major weight is represented by the vibrational relaxation of the "resonance between identical vibrators" type, a relaxation which is dependent on the solution concentration. Kakimoto and Fujiyama [20] calculated the band-width resulted from this type of relaxation, applying Valiev's formula [21]

$$\Delta\nu_{1/2} = \frac{c}{\pi}\sqrt{\rho\,\frac{c_m}{3W_m}\cdot S\cdot\Gamma} \qquad (2)$$

in which ρ is the density of the dissolved substance, c_m — the molar concentration in solution, W_m is the molecular weight and Γ the absolute intensity of the absorption band (expressed in cm^2 · mol^{-1}).

[21] K. A. Valiev, *Optika i Spektroskopiya*, **11**, 253 (1961).

Vincent-Geisse [22] developed a formula for the calculation of a band-width when passing from the solution in an inert solvent to the state of pure liquid and explained this width by a coupling between identical vibrators:

$$\delta(\Delta\nu_{1/2}) = 0.04 \cdot 10^3 \, \frac{d}{M} \cdot \frac{A}{g\,\nu_0} \qquad (3)$$

In formula (3), A is the intensity of the band corresponding to the isolated (gaseous) molecule, expressed in *darks*, ν_0 — the wavenumber of the band of the molecule in an inert solvent, g is the vibrational degenerescence degree and 0.04 is a coupling coefficient (calculated by the author by using a large number of data from the literature). Thus, for carbon disulphide—pure liquid — , the author found [22] a broadening by 24 cm^{-1} of the band ν_3 (the total width of the band being 30 cm^{-1}, as compared to 6 cm^{-1} in carbon tetrachloride solution).

We considered of interest to apply formula (3) in order to calculate the ν_3 band-width of carbon disulphide in liquid mixtures with chloroform, introducing in the formula the molar fraction of the carbon disulphide from the respective solution (which expresses in fact the percentage of identical oscillators which may be coupled and which relax through resonance). The results obtained in this manner are compared with Kakimoto and Fujiyama's[20] experimental data in table 4, and a very good agreement is observed in the concentration range from 0.6 to 50%. In the case of a relaxation of this type, the relaxation time would depend only on the number of the identical oscillators and on the absolute intensity of the vibration corresponding to the isolated molecule rather than on the molecular environment and on its characteristics. For this reason, for the calculation of the relaxation time it is more appropriate to use the intensity of the vibration of the isolated molecule than that of the value of the intensity in the respective solvent, as postulated by Valiev. [21] Although some data in the literature referring to the ν_3 half band-width of CS_2 in various molecular environment support this idea, [23] the extreme scarcity of data in this field does not allow a generalization.

Table 4

Half band-width values of ν_3 (CS_2) band

CS_2 moles %	$\Delta\nu_{1/2}$ calculated accord. to (3)	$\Delta\nu_{1/2}$ from data [20]
100	30.0	20.6
80	25.2	19.3
60	20.4	17.5
40	15.6	15.0
20	10.8	11.5
0.6	7.4	6.4

[23] J. Jacob and J. P. Benaich, *J. Chim. phys.*, **64**, 1282 (1967).

Additional data with regard to the relaxation of these vibrations may be obtained from the study of ST half band-width corresponding to the collision complexes occurring in solutions. The half band-width is maximum at a 0.5 mixing ratio (fig. 1, curve *a*) which indicates the existence of bimolecular collision complexes. In the process of simultaneous vibrational transition a modification of the charge distribution takes place along the carbon — sulphur and carbon — hydrogen bonds aligned in the complex, as a result of the simultaneous interaction of vibration ν_3 (CS_2) and ν_1 ($CHCl_3$) with the exciting radiation. The absorption process occurs practically instantaneously and the molecules surrounding the complex do not manage to reorient so as to "adjust" to the new charge distribution in the complex. The deactivation of the complex occurs by molecular interactions which modify the reciprocal orientations of molecules in such a way as to reduce the interaction energy.

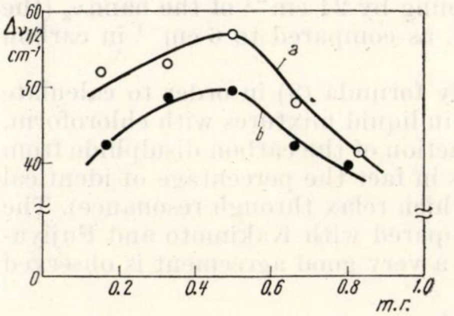

Fig. 1. — Dependence of the half band-width of $ST_{(CS_3+CHCl_2)}$ band on the mixing ratio $\left(\text{m.r.} = \dfrac{\text{ml. } CHCl_3}{\text{ml.} CHCl_3 + \text{ml. } CS_2}\right)$: *a*, $ST_{(CS_2+CHCl_3)}$ half band-width; *b*, $ST_{(CS_2+CHCl_3)}$ half band-width, in the presence of CCl_4.

The half band-width of the ST band reflects the relaxation time of the molecular interactions τ_{ST} and the lifetime of the collision complex, respectively. The variation manner of $\Delta\nu_{1/2\,ST}$ with the mixing ratio provides indications concerning the process of equilibration in the system "collision complex — surrounding solvent molecules". Thus, it seems that the intermolecular relaxation (the deactivation of the complex) does not take place continuously but rather in jumps, the passage from $U_{\max}$ to $U_{\min}$ being made over a potential barrier owing to the local interactions between the two bonds of the molecules participating in the simultaneous transition process.

The lifetime of the complex is also dependent on the relaxation times of the fundamental vibrations involved in the simultaneous transition as they constitute a measure of the reorientation rates of the molecules. The vibrational relaxation leads to the modification of the reciprocal orientation of the dipoles of the respective bonds and hence to the deactivation of the collision complex. Thus, if the relaxation times are increased it means that the orientation of dipoles is maintained longer and the lifetime of the complex is longer. On the contrary, the short relaxation times indicate rapid change of the reciprocal orientation and therefore a rapid deactivation of the complex.

By calculating the lifetime of the collision complex (τ_{ST}) from the experimental value of the corresponding simultaneous transition half band-width, it results $\tau_{ST} = 1.9 \cdot 10^{-12}$ sec. This value roughly corresponds to the difference of the relaxation times of the two fundamental vibrations $\nu_3(CS_2)$ and $\nu_1(CHCl_3)$:

$$\tau_{ST} = \tau_3(CS_2) - \tau_1(CHCl_3) \tag{4}$$

The experimental data of the investigated systems (table 3) seem to obey this empirical relation. From equation (4) we may write :

$$\Delta\nu_{1/2\,(ST)} = \frac{\Delta\nu_{1/2}(\nu_3) \cdot \Delta\nu_{1/2}(\nu_1)}{\Delta\nu_{1/2}(\nu_1) - \Delta\nu_{1/2}(\nu_3)} \tag{5}$$

and, by means of this relation, we may calculate the half band-width of the vibration, knowing the ST half band-width and that of one of the vibrations participating in the simultaneous transition. Table 5 shows the values of ν_1 half band-width ($CHCl_3$) calculated in this manner and it can be seen that they are quite equal with the values obtained experimentally. Similarly, table 6 presents the results of the calculation of ν_3 (CS_2) half band-width in iodoform and deuteriochloroform, respectively, from $\Delta\nu_{1/2\,ST}$ and the half band-width ν_{C-H} (ν_{C-D}).

Table 5

Half band-width of the ν_{C-H} calculated from τ_{ST}

	CS_2 moles %	$\Delta\nu_{1/2}$ (cm^{-1})			
		$\nu_3(CS_2)$	ν_{ST}	$\nu_1(CHCl_3)$ calculated	$\nu_1(CHCl_3)$ found

The half band-width of some Raman bands of carbon tetrachloride involved in simultaneous transition with the ν_3 band of carbon disulphide were calculated in the same manner and the results are given in table 7.

Table 7

Some Raman half band-width of CCl_4 from τ_{ST}

			calculated*	found
219	1734	32	5	
313	1828	38	5.1	
455	1927	43	5.2	5.4[27]

* Half band-width $\nu_3(CS_2)$ in carbon tetrachloride was taken[2] equal to 6 cm^{-1}

In a previous paper[1] we reported that the carbon tetrachloride added to chloroform solutions in carbon disulphide determines an increase of the ν_{C-H} half band-width which reaches a maximum for about 40% CCl_4, after which the half band-width decreases again. In the mixture of the two solvents ($CS_2 + CCl_4$) the chloroform molecules may reorient easier than in CS_2 (as has been shown, ν_{C-H} of chloroform in CCl_4 is smaller than in CS_2). However, when the CCl_4 concentration in mixture is high, the interactions between CS_2 and CCl_4 molecules are more effective and the ν_{C-H} vibrational relaxation in the environment of these complexes occurs difficultly and consequently the half band-width decreases (Fig. 1*b*).

The results obtained in this work are in accordance with the existing experimental data and prove the dependence of the lifetime of the complex on the relaxation times of the vibrations participating in a simultaneous transition. Similarly, the half band-widths in the haloform series in an environment of carbon disulphide reveal close values, which indicate similar relaxation mechanism. On the other hand, the reorientation movements are inhibited (to a certain extent) by the formation of collision complexes and the bands appear to be narrower than in totally inert solvents but larger than in solvents in which stable complexes (of the donor-acceptor type) are formed.

As an additional observation we note the fact that the ST half band-width in the $CS_2 - CDCl_3$ system is much smaller than that corresponding to the $CS_2 - CHCl_3$ system. This may be explained to be due to a slower relaxation of ν_{C-D} vibration as compared to the ν_{C-H}, which agrees with the data from literature concerning the relaxation of deuterated molecules.[28]

The above data constitute experimental proofs of some weak interactions of a peripheral type in which only certain parts of the molecule are involved by the corresponding vibrations. In general, our results favour the idea of some binary interactions in solutions in view of expressing the shape of bands, in agreement with works of Vincent-Geisse et al.[6]

SOME CONSIDERATIONS CONCERNING GIBBS FREE ENERGY OF GAS-SOLID INTERFACE

P. BUDRUGEAC and M. I. VASS

Institute of Physical Chemistry, str. Dumbrava Roşie 23,
Bucharest, Romania

Received December 25, 1973

Starting with several hypotheses, a more general expression for the infinitesimal variation of internal energy of gas-solid interface is given. A new way of expressing the Gibbs free energy of gas-solid interface is advanced.

In the thermodynamic treatments of gas adsorption on solid adsorbents, developed by different authors, [1–5] the surface area is an important variable which characterizes the adsorption equilibrium. By making an analogy between disperse and porous solids, Dubinin [6] has shown that the above assumption is valid only for the non -porous and wide-pore adsorbents. From the thermodynamic viewpoint, the process of adsorption in micropores is similar to the formation of a sort of solution, resulting in a change of the chemical potentials of both components of the system. [6,7]

In order to find a more general expression for the variation of internal energy of gas-solid interface, the following hypotheses about the adsorption system and the adsorption phenomenon are made:

(a) The thermodynamic system consists of: the adsorbent with an energetic homogeneous surface, the interface and the gas.

(b) The chemical nature of the adsorbent is not changed by adsorption.

(c) The adsorption is reversible.

(d) The number of molecules of the adsorbed gas is negligible as compared to the number of molecules from the gaseous phase.

For all the extensive thermodynamic quantities, X, an excess surface quantity, X^s, can be defined as:

$$X^s = X - X^0 \tag{I}$$

[7] B. P. Bering, A. L. Myers and V. V. Serpinsky, *Doklady Akad. Nauk S.S.S.R.*, **193** (1970).

where : X^0 is the extensive thermodynamic quantity of the hypothetical gas-solid system in which adsorption does not occur and X is the same quantity in case adsorption occurs.

The symbols used below stand : E for internal energy, G for Gibbs free energy, S for entropy, V for volume, n for number of molecules, A for surface area, T for temperature, P for pressure, μ for chemical potential. Subscript a denotes the adsorbent while subscript g stands for gas ; uper indexes 0 and s refer to the gas-solid system in which the adsorption does not occur, and to the interface, respectively.

The expression of the infinitesimal change of internal energy of the system defined in (a) is usually given by the relation :

$$dE = TdS - PdV + \mu_a dn_a + \mu^s dn^s - \gamma dA \tag{II}$$

where :

$$\gamma = -\left(\frac{\partial E}{\partial A}\right)_{S,V,n_a,n^s} \tag{III}$$

The expression of the infinitesimal change of internal energy of the system in which the adsorption does not occur is given by the relation :

$$dE^0 = TdS^0 - PdV^0 + \mu_a^0 dn_a - \gamma^0 dA \tag{IV}$$

Subtracting, member by member (IV) from (II) we obtain :

$$dE^s = TdS^s - PdV^s + (\mu_a - \mu_a^0)dn_a + \mu^s dn^s - (\gamma - \gamma^0)\, dA \tag{V}$$

Relation (V) may be applied to all types of adsorbents described in reference [6] and to adsorbents with mixed structures. This relation includes the cases for which $\mu_a = \mu_a^0$ (the adsorbent is not microporous) as well as the case for which $\mu_a \neq \mu_a^0$ (the adsorbent is microporous). The same as for the treatments given by Hill [1] and Guggenheim, [3] in the eq. (V) V^s is taken as different from zero, while Gibbs, [1,4] Schay [5] and Bering and co-workers [7] consider V^s zero.

In the above-mentioned papers two expressions for G^s are given :

$$G^s = E^s + PV^s - TS^s \tag{VI}$$

$$G^s = E^s + PV^s + (\gamma - \gamma^0)\, A - (\mu_a - \mu_a^0)\, n_a - TS^s \tag{VII}$$

Expression (VI) was given by Schay [5] and expression (VII) by Hill, [1] Gibbs, [1,4] Guggenheim [3] and Bering and co-workers. [7]

Starting with hypotheses (a—d), we aim at finding the expression of G^s.

Let the system defined as in (a) be in equilibrium with the environment with which our system does not exchange any substance.

The subscript t refers to the environment.

In accordance with the second law of thermodynamics, we can write :

$$dS + dS_t = 0 \tag{VIII}$$

We make the following assumption :

$$\begin{aligned} dE + dE_t &= 0 \\ dV + dV_t &= 0 \end{aligned} \tag{IX}$$

Obviously :

$$dS_t = \frac{dE_t + PdV_t}{T} \qquad (X)$$

Relations (II), (VIII), (IX) and (X) lead to :

$$-\gamma dA + \mu_a dn_a + \mu^s dn^s = 0 \qquad (XI)$$

At equilibrium, from (II) and (XI), it results that :

$$dE - TdS + PdV = -\gamma dA + \mu_a dn_a + \mu^s dn^s = 0 \qquad (XII)$$

For $dT = dP = 0$, we have :

$$dG = d(E + PV - TS) = 0 \qquad (XIII)$$

For the above given system, without adsorption, dG^0 is given by :

$$dG^0 = d(E^0 + PV^0 - TS^0) \qquad (XIV)$$

Subtracting, member by member, (XIV) from (XIII), it results that :

$$dG^s = d(E^s + PV^s - TS^s) \qquad (XV)$$

and by integration one gets :

$$G^s = E^s + PV^s - TS^s \qquad (XVI)$$

Eq. (XVI) is identical to (VI).

Since there are two different expressions for G^s((VI) and (VII)) we expect to have also different expressions for $d\mu^s$. However, in papers [1-5,7] similar expressions are given for $d\mu^s$. This could be explained by the fact that an expression of $d\mu^s$ is obtained from (V) for which the following Gibbs-Duhem equation is written :

$$S^s dT - V^s dP + n_a d\mu_a^0 + n^s d\mu^s - Ad(\gamma - \gamma^0) = 0 \qquad (XVII)$$

which leads to :

$$d\mu^s = -\frac{S^s}{n^s} dT + \frac{A}{n^s} d(\gamma - \gamma^0) - \frac{n_a}{n^s} d\mu_a + \frac{V^s}{n^s} dP \qquad (XVIII)$$

Hence it is possible to obtain an expression of $d\mu^s$ which does not depend on the expression of G^s.

Acknowledgments. The authors wish to acknowledge many clarifying discussions with Dr. V. Vasilescu, A. Ivanov and I. Sitaru.

obtained:

$$[illegible] \qquad (X)$$

Equations (II), (VIII), (IX) and (X) lead to:

$$s_a dT + \rho_a d\sigma - v_a dp' = 0 \qquad (XI)$$

By combining equations, from (II) and (XI), it results that:

$$dG = [illegible] \qquad (XII)$$

For $dT = dp = 0$, we have:

$$dG = [illegible] \qquad (XIII)$$

For the adsorptive system, without adsorption, dG^0 is given by:

$$dG^0 = [illegible] \qquad (XIV)$$

Subtracting equation (XIV) from (XIII), it results that:

$$[illegible] \qquad (XV)$$

and by integration one gets:

$$[illegible] \qquad (XVI)$$

Eq. (XVI) is identical to (VI).

Since there are two different expressions for G (VI) and (XVI) we expect to have also different expressions for dσ. However, in papers [illegible] similar expressions are given for dσ. This could be explained by the fact that an expression of dσ is obtained from (I) for which the following Gibbs-Duhem equation is written:

$$[illegible] \qquad (XVII)$$

which leads to:

$$[illegible] \qquad (XVIII)$$

Hence it is possible to obtain an expression of dσ which does not depend on the expression of G.

Received September 26, 1973

The authors report the results obtained in the synthesis and structural investigation of complex cobalt (II) thio- and selenocyanates with diamino derivatives. Compounds of the following type were obtained : $Co(NCX)_2.nL$, where X = S, Se, and L = *o,o'*-DABF (n = 2) ; L = *m,m'*-DABF (n = 1) ; L = *p,p'*-DABF ((n = = 1 and 3) ; L = *p,p'*-DADFM (n = 3) and 2,7-DAF (n = 2.5). The compounds obtained are high spin complexes, having magnetic moments characteristic of a cobalt (II) ion in a six-coordinate configuration, with ${}^4T_{1g}$ ground term. Electronic spectra were recorded, either as diffuse reflection spectra or solution spectra (in DMF), as well as infrared spectra. The data show that all the compounds reported are six-coordinate, with a various degree of tetragonal distortion. Some of the compounds are monomeric, others are polymeric ; both the inorganic and organic ligands used coordinate in two ways : monodentate and/or bidentate, forming – in the last case – bridges between two metallic ions.

INTRODUCTION

In a broad program of investigating the coordinative ability of some divalent metals and organic (diamino derivatives) and inorganic (pseudohalide) ligands, we have undertaken the study of complex pseudohalides of Mn(II), [1] Co(II), [2] Ni(II), [2,3] and Cu(II) [4–6] with diamino compounds, particularly diaminobiphenyl derivatives. These metals are known to form several complex compounds derived from benzidine [7,8] and some from *o,o'*-DABF [8-11] and *m, m'*-DABF. [8]

In this paper we report the results obtained with *o,o'*-, *m,m'*- and *p,p'*-diaminobiphenyl (DABF), *p,p'*-diaminodiphenylmethane (*p,p'*-DADFM) and 2,7-diaminofluorene (2,7-DAF). These ligands are known to form metal complexes with the following combination ratios: 1 M : 1L for L = *m,m'*- and *p,p'*-DABF; 1M : 2L for L = *o,o'*- and *p,p'*-DABF; and 1 M : 3 L for L = *o,o'*- and *p,p'*-DABF, and *p,p'*-DADFM; the local symmetry of the complexed metal ion is D_{2h} or D_{4h}. The highest symmetry is exhibited by the compounds of $M(o,o'\text{-DABF})_3X_2$ type. [11] The existence of some Co(II),[12] Co(III) [13] and Pt(II) [14] complexes with *o,o'*-DABF as ligand is also worth mentioning; these complexes exhibit optical activity and some of them have been resolved into the corresponding optical isomers. The investigation of the optical properties of complexes containing *o,o'*-DABF showed, surprisingly, that the diamine is a good ligand, in spite of the known modest coordinating ability of aromatic amines. The chelate ring with this ligand is a seven-membered ring. The coordination of *o,o'*-DABF becomes possible through a reciprocal rotation of the aromatic rings, and the readiness of this rotation confers stability on the chelate ring. [13] It was demonstrated that *o,o'*-DABF is the source of asymmetry in its complexes. [14]

The two other isomers, namely *m,m'*- and *p,p'*-DABF were found unable to form chelates; these diamines coordinate with one or/and both amine functions, in the last case forming polymers, or at least dimers. [1,5,8,15]

In this paper we report and discuss the results obtained in the investigation of cobalt (II) thio- and selenocyanate complexes containing the diamines mentioned above.

EXPERIMENTAL PART

Preparation of complexes. The synthesis of the compounds under discussion was generally simple, and it was described for other similar compounds. [1,2,6,16] The experimental data concerning combination ratios, elemental analyses and some properties were listed in table 1. The yields were in the range 60 – 80 %. It should be noted that some of these compounds have been also synthesized by other authors: $Co(NCS)_2(p,p'\text{-DABF})$ [17] and $Co(NCSe)_2(p,p'\text{-DABF})_3$, [18] but no detailed investigation upon them was done; the compound $Co(NCS)_2(o,o'\text{-DABF})_2$ has been prepared [9] and investigated [11] only recently.

Physical measurements. Magnetic susceptibility measurements were carried out at room temperature, with a Faraday balance, calibrated with CoHg(SCN)$_4$. The magnetic moments have been calculated with the relation : $\mu_{eff} = 2.84\sqrt{\chi_{Mc} \cdot T}$. The results are given in table 2.

The electronic spectra were obtained with the aid of a VSU–1 Carl Zeiss–Jena type spectrophotometer, equipped with a reflexion device, by using pressed pellets of the compounds investigated and MgO as reference. The absorption bands are listed in table 3.

Infrared spectra were recorded with a UR–20 Carl Zeiss–Jena instrument, in the range 3 600 – 400 cm^{-1}, in KBr pellets. The bands and their assignments are listed in table 4.

RESULTS AND DISCUSSION

Along with the synthesis of the new coordination compounds the combination ratios were established, as well as some of their properties. It was found that the combination ratios M : DABF are similar to those obtained for metals other than cobalt ; thus, for L = *p*, *p'*-DADFM the ratio is 1M : 3L and for L = 2,7-DAF, a compound with the combination ratio 1M : 2.5 L is obtained.

The solubility of the compounds obtained is lower than that of similar Mn(II) complexes, but sensibly higher than that of the related Ni(II) compounds.[3] They are partially soluble in ethanol and acetone, forming blue or dark-green solutions, probably, in a manner similar to the complex cyanates of the same type. [2] Dimethylformamide (DMF) dissolves well the compounds investigated, and forms blue solutions (the thiocyanates) and beige-brown solutions (the selenocyanates). This behaviour suggests, from the very beginning, essential changes in the coordination sphere of the metallic ion. Pyridine also dissolves these compounds, and gives solutions coloured in pink, beige or brown.

The solubility of compounds containing only one diamine molecule per metal (*m,m'*- or *p,p'*-DABF) is lower than the solubility of the other ones, whereas their thermal stability is higher (table 1). It was also noted a higher thermal stability of the thiocyanates, as compared with the selenocyanates. The complex compounds, containing three molecules of *p,p′*-DABF per metal, exhibit a behaviour similar to that of the related Mn (II) derivatives. [1] This makes us believe that the three ligand molecules do not occupy identical positions in the coordination sphere and probably one of them is weakly bonded and can be easily split off on heating.

The *magnetic properties* of the cobalt (II) ion are strongly dependent on the symmetry of the crystal field around the metal. The magnetic moments for a six-coordinate configuration exhibit values in the range 1.8 to 5.6 BM, depending on the strength of the crystal field. [19-21] In a field of tetrahedral symmetry, the magnetic moments show values in the range 4.30 to 4.8 BM. [19,22]

The values obtained by us for the diaminobiphenyl and related derivatives indicate high-spin metal ions and are in the range characteristic of six-coordinate complexes (table 2). In some cases the μ values are somewhat higher for selenocyanates than for thiocyanates, but are smaller than those for the corresponding cyanates. [2] They remain, however, in the range specific for an octahedral coordination of the ligands around the metal ion.

The *electronic spectra* were recorded only for the compounds containing diaminobiphenyl derivatives, both in solution (dimethylformamide, DMF as solvent) (fig. 1) and in solid state (diffuse reflection electronic spectra) (figs 2 and 3). The magnetic moments suggest that the ground state of the cobalt (II) ion in these compounds is a $^4\Gamma_{1g}$ triplet. From the succession of the following terms in a six-coordinate configurations, one can expect the occurrence of three bands in the electronic spectrum, corresponding

to the following transitions: ${}^4T_{1g} \rightarrow {}^4T_{2g}(\nu_1)$; ${}^4T_{1g} \rightarrow {}^4A_{2g}(\nu_2)$; ${}^4T_{1g} \rightarrow {}^4T_{1g}(P)(\nu_3)$. The shapes of spectra (figs 2 and 3) and the values of the absorption bands (table 3) indicate indeed the six-coordinate configuration of the compounds investigated. The ν_1 transition occurs as a single band for most of the compounds and it is found in the range 8800–9500 cm^{-1}. The ν_2 band occurs as shoulders [11,23-25] or less well resolved bands, in the range 16,600 to 18,200 cm^{-1} usually higher for selenocyanates. Generally, the assignment of this band is difficult, due to the nature of the transition. It was stated [25] that the ν_2/ν_1 ratio should be between the limits 2.1—2.2. for six-coordinate cobalt compounds; anyway, a band or a shoulder located at more than 2.2 ν_1 cannot be due to a transition to ${}^4A_{2g}$. The values of the ν_2/ν_1 ratio obtained for our compounds are somewhat lower than 2.00 (being in the range 1.79 to 1.95), as in the case of the $Co(H_2O)_6{}^{2+}$ complex; therefore, we conclude that the assignment of the ν_2 band to a shoulder located on the lower value branch of the ν_3 band is not incorrect.

$\star$ υ_3 (tetrahedron)

The ν_3 band is split into 2–3 components (sometimes it appears as a single band but then it is much broadened) in the range 21,400 – 18,200 cm^{-1}. The lifting of the degeneracy may be due to the spin-orbit coupling or to low symmetry ligand field efects. It is known that the degree of distortion can be correlated with the energy difference between components of higher and lower energy of the ν_3 band. Accordingly, it is observed that the thiocyanates are more distorted than selenocyanates (table 3), and the compounds with only one molecule of amine (*m,m'*- and *p,p'*-DABF) (figs 2 and 3, *b* and *c*) are of a lower symmetry than those with two molecules of ligand (*o,o'*-DABF) (table 3 ; figs 2 and 3, *a*). This can be understood if one accepts that for achieving six-coordination, one of the ligands has to coordinate by forming a bridge, which imposes some steric restrictions.

From the difference between ν_2 and ν_1 the magnitude of the crystal field (10D$_q$) can be estimated.[11] It is found that this value is higher for selenocyanates, in accordance with the sense of the crystal field increase.

The spectra also show some shoulders in the ranges 15,000 – 14,000 cm^{-1}, which can be due either to some spin-forbidden transitions (to the

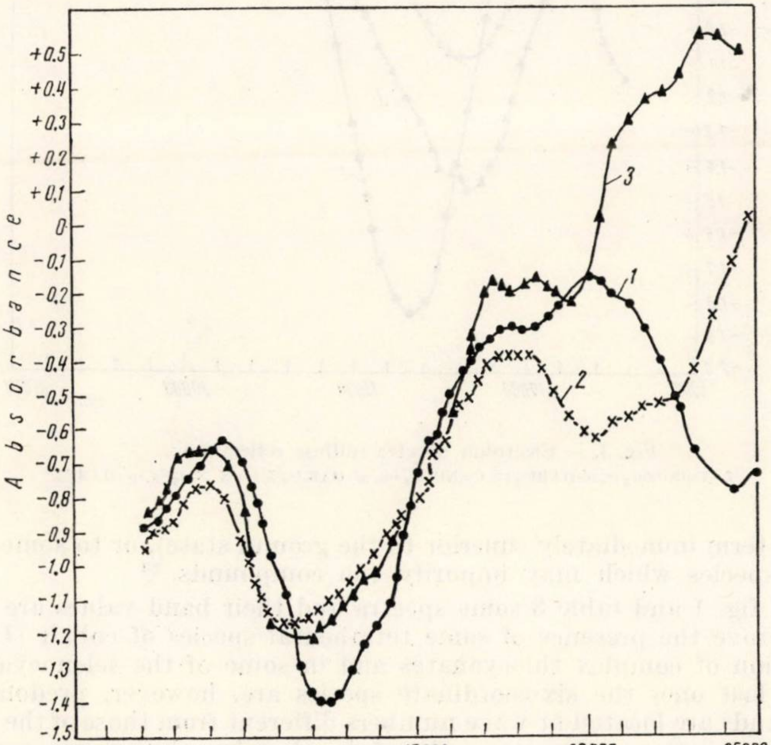

Fig. 2. — Electronic spectra (diffuse reflection) :

1, Co(NCS)$_2$ (*o*, *o'*-DABF)$_2$; *2*, Co(NCS)$_2$ (*m*, *m'*-DABF) ; *3*, Co(NCS)$_2$ (*p*, *p'*-DABF).

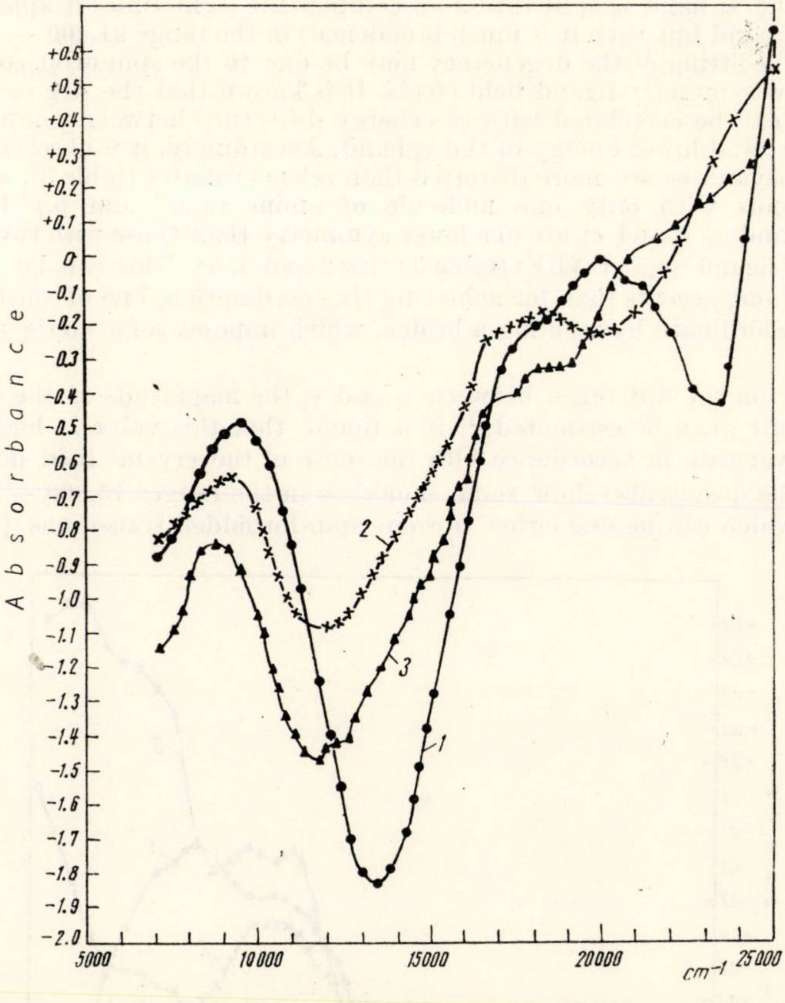

Fig. 3. — Electronic spectra (diffuse reflection) :

doublet term immediately superior to the ground state), or to some tetrahedral species which may impurify the compounds. [23]

In fig. 1 and table 3 some spectra and their band values are given, which prove the presence of some tetrahedral species of cobalt (II) ions in solution of complex thiocyanates and in some of the selenocyanates; for the last ones the six-coordinate species are, however, predominant. Their bands are located at wave numbers different from those of the diffuse reflection spectra; we suppose, therefore, that in solution, six-coordination is achieved by coordinating two solvent molecules.

With the aid of *infrared spectra* we followed the occurrence and the shift of the bands characteristic of the anions, on the one side, and on the other side the bands of the diamines, as compared with the uncoordinated ligands.

The difunctional coordinative capacity of pseudohalides and/or their ability to form bridges between two metal atoms are well known [26,27]; both anions have characteristic frequencies, which occur in three regions of the three infrared active vibrations, and which exhibit different values, depending on the types of bonds which they form. [28-31]

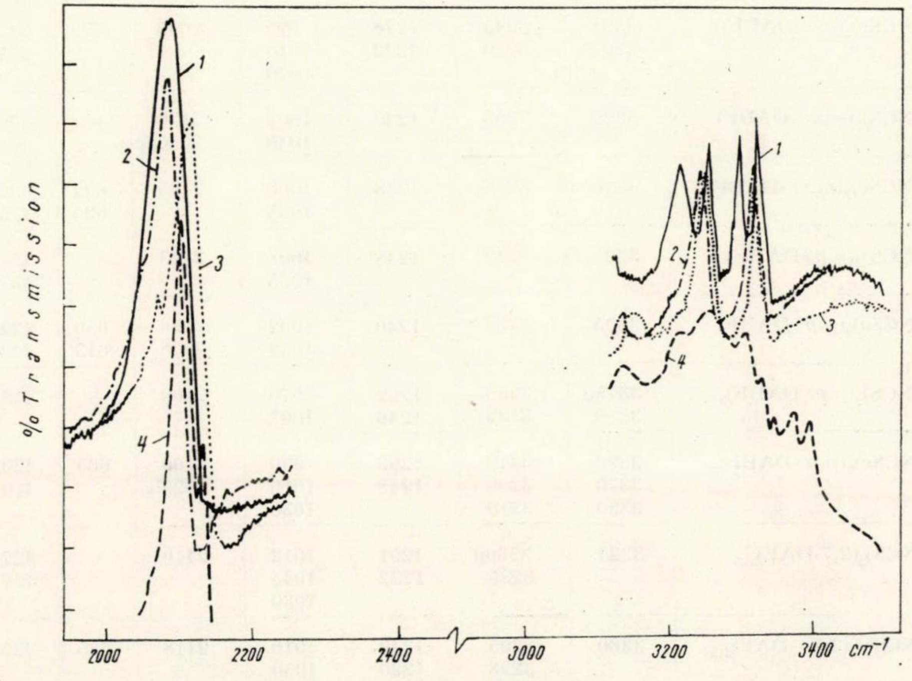

Fig. 4. — Infrared spectra of :

1 $Co(NCS)_2$ (*o,o'*-DABF)$_2$; 2, $Co(NCSe)_2$ (*m,m'*-DABF); 3 $Co(NCS)_2$ (*p,p'*-DABF); 4, $Co(NCSe)_2$ (*p p'*-DABF)$_3$.

The anion bands in our spectra (table 4) are found in the expected regions. Thus, ν_{CN} exhibits higher values for the compounds containing only one amine molecule (*m,m'*- and *p,p'*-DABF), then, in decreasing sequence, for the compounds with three molecules of amine, with 2.5 molecules of 2,7-DAF and, finally, the lowest values are obtained for compounds with *o,o'*-DABF (fig. 4). It is obvious that in the first case the pseudohalide group forms bridge (weak), whereas in the last case, a bond through the nitrogen atom. In the compounds containing several amine molecules per metal, the ν_{CN} values suggest the occurrence of a coordinated anion, in spite of the

possibility to achieve six-coordination without its coordinative participation; this is in agreement with our previous observations[1] concerning the thermal behaviour of the benzidine complexes, which suggests that not all of the amine molecules occupy equivalent positions in the complex.

Regarding the vibrations ν_{CX} it is not possible to make correct assignments for thiocyanates, because of the superposing of their bands in the range 800 — 700 cm^{-1} with the rocking vibrations of the amines, but ν_{CSe} can be identified in certain cobalt compounds, being in accordance with the bonding suggested above.

The frequency of the δ_{NCX} vibrations can be localized in all compounds investigated, but the information they provide concerning the bonding of the anion is insignificant; the δ_{NCSe} bands occur, as expected, at lower wave numbers than those of the thiocyanate.

Concerning the spectroscopic behaviour of the coordinated amines, it is observed that some of their characteristic bands are shifted, generally towards lower wave numbers, as compared with the free (uncoordinated) amines (table 4; fig. 4). Thus, in the range of ν_{NH_2} frequencies, only two bands occur in the spectra of the complexes containing only one amine molecule per metal; this is the case with the complexes of *m,m'*- and *p,p'*- DABF and the bands are due to ν_{as} and ν_s (NH_2). This suggests that the amine functions are equivalent and coordinated, without the formation of a chelate ring.[15,16] Therefore, *m,m'*- and *p,p'*-DABF from bridges between two cobalt atoms. The occurrence of several bands (four) in the compounds containing *o,o'*-diaminobiphenyl is due to the existing distortions, first in the molecule of the amine, all the amino groups being coordinated; in other compounds this number of bands can be correlated with the presence of both coordinated amine groups and non-bonded (free) amine groups. The frequency of the stretching vibration $C_{aromatic} - N_{amin}$ in the range 1300 — 1200 cm^{-1} follows exactly the behaviour of the frequencies ν_{NH_2} in the range 3 400 — 3 200 cm^{-1}.

In other regions of the infrared spectra, characteristic of the amines, the occurrence of a remarkably strong band in the range 1 100 — 1 000cm^{-1} is observed. This band is absent in the infrared spectrum of the free (uncoordinated) amine and can be assigned to a skeleton vibration[32,33] or to a deformation band δ_{NH_2}, infrared inactive for the free amine, which becomes infrared active by coordination.

A somewhat higher value is generally noticed for the ν and δ bands in the spectra of cobalt compounds, as compared with the spectra of manganese compounds.[1] If we take into account that the bands in the range 1010 — 990 cm^{-1} belong to δ_s NH_2 vibrations, we find that their value is somewhat lower than in manganese compounds, which is in accordance with the shift of the symmetrical deformation bands by coordination.[34,35]

With the aid of electronic and infrared spectra and magnetic properties we proved that the complex thio- and selenocyanates of cobalt (II) with diamine derivatives, investigated in the present work, are monomeric compounds with the pseudohalide group coordinated in *trans* via the nitrogen atom (the compounds with *o,o'*-DABF) or polymeric compounds, with the anion and amine bonded as bridges (the compounds with *m,m'*- and *p,p'*-DABF, 2,7-DAF and *p,p'*-DADFN). In the compounds containing a larger number of organic ligands per metal atom, we established the coordination of the pseudohalide — probably in *trans* — and the nonequivalent bonding of the amines.

Co(II) CHELATES WITH 1-METHYL-2-CARBETHOXY-GLYOXALANIL-(1)-METHOXY-PHENYLHYDRAZONES-(2)

A. C. BANCIU and P. SPACU

Centre of Physical Chemistry, str. Dumbrava Roșie 23, Bucharest 9, Romania

Received November 28, 1973

From the three new compounds, derivatives of 1-methyl-2-carbethoxy-glyoxalanil-(1)-phenylhydrazone-(2), methoxy-substituted at the phenyl radical of the hydrazone group, the derivatives *para-* and *meta*-substituted are able to form chelates with the Co(II) ion, while the *ortho*-derivative cannot complex the metal ion. The elemental analysis data, IR and electronic spectra as well as the magnetic measurements show that both obtained complexes are tetracoordinate chelates, with high spin tetrahedral d^7 electronic configuration and with a noticeable but in each case different covalency degree of the metal-ligand bonds. The chelate with the *meta*-derivative has the mean nephelauxetic ratio $\beta \approx 0.76$, whereas the chelate with the *para*-derivative has $\beta \approx 0.71$, that is lower than in the well-known $CoCl_4^{2-}$ ion ($\beta \approx 0.73$).

The present paper carries further our research presented in notes [1,2] concerning the Co(II) complexes with ligands from the class of 1-methyl-2-carbethoxy-glyoxalanil-(1)-arylhydrazones-(2), dealing with the preparation of the three possible ligands from the group of 1-methyl-2-carbethoxy-glyoxalanil-(1)-methoxy-phenylhydrazones-(2), the synthesis of the two Co(II) complexes which can be obtained by means of these potentate ligands, and with the main chemical and physical properties (spectral and magnetic) of both chelates prepared . For this reason, besides the already mentioned [1] compound Ia, the present note describes the synthesis of the new compounds Ib and Ic

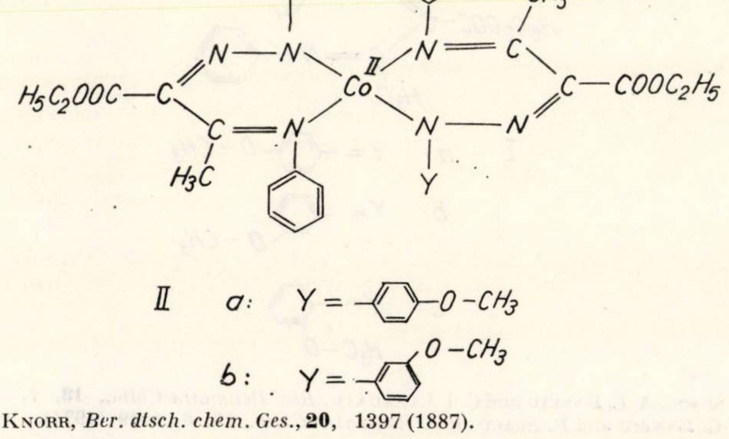
as well as the preparation attempts of the Co(II) complexes formed with these possible ligands.

EXPERIMENTAL

Reagents. Acetylacetic ester (Merck, reagent for synthesis, min. content 98%), aniline (tridistilled), *p*-anisidine (VEB-Berlin-Chemie, p.a.), *m*-anisidine (B.D.H., reagent for laboratory, boiling interval 243–248°), *o*-anisidine (B.D.H., reagent for laboratory, boiling interval 222–226°), anhydrous $NaCH_3COO$ (Austranal, p.a.), $CoCl_2 \cdot 6H_2O$ (Reactivul, Bucharest, p.a.), $NaNO_2$ (Reactivul, Bucharest, p.a.).

The preparation of the compounds Ia–c was similarly made with that already reported,[1,2] starting from acetylacetic ester. By its condensation with aniline the corresponding anil [3] was obtained, from which, through azoic coupling reactions with freshly prepared solutions of diazonium salts of the anisidines, instantly buffered with solid amounts of $NaCH_3COO$, until pH = 3, the compounds Ia–c were thereby obtained. The compounds Ia and Ib were separated as a solidified oil, which, dried on a porous plate and repeatedly washed with cooled methanol, could be brought to a dry form able to be recrystallized. After recrystallizations done from ethanol in the presence of active charcoal, the pure compounds Ia–c were obtained, but with scarce yields, of 18%, 14% and 38% from the theoretical ones, respectively. The syntheses of the complexes were made using these compounds but for their chemical analyses they were once more recrystallized and the products dried under vacuum on di-P_2O_5.

The preparation of the chelates. The attempts at obtaining the Co(II) chelates were performed in the same manner as earlier described, [1,2] under the refluxing conditions of the alcoholic solutions of the reagents, in the presence of small amounts of triethylamine (about 1 ccm), working with amounts of 1/100 m ligand and 1/200 m $CoCl_2 \cdot 6H_2O$ plus a little excess of 15% from this theoretical value of the last reagent, in order to ensure the completeness of the reaction. After cooling of the reaction mixture and the partial evaporation of the solvent, if the complexation took place, dark blue till black crystals of complex were separated, impurified with degradation products of the ligands, of obviously lighter colour than that of the used ligands. This heterogeneous mass was repeatedly washed with 3% acetic acid warmed at 40°, to remove completely the unreacted Co(II) ions, and then two recrystallizations were made from alcoholic solutions in the presence of active charcoal, followed by the drying of the purified complexes, under vacuum on di-P_2O_5. Using the compounds Ia and Ib, the following complexes IIa and IIb have been synthesized:



---

[3] L. Knorr, *Ber. dtsch. chem. Ges.*, **20**, 1397 (1887).

The attempts made under the same conditions in order to obtain the compound Ic have failed, after the cooling of the reaction mass, the ligand being separated practically as unreacted.

The elemental analyses of C, H and N were made by microcombustion. The Co amount was determined by disintegration with H_2SO_4 and H_2O_2 followed by precipitation as $Co(C_5H_5N)(SCN)_2$, according to. [4]

The adsorption spectra of the compounds were recorded with a VSU–2 Carl Zeiss (Jena) spectrophotometer on $0.5 \times 10^{-4} - 0.5 \times 10^{-3}$ m/l solutions in absolute ethanol and acetone.

The reflectance spectra of the chelates were recorded on a VSU-1 Carl Zeiss (Jena) spectrophotometer using MgO as standard.

The IR spectra of the compounds were recorded within 400–4 000 cm^{-1} range by means of a UR-10 Carl Zeiss (Jena) spectrophotometer, using KBr pellets.

The magnetic susceptibilities were measured at the room temperature, according to the Faraday method, using $Hg[Co(NCS)_4]$ as standard. The magnetic moments were calculated from $\mu = 2.828(\chi'_M \cdot T)^{1/2}$, where $\chi'_M = \chi_M - \chi_{dia}$ is the corrected molar susceptibility. In the case of both isomer chelates the diamagnetic correction was $\chi_{dia} = -375 \times 10^{-6}$ (c.g.s.u.).

RESULTS AND DISCUSSIONS

The analytical data for the compounds Ia–c have been systematized in table 1 and agree well with their formulation I.

Table 1

1-Methyl-2-carbethoxy-glyoxalanil-(1)-methoxy-phenylhydrazones-(2) (Compounds Ia – c)

Compounds I Y	C%		H%		N%		Colour	m.p. °C
	Calc.	Found	Calc.	Found	Calc.	Found		
$C_6H_4-p-OCH_3$	67.24	67.62	6.24	7.00	12.38	12.79	orange	88–90.5
$C_6H_4-m-OCH_3$	67.24	67.13	6.24	6.80	12.38	12.65	yellow-orange	86.5–89
$C_6H_4-o-OCH_3$	67.24	67.89	6.24	6.53	12.38	12.71	yellow	89–91.5

The analytical data for the two obtained Co(II) complexes are given in table 2. These data and the IR spectral results allow us to ascribe the chelatic structural formulas IIa–b for these complexes.

The fact that the compound Ic behaves differently than the compound Ia–b, being deprived of the specific properties of a ligand, could be explained by the relevant steric hindrances due to the OCH_3 substituent when attached in the *ortho* position to the phenyl radical of the hydrazonic group. A strong steric hindrance which hampered the chelation has been also observed with the CH_3 substituent attached in the *ortho* position to the phenyl radical of the hydrazonic group. [2]

The IR spectra of both compounds having ligand properties, Ia and Ib, as well as of their corresponding Co(II) chelates are summarized in table 3.

Table 2

Co(II) chelates. Analytical data

Chelate	Co%		C%		H%		N%		m.p. °C
	Calc.	Found	Calc.	Found	Calc.	Found	Calc.	Found	
IIa	8.01	7.52	62.04	62.11	5.48	5.88	11.42	11.64	149–152
IIb	8.01	7.73	62.04	62.27	5.48	5.90	11.42	11.83	134–136

One may observe obvious differences between the IR spectra of the free ligands and of the corresponding chelates in the range comprised within 1290 –1370 cm^{-1}. For the two free ligands there appear bands of mean intensity. In the case of the chelates, one may observe the appearance of a very broad band with maxima placed at 1290, 1310, 1340, and 1370 cm^{-1}, which are the most intense bands from the whole spectrum of the chelates. One knows that in the domain between 1280 and 1360 cm^{-1} there is an intense band in the case of the secondary aromatic amines (C_6H_5-NH-) and almost in the same region (1310–1360 cm^{-1}) an intense band in the case of the tertiary aromatic amines ($C_6H_5-N=$), both bands being due to the C–N stretching vibration inside these groups.[5] According to the structural formulations assumed for the Co(II) chelates, changes should be expected in the IR spectra in this region, caused by the coordination of the donor nitrogen atom from the hydrazonic group, which is straightforwardly attached to the phenyl radical. The fact that the intense band at 1700 cm^{-1}, which may be undoubtedly ascribed[5] to the esteric group ($COOC_2H_5$), appears as unshifted in the spectra of the two chelates shows that this group does not participate in coordination, an alternative which could not be *a priori* excluded. If the esteric group coordination took place, its proper band would have been strongly moved,[5] at approximately 1635 –1665 cm^{-1}, which obviously is not the case. One may conclude that the IR data are in a good agreement with the structural formulas IIa and IIb for the Co(II) chelates.

Electronic spectra and magnetic properties

The only small shifts of the bands in the reflectance spectra recorded in the solid state of the compounds compared with those in the absorption spectra of the chelates recorded in solutions (absolute ethanol and acetone) show that the chelates dissolved in the above-mentioned solvents did not lead to important structural modifications (dissociation, etc.) the same molecular species being therefore present in both solution and solid state.

The electronic spectra of the two chelates recorded on acetonic solutions of $0.5 \times 10^{-4} - 0.5 \times 10^{-3}$ m/l are plotted in figure 1. The vertical lines in this figure show the position of the absorption maximum of the bands

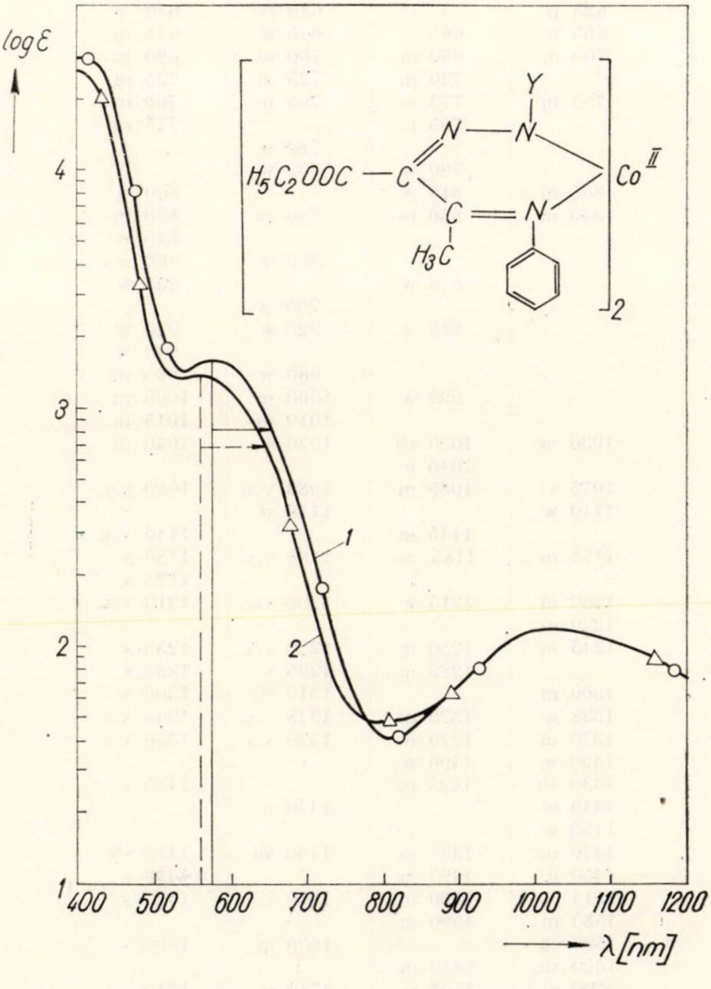

Fig. 1. – The electronic spectra of the Co(II) chelates. *1*, chelate IIa : $Y = p-CH_3O-C_6H_4$; *2*, chelate IIb : $Y = m-CH_3O-C_6H_4$.

occurring approximately at 570 nm, and the horizontal arrows show the half of the half-widths of these bands. One may observe that even though the spectra are almost similar and practically coincide in the near IR region, there are obvious differences in the visible range, especially the bathocromic shift of about 20 nm in the spectrum of the chelate IIa (with the OCH_3 substituent placed in the *para* position at the phenyl radical of the hydrazonic group) compared with that of the chelate IIb (with the same substituent but in the *meta* position). These differences occurring in the spectra of the chelates are much more obvious than those yet detectable but very small, observed with chelates of type II, in the case of the CH_3 substituent.[2]

The bands placed approximately at 560 and 1020 nm could be ascribed to the *d*–*d* transitions proper to a high spin tetrahedral d^7 electronic configuration. The energetic expressions for the spin-allowed d–d transitions for d^7 (T_d) obtained in a weak field coupling are as follows[6–8]:

$$ {}^4A_2(e^4\,t_2^3) \rightarrow {}^4T_2(e^3\,t_2^4) \qquad \Delta $$

$$ {}^4A_2(e^4\,t_2^3) \rightarrow {}^4T_1^{a}(e^3\,t_2^4) \quad 1.5\,\Delta + 7.5\,B - Q $$

$$ {}^4A_2(e^4\,t_2^3) \rightarrow {}^4T_1^{b}(e^3\,t_2^4) \quad 1.5\,\Delta + 7.5\,B + Q $$

where :

$$ Q = \frac{1}{2}\,[(0.6\,\Delta - 15\,\mathrm{B})^2 + 0.64\,\Delta^2]^{1/2}, $$

Δ is the orbital splitting parameter (the energetic separation between t_2 and e subshells), and *B* is the Racah parameter for the interelectronic repulsion energies ($B_{\mathrm{Co(II)}} = 980\ \mathrm{cm}^{-1}$). The energy of the first transition is just equal to the parameter Δ, and taking into account that $\Delta_{T_d} = 4/9\ \Delta_{O_h}$ and $\Delta_{O_h} = 10{,}000 - 15{,}000\ \mathrm{cm}^{-1}$ (relationship also valid in the framework of LCAOMO theory[9]), it results that this transition must occur in infrared, beyond the measuring possibility of the used instrument.

The two absorption bands occurring in the electronic spectra should be assigned to the other remaining d–d transitions, as follows :

$$ \nu_2\,({}^4A_2 \rightarrow {}^4T_1^{a}) = 9{,}800\ \mathrm{cm}^{-1} \text{ for both chelates II a–b} $$

$$ \nu_3\,({}^4A_2 \rightarrow {}^4T_1^{b}) = 17{,}390\ \mathrm{cm}^{-1} \text{ for the chelate IIa} $$

$$ = 17{,}860\ \mathrm{cm}^{-1} \text{ for the chelate IIb} $$

---

[6] A. B. P. Lever, "Inorganic Electronic Spectroscopy", Elsevier Publishing Company, Amsterdam–London–New York, 1968, chap. 8–9.

[7] Y. Tanabe and S. Sugano, *J. Phys. Soc. Japan*, **9**, 753 (1954).

[8] E. König, *Struct. and Bonding*, **9**, 175 (1971).

[9] H. H. Schmidtke, *Z. Naturforsch.*, **19a**, 1502 (1964).

Solving the energetic expressions for these transitions, the following values are obtained:

$$\Delta = 5{,}580\ \mathrm{cm}^{-1} \text{ for the chelate IIa}$$

$$= 5{,}540\ \mathrm{cm}^{-1} \text{ for the chelate IIb}$$

and with these values

$$B = 698\ \mathrm{cm}^{-1} \text{ for the chelate IIa}$$

$$= 736\ \mathrm{cm}^{-1} \text{ for the chelate IIb}$$

and finally

$$\beta = \frac{B}{B_0} = 0.71 \text{ for the chelate IIa}$$

$$= 0.75 \text{ for the chelate IIb.}$$

The Δ and *B* values thus obtained reproduce the absolute values of the absorption maxima as well as the difference between their wavenumbers.

In order to check how much reproducible are the spectra of the chelates as well as the spectrally estimated parameters, the electronic spectra have been also recorded on solutions of absolute ethanol. The band positions, their intensities and the Δ, *B* and β values calculated for these bands are collected in table 4.

Table 4

Electronic spectra recorded on solutions of acetone and abs. ethanol ($c = 0.5 \times 10^{-4} - 0.5 \times 10^{-3}$ m/l) and the Δ, B and β values of the Co(II) chelates

Chelate type II	Solvent	ν_3 nm	ν_3 cm^{-1}	ε_3 max $\times 10^3$	ν_2 nm	ν_2 cm^{-1}	ε_2 max $\times 10^2$	Δ cm^{-1}	B cm^{-1}	β

	ethanol	575	17,390	1.432	1,020	9,800	1.066	5,580	698	0.71
$Y = m-CH_3O-C_6H_4$	acetone	560	17,860	1.380	1,020	9,800	1.160	5,540	736	0.75
	ethanol	560	17,860	1.268	1,030	9,710	1.080	5,480	743	0.76

One observes that in the case of the chelate IIa the solvent effect is reduced to a hyperchromic shift of both absorption maxima ν_3 and ν_2, when the solvent is changed, i.e. absolute ethanol instead of acetone. The positions of the absorption maxima remain practically unchanged, and so do the Δ, *B* and β values.

In the case of the chelate IIb, besides the above-mentioned hyperchromic shift when the used solvent is changed, acetone being replaced by absolute ethanol, a shift of about 10 nm (cca 100 cm^{-1}) of the maximum position of the band ν_2 takes place, which causes a slight modification, of about

10 cm^{-1}, in the B value and finally modifies with a figure of the second decimal the nephelauxetic ratio β (from 0.76 to 0.75). In an earlier paper [2] we have already shown that such a change in the β ratio constitutes the expected recording error which may appear not only when the used solvent is changed, but even for the same solvent, due to the lack of precision in the establishing of the assumed exact positions of the absorption maxima (determination error up to ± 200 cm^{-1}).

The change in the nephelauxetic ratio β value with 5 centesimal units (from 0.76 for the chelate IIb to 0.71 for the chelate IIa) clearly overpasses the experimental errors of measurements and shows a real increasing in the covalency degree of the metal-ligand bonds for the chelate IIa, when compared with IIb.

This result is not surprising. The fact that the OCH_3 substituent placed in the *meta* position at the phenyl radical of the hydrazonic group does not practically change the covalency degree of the complex against that of the chelate having only unsubstituted phenyl radicals attached to the donor nitrogen atoms is explained by that the OCH_3 substituent placed in the *meta* position does influence only through a feeble inductive effect [10] the electronic density of the substituted benzenic ring, as well as that of the donor nitrogen atoms directly bound to the aryl group. For these reasons the nephelauxetic ratio β rests practically unchanged (0.75 — 0.77).

In the *para* position the OCH_3 substituent exerts, however, a strong mesomeric effect, [10] leading to a marked increase in the electronic density values of the nitrogen donor atoms directly bound to the aryl group, and thence to the increase in the covalency degree value (lowering of the β ratio from 0.76 to 0.71).

The β ratio value in the case of the chelate IIa shows that its covalency degree is higher than that of the well-known $CoCl_4^{2-}$ion ($\beta = 0.73$) and practically equal to that of the $CoBr_4^{2-}$ ion ($\beta \approx 0.71$).

For a high spin tetrahedral d^7 configuration the magnetic moment may be calculated from [11,12]

$$\mu = \left(\mu_s - 15.59\frac{\lambda}{\Delta}\right) BM$$

where $\lambda = - 178$ cm^{-1} is the spin-orbit coupling constant, Δ the orbital splitting parameter, which in the case of both Co(II) chelates has been spectrally determined (see table 4), and $\mu_s = 3.89$ *BM* is the spin-only contribution to the magnetic moment value. Using the found Δ values (table 4) one finds that the quantity $(-15.59\lambda/\Delta)$, which is the orbital contribution to the magnetic moment value, is for both chelates of about 0.50 BM, so that their calculated magnetic moments are of 4.39 BM.

[12] F. A. Cotton and M. Goodgame, *J. Amer. Chem. Soc.*, **83**, 1777 (1961).

Experimentally, one finds:

$$\lambda = 4.35 \pm 0.05 \ BM \text{ for the chelate IIa}$$

$$\mu = 4.41 \pm 0.05 \ BM \text{ for the chelate IIb}$$

which are in good agreement with those spectrally determined.

The agreement between the spectral and magnetic properties allows us to assign a preponderant tetrahedral symmetry for the Co(II)–nitrogen bonds and a high spin electron distribution of the central metal ion in the case of both studied Co(II) chelates.

THE $PdCl_2$-INDUCED REARRANGEMENT OF DIBENZOBULLVALENE INTO DIBENZO [*g,h*] BICYCLO [4.3.2.] DECA-2,4,7,9-TETRAENE

M. BANCIU, M. ELIAN, C. DRĂGHICI and ECATERINA CIORĂNESCU

Organic Chemistry Research Center, Spl. Independenţei 202-B, Bucharest 15, Romania

Received February 4, 1974

By treating dibenzobullvalene (**1**) or dibenzo [*g, h*] bicyclo [4.2.2] deca-2,4,7,9-tetraene (**2**) with $PdCl_2 \cdot (C_6H_5CN)_2$, the same complex **3** of the $(C_{18}H_{14})_2 \cdot (PdCl_2)_3$-type was obtained; the decomposition with aqueous pyridine led to the diene **2**. Similar results were obtained working with deuterated hydrocarbons (10-*d*-**1** and 3-*d*-**2**). A mechanism for this valence isomerization is proposed which is also consistent with the behaviour of *d*-compounds.

In a previous paper [1] the synthesis, the thermal and photochemical rearrangements of dibenzobullvalene and of some other dibenzo $(CH)_{10}$-hydrocarbons have been reported.

The metal-induced skeletal rearrangements of bullvalene were extensively investigated in the last years.[2] The recent report of Vedejs and co-workers[3] about homotropylidene-palladium dichloride complexes prompted us to report our results with dibenzobullvalene.

RESULTS AND DISCUSSIONS

By treating dibenzobullvalene (**1**)[1] with bis (benzonitrile)palladium dichloride in anhydrous benzene at 70° for 3 hrs, a reddish-brown complex (m.p. $>350°$) precipitates in good yield, with the expected displacement of benzonitrile. The elemental analysis of the complex indicates the composition $(C_{18}H_{14})_2. (PdCl_2)_3$. The same complex was invariably obtained with different molar ratios of reactants, between 1-2 moles $PdCl_2 (C_6H_5CN)_2$ per mole of **1**.

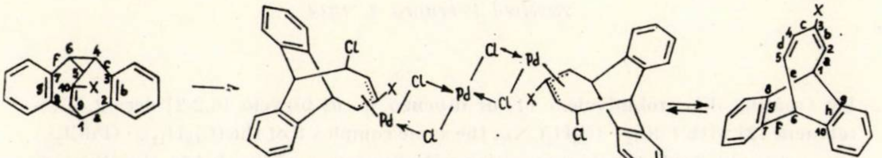
[3] E. Vedejs, M. F. Salomon and P. D. Weeks, *J. Amer. Chem. Soc.*, **95**, 6770 (1973).

On decomposition of this complex with pyridine-water solution at room temperature, dibenzo[*g, h*]bicyclo[4.2.2]deca-2,4,7,9-tetraene (**2**) was isolated in 75% yield and more than 92% purity.

The same complex (IR spectrum, elemental analysis) precipitates in nearly quantitative yield by treatment of the diene **2** with bis(benzonitrile)palladium dichloride at room temperature for 24 hrs.

Unfortunately, the insolubility of the complex renders impossible its characterization through NMR spectrum or by borohydride reduction. Nevertheless, taking into account the composition and the easier formation of the complex when **2** was used as starting material (as compared to **1**), the structure **3** is suggested :



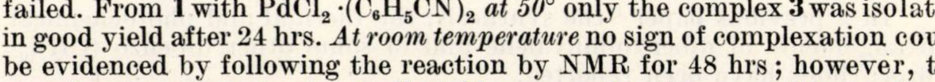
1 (X=H)
d-1 (X=D)

3 (X=H)
d-3 (X=D)

2 (X=D)
d-2 (X=D)

Attempts to obtain a complex having dibenzobullvalene as ligand failed. From **1** with $PdCl_2 \cdot (C_6H_5CN)_2$ *at 50°* only the complex **3** was isolated in good yield after 24 hrs. *At room temperature* no sign of complexation could be evidenced by following the reaction by NMR for 48 hrs ; however, the complex 3 precipitates in small yield even under these conditions after a week.

In order to obtain additional information concerning the valence isomerization, the same reactions were performed with deuterated compounds. The synthesis of *d*-compounds was realized by reduction of the ketone **4**[1] with $LiAlD_4$:



4

5

d-2

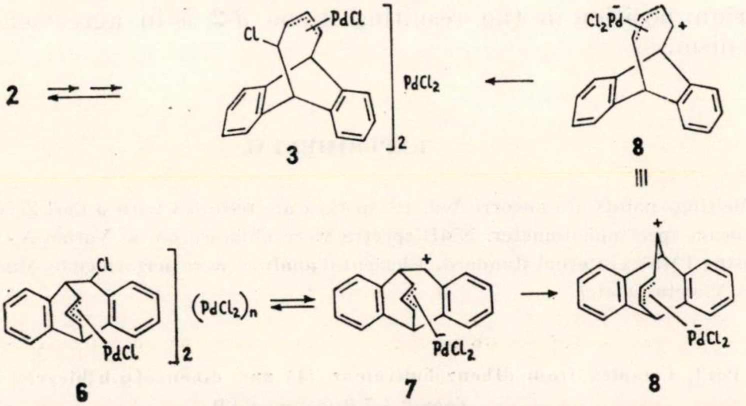
d-1.

The *d*-alcohol **5** (m.p. 115 — 116°) obtained in a good yield was dehydrated, affording a mixture of alkenes. From this mixture the pure *d*-**2** (m.p. 177—179°) was separated through recrystallization from methanol, while *d* - **1** (m.p. 109—115°) was isolated in 85% purity (the only impurity being *d* - **2**) through column chromatography on neutral alumina.

The NMR spectra (see Experimental) of the compounds 10-*d*-**5**, 10-*d*-**1** and 3-*d*-**2** are in agreement with the position of deuterium label.

By treating the *d*-**1** or *d*-**2** hydrocarbon with $PdCl_2 \cdot (C_6H_5CN)_2$ under the same conditions as described for **1** and for **2** respectively, a complex with the same composition $(d\text{-alkene})_2 \cdot (PdCl_2)_3$ was obtained. After pyridine-water decomposition of this complex only the deuterated hydrocarbon *d*-**2** was isolated.*

As in other cases,[4] it is difficult to know exactly the stepwise process by which the rearranged structure is attained. Nevertheless the following scheme, which is in agreement with the results of experiments using deuterated compounds, could be suggested :



The complex **3**, obtained from the diene **2** and $PdCl_2 \cdot (C_6H_5CN)_2$ is very probably of the π-allylic type. The formation of π-allylic complexes from 1,3-dienes is generally accepted and supported by many examples.[5] However, the same complex **3** resulted also from dibenzobullvalene (**1**), evidently after skeletal rearrangement.

For the first intermediate which occurs on treatment of dibenzobullvalene with $PdCl_2 \cdot (C_6H_5CN)_2$, the structure **6** could be admitted. Formation of π-allylic complexes of this type from vinylcyclopropanes is also known.[4,5,6] An analogous structure has been proposed by Vedejs[3] for the complexes of bullvalene and benzobullvalene (by analogy with the more soluble complex of dihydrobullvalene which could be characterized spectrally and by usual reactions).

---

* The converse valence isomerization **2**→**1** reported to occur photochemically[1] was also performed with d-**2** under the same conditions ; in the resulted dibenzobullvalene the label was equally distributed in 5- and 10-positions.

[6] D. T. Shono, T. Yoshimura, Y. Matsumura and R. Oda, *J. Org. Chem.*, **33**, 876 (1968) ; R. Aumann, *Angew. Chem.*, **83**, 175, 176, 177 (1971) ; A. Eisenstadt, *Tetrahedron Letters*, **1972**, 2005 ; R. M. Moriarty, C. L. Yeh and R. Srinivasan, *Tetrahedron Letters*, **1972**, 5325.

In dibenzobicyclic systems, having a benzylic leaving group, rearrangements accompanied by ring contraction occur very easily[7]; this could account for the failure to isolate a complex of the **6**-type which could regenerate dibenzobullvalene on decomposition. The skeletal rearrangement leading to the complex **3** fits pretty well with an ionic mechanism. The conversion of **6** to **8** could occur through a benzylic intermediate **7** which undergoes a phenyl migration or by displacement of the chlorine group assisted by the aromatic ring from the β-position. The homobenzylic intermediate **8** leads then to the complex **3** (much more stable than **6**). The deuterium position in the resulting diene *d*-**2** is in agreement with this mechanism.

EXPERIMENTAL

Melting points are uncorrected. IR spectra are recorded with a Carl Zeiss-Jena UR 20 double beam spectrophotometer. NMR spectra were obtained on a Varian A - 60 A spectrometer using TMS as internal standard. Elemental analyses were performed by Miss Elvira Sliam and Mrs Violeta Daniel.

$PdCl_2$ Complex from dibenzobullvalene (1) and dibenzo[g,h]bicyclo[4.2.2]-deca-2,4,7,9-tetraene (2)

A filtered solution of bis (benzonitrile) palladium dichloride[8] (175 mg; 0.45 mmole) in anhydrous benzene (8 ml) was dropped during 30 min over a solution of dibenzobullvalene (**1**)[1] (70 mg; 0.3 mmole) in anhydrous benzene (3 ml). The solution was heated to 70° for 3 hrs; then the precipitated reddish-brown complex was filtered from the cooled reaction mixture. The complex was triturated with petroleum ether (removal of benzonitrile traces), filtered and dried. The complex **3**, m.p.$>$350°, was obtained, 92 mg (62% yield). Found: C, 43.28; H, 3.22; Pd, 33.54; Cl, 20.04. $(C_{18}H_{14})_2 \cdot (PdCl_2)_3$ requires: C, 43.54; H, 2.84; Pd, 32.21 and Cl, 21.41%.

IR spectrum (Nujol, cm^{-1}): 434 m, 448 m, 569 m, 588 m, 620 m, 669 s, 698 s, 728 vs, 751 s, 779 m, 951 m and 1119 w.

The same complex was obtained working at 50° for 24 hrs (precipitation begins in less than 1 hr). At room temperature the NMR spectrum of this reaction mixture remained unchanged for 48 hrs; after a week the complex **3** precipitates in about 10% yield. When different molar ratios of dibenzobullvalene to bis(benzonitrile)palladium dichloride were used (1 : 1 or 1 : 2) the same complex as above was always obtained.

[8] M. S. Kharasch, R. C. Seyler and F. R. Mayo, *J. Amer. Chem. Soc.*, **60**, 882 (1938).

By treating a solution of dibenzo [*g*, *h*] bicyclo [4.2.2] deca-2, 4, 7, 9-tetraene (**2**)[1] (45 mg ; 0.195 mmole) in anhydrous benzene (3 ml) with a filtered solution of bis (benzonitrile) paladium dichloride (76 mg ; 0.198 mmole) in anhydrous benzene (7 ml) *at room temperature*, a reddish-brown precipitate sedimentates in 24 hrs, after which time the supernatant solution becomes practically colourless. Filtration and washing of the precipitate with petroleum ether afforded the complex **3**, 55 mg (85 % yield, calculated on bis(benzonitrille)palladium dichloride). This complex was found to be identical (by elemental analysis and IR spectrum) with that obtained from dibenzobullvalene. The combined filtrates afforded on evaporation about 10 mg of unreacted diene **2**. The same complex **3** was obtained using 2 — 3 equivalents of bis (benzonitrile)palladium dichloride for 1 equivalent of **2** ; in this case from the evaporated filtrates a solid was formed (on petroleum ether addition) whose IR spectrum was identical with that of authentic bis-(benzonitrile)palladium dichloride.

From reaction of **2** and Na_2PdCl_4 in methanol an isoluble complex resulted which was not characterized.

$PdCl_2$ Complex from 3-d-dibenzo[g, h]bicyclo[4.2.2]deca -2,4,7,9-tetraene (d-2) and 10-d-dibenzobullvalene (d-1)

From *d* - **2** (see later) and bis(benzonitrile)palladium dichloride (in 2 : 3 molar ratio) as described above for **2**, the deuterated $PdCl_2$-complex precipitated and could be separated in 85 % yield, by working at room temperature. Found : C, 43.96 ; H, 3.21 ; Pd, 33.04 ; Cl, 19.84. $(C_{18}H_{13}D)_2 \cdot (PdCl_2)_3$ requires : C, 43.44 ; H, 3.03 ; Pd, 32,16 and Cl, 21.37 %.

IR spectrum (Nujol, cm^{-1}) : 441 m, 531 w, 546 m, 575 m, 589 m, 621 m, 671 s, 685 s, 731 vs, 751 s, 778 m, 940 w and 1114 w.

In the case of deuterated dibenzobullvalene (*d* - **1**) (see later) the reaction mixture (the same quantities as described above for **1** being used) was initially maintained for 24 hrs at room temperature, when a little amount (10 mg) of complex from the *d* - **2** (existing as contaminant of *d* - **1** ; see later) precipitates. The clear supernatant liquid was then heated for 3 hrs at 70°, when the same complex (elemental analysis, IR spectrum) as from *d* - **2** was obtained (86mg ; 58 %).

Experiments using alkene (*d* - **1** or *d* - **2**) : $PdCl_2 \cdot (C_6H_5CN)_2$ molar rations of 1 : 1 or 1 : 2 afforded always the same complex ; the unreacted component (alkene or bis (benzonitrile)-palladium dichloride) was recovered.

Decomposition of the $PdCl_2$ complexes 3 and d - 3

A pyridine : water 1 : 2 solution (7.5 ml) was added with stirring at room temperature over the $PdCl_2$ complex **3** (or *d* - **3**) 60 mg. In a few minutes the complex was decomposed (decoloration) and a white microcrystalline product was formed. The reaction mixture was ether extracted, the extract was washed with water, dil. HCl, again with water, then dried and evaporated. The crystalline product obtained (19.2 mg ; 70 %) was (as indicated by its NMR spectrum) *dibenzo* [*g*, *h*] *bicyclo* [*4.2.2*] *deca-2, 4, 7, 9-tetraene* (**2**)[1] (or *d* - **2**, respectively). The purity of these products checked on v.p.c. (20 % Silicone OV7 on Chromosorb P columns, 220°) was more than 92 %.

10-d-Dibenzo [b,g] tricyclo [3.3.2.0.^{4,6}] deca-2,7-dien-10-ol 5

Over a cooled stirred suspension of $LiAlD_4$ (0.3 g ; 7.15 mmoles) in anhydrous ether (25ml), a suspension of dibenzo *[b, g]* tricyclo [3.3.2.0 ^{4,6}] deca-2,7-dien-10-one (**4**)^1 (2.2 g ; 9 mmoles) in anhydrous ether (200 ml) was dropped during 1 hr. The reaction mixture was then refluxed for 7 hrs and left overnight. The usual work-up afforded 2.1 g (94 %) *10-d-dibenzo[b, g]tricyclo-[3.3.2.0.^{4,6}] deca-2,7-dien-10-ol* (**5**) m.p. 115–116° (methanol).

IR spectrum (KBr ; cm^{-1}) : 756 vs, 1065 s, 1075 s, 1493 m, 2105 w, 2155 w, 2863 w, 2926 m, 3013 m, 3058 m and 3100–3450 ms.

NMR spectrum ($CDCl_3$; δppm) : 6.95–7.50 (m ; 8H ; H_{arom}) ; 3.71 (t ; 1H ; J = 5.5Hz ; H_1) ; 1.9–2.7 (m ; 6H ; $H_{4,5,6,9,OH}$).

3-d-Dibenzo[g, h] bicyclo[4. 2.2] deca 2, 4, 7, 9-tetraene (d-2) and 10-d-dibenzobullvalene (d-1) from the d-alcohol 5

An intimate mixture of *d*-alcohol **5** (**2**g ; 8 mmoles) and H_3BO_3 (1.6 g ; 25.7 mmoles) was sublimated in 4 equal portions at 180°/1 mm Hg (every portion required approximately 1 hr for sublimation). The partially crystallized products were combined (0.6 g ; 33 %) then recrystallized from methanol affording 0.17 g of crude *d*-**2** (m.p. 165 – 172°). After a new recrystallization from ethanol 0.12 g pure *3-d-dibenzo[g, h]bicyclo [4.2.2.]deca-2,4,7,9-tetraene* (*d*-**2**) was obtained, m.p. 177–179°.

IR spectrum (CS_2 ; CCl_4 ; cm^{-1}) : 550 ms, 570 ms, 648 s, 744 vs, 880 m, 1369 s, 1480 m, 2234 vw, 2924 m, 3024 s and 3070 m.

NMR spectrum ($CDCl_3$, δ ppm) : 7.0–7.3 (m ; 8H ; H_{arom}) ; 6.1–6.7 (m ; 2H ; $H_{2;5}$) ; 5.45 (d ; *J* = 12.5 Hz ; 1H ; H_4) ; 4.47 (d ; J = 9.5 Hz ; 2H ; $H_{1;6}$).

The combined filtrates from the above recrystallizations were evaporated *in vacuo,* and the partially crystallized residue (0.4 g) was chromatographed on a short neutral alumina column which was eluted with petroleum ether (b.p. 30–40°). The first eluates (75 ml) afforded on evaporation an uncrystallizable oil (0.2 g), a mixture of *d*-**2** and *d*-**1**. The following eluates (200 ml) afforded on evaporation white crystals (0.17)g) of crude *10-d-dibenzobullvalene* (*d*-**1**) which, after washing with cold ethanol, showed a m.p. of 109–115°. The v.p.c. analysis (20 % Silicone OV 7 on Chromosorb P columns, 220°) of this product indicated a purity of 85 % *d*-**1**, the single contaminant being *d*-**2**.

IR spectrum (CS_2 ; CCl_4 ; cm^{-1}) : 754 vs, 773 s, 905 m, 1370 s, 1494 m, 2252 vw, 2850 vw, 2926 m, 3026 s and 3066 m.

NMR spectrum (CCl_4, δ ppm) : 6.9–7.2 (m ; 8H ; H_{arom}) ; 5.95 (d, J = 9.2 Hz ; 1H ; H_9) ; 3.68 (d ; J = 9.2 Hz ; 1H ; H_1) ; 2.1–2.95 (A_2B-type spectrum ; 3H ; $H_{4,5,6}$).

CHEMICAL GRAPHS. XXI[1]

VALENCE ISOMERS OF BENZOANNULENES

A. T. BALABAN
Institute of Atomic Physics, P.O.B. 35, Bucharest, Romania

Received February 28, 1974

Starting from tables of cubic multigraphs corresponding to the formulas of valence isomers of annulenes, two procedures are presented for obtaining the formulas of valence isomers of monobenzoannulenes (or polybenzoannulenes, noted by [b] benzo-[n]annulenes): (i) the trivial one, selecting from the table of cubic multigraphs with n + 4b points those graphs which have b 1,3-cyclohexadienic rings, and (ii) a direct procedure based on the table of cubic multigraphs with n points and at least b double bonds, replacing b double bonds by condensed benzenoid rings.

INTRODUCTION

The enumeration of valence isomers * of [n]annulenes [3,4] was possible starting from the observation that their formulas are cubic (trivalent) multigraphs with n points, where a point corresponds to a CH group and a line to a covalent band. Hence the enumeration of all such graphs was at the same time the enumeration of valence isomers of annulenes. However, this was an unsolved problem of graph theory, [5] so that an algorithm based on general graphs had to be found,[6] enabling the construction of complete tables for cubic multigraphs with 4 — 10 points, [3] and later with 12 points. [4] Since chemically only molecules corresponding to planar graphs can be synthesized, the table for cubic multigraphs with 12 points was restricted to planar ones in order to reduce the number of formulas and to provide a table of significant isomers.

In the meantime, a mathematical procedure for counting graphs and multigraphs has been found, [7,8] but it is not amenable to numerical computation and even less to providing the pictures of the graphs.

---

* The definiton of valence isomeric formulas is : these formulas correspond to connected graphs having the same partition of degrees of their vertices. [2]

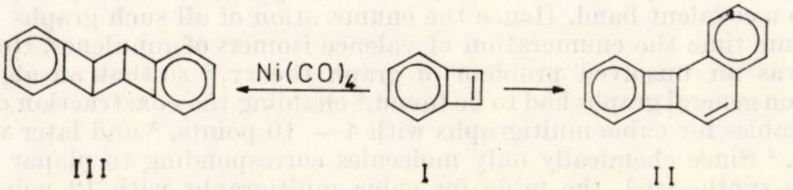
[8] F. Harary and A. R. Palmer, "Graphical Enumeration", Academic Press, New York, 1973.

Benzoderivatives of annulenes are hydrocarbons possessing an *ortho*-fused benzenoid ring condensed with the annulene, and can be theoretically derived by replacing a double bond with such a benzenoid ring. If b benzenoid rings are thus condensed to an [n]annulene, we obtain a polybenzo-[n]annulene which will be denoted by [b]benzo-[n]annulene.

Thus, a valence isomer of an [n]annulene is $(CH)_n$, but its [b]benzoderivative has b pairs of adjacent CH group replaced by b *ortho*-phenylene groups C_6H_4. Therefore the molecular formula of a [b]benzo-[n]annulene or of any of its valence isomers is $C_{n+4b}H_{n+2b}$; these compounds possess 2b quaternary carbon atoms and n + 2b CH groups.

In [b]benzo-[n]annulenes, we have necessarily $1 \leqslant b \leqslant n/2$. Starting from a valence isomer of an [n]annulene $(CH)_n$ and conserving the number of carbon atoms, one can obtain by theoretical stepwise abstractions of two hydrogen atoms, valence isomers of mono-benzo-[n — 4] annulene C_nH_{2n-2}, then of dibenzo-[n — 8] annulene C_nH_{2n-4}, etc., arriving in the end to valence isomers of $\left[\left\langle \frac{n}{6} \right\rangle\right]$ benzo-$\left[n - 4\left\langle \frac{n}{6} \right\rangle\right]$ annulene $C_nH_{n-2}\left\langle \frac{n}{6} \right\rangle$, where $\left\langle \frac{n}{6} \right\rangle$ is the integer part of n/6. The ratio of carbon *versus* hydrogen atoms in a [b]benzo-[n]annulene valence isomer being denoted by x, $\left(\frac{n+4b}{n+2b} = x\right)$, we have $1 < x \leqslant 1.5$. The highest value of x, i.e. 1.5, is attained in polyphenylenes $(C_6H_4)_{n/2}$, i.e. in $\left[\frac{n}{2}\right]$ benzo-[n] annulenes.



III I II

The simplest example of a monobenzoannulene* is benzocyclobutadiene I [9,**] an elusive compound which dimerizes spontan-

---

[*] The smallest annulene is considered to be [4] annulene. Theoretically, one could consider acetylene to be the smallest annulene, as in ref. 6, but for the present discussion this would be too far-stretched, since one would have to devise a convention as to how many "double bonds" there are in acetylene.

[**] The nomenclature in this paper follows the traditional usage and is at variance with the *Chemical Abstracts* nomenclature, adopted also by Beilstein's Dritter Ergänzungswerk. According to *Chem. Abstr.* Index Guide Introduction **76**, § 151 (1972), "cyclooctene as part of a fused system is not meant to imply the presence of a *single* bond; instead, saturated carbon atoms are indicated by 'hydro' prefixes". We shall, however, use [b]benzocyclooctatetraene instead of [b]benzocyclooctene, benzocyclobutadiene instead of benzocyclobutene, and dibenzocyclobutadiene instead of dibenzocyclobutene, in such names.

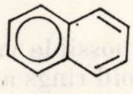
Cook), Butterworths, London, **3**, 44 (1955); "Non-Benzenoid Aromatic Compounds" (ed. D. Ginsburg), Interscience, New York, 1959; J. W. Barton, in "Nonbenzenoid Aromatics" (ed. J. P. Snyder), Academic Press, New York, 1969.

eously to give II,[10] or in the presence of $Ni(CO)_4$ catalyst to give III.[11]

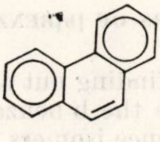
Naphthalene IV is a monobenzo-[6]annulene, phenanthrene V and anthracene VI are dibenzo-[6] annulenes, and triphenylene VII is tribenzo-[6]annulene. It is apparent that all polybenzoannulenes are *cata*-condensed systems.[12]

Whereas naphthalene, phenanthrene and triphenylene can be obtained from the Kekulé formula of benzene by replacing one or more double bonds with condensed benzenoid rings, anthracene cannot, hence it is somewhat different from the other ones; we will call it an *o*-quinonoid benzoderivative.*

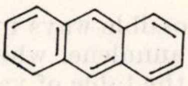
We shall inscribe in benzenoid rings a circle according to the usual convention when the structure is not *o*-quinonoid, but shall write double bond structures in *o*-quinonoid derivatives, as exemplified by formulas IV – VI, throughout the present paper.



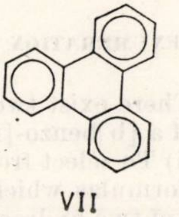
IV



V



VI



VII

No special significance of the type proposed by Clar[13] will be attached to the presence or absence of inscribed circles, this being only a convention to discriminate *o*-quinonoid formulas (as will be shown below, an asterisk will serve the same purpose in notations). The structural condition for the existence of *o*-quinonoid benzoderivatives is to have an initial structure VIII with at least two conjugated double bonds. Then, in addition to the normal mono- and polybenzoderivatives IX and X, *o*-quinonoid benzoderivatives XI are possible.

---

* The name *o*-xylylenoid would be more correct, but is less convenient.

X IX VIII XI

In the following discussion only constitutional (topological) isomerism will be considered, ignoring stereoisomerism. The formulas are drawn so as to avoid crossing lines, emphasizing that all graphs are planar, rather than so as to mimic the geometry of the molecules.

ENUMERATION OF VALENCE ISOMERS OF [b]BENZO-[n]ANNULENES

There exist two possible ways in finding out all possible valence isomers of a [b]benzo-[n] annulene, where the b benzenoid rings are intact :

(i) To select from the table of valence isomers of [n + 4b] annulenes those formulas which have b condensed 1,3-cyclohexadienic rings, which by loss of two hydrogen atoms can be converted into b annelated benzenoid rings.

This is the trivial, crude approach. Since tables for valence isomers of [4]- through [12] annulene are available, only valence isomers of monobenzoderivatives of [4]- to [8]annulene and the dibenzoderivative of [4]annulene (biphenylene) can thus be found. We are interested, however, especially in valence isomers of polybenzo-[10]annulene.

(ii) To start from the table of valence isomers of [n]annulenes and replace b double bonds by benzenoid rings. We shall follow this latter approach, which is called annelation.

Tables 1 and 2 present the number of valence isomers of [n] annulenes having exactly β double bonds : planar and non-planar graphs in table 1, only planar graphs in table 2. They were compiled on the basis of data provided in references 3, 4 and 6.

Starting from the data in table 2, we can construct table 3 giving the number of planar valence isomers of [n]annulenes having *at least* β double bonds. Each entry (n, β) from table 3 is the sum of entries $\sum_i (n, \beta_i)$ from table 2 with $\beta_i = \beta, \beta + 1, \ldots, n/2$.

For obtaining the valence isomers of a [b]benzo-[n]annulene we have to replace b double bonds in each valence isomer having at least b double bonds (cf. table 3) by b benzenoid rings. We have to find out whether the double bonds are equivalent or not, i.e. whether there exists an automorphism of the multigraph mapping the double bonds on one another.

Table 1

Number of ***planar and non planar*** **valence isomers of [n]annulenes having** ***exactly*** **β double bonds**

β \ n	4	6	8	10
0	1	2	5	19
1	0	1	5	23
2	1	2	5	25
3	—	1	4	16
4	—	—	1	7
5	—	—	—	1
Total	2	6	20	91

Table 2

Number of ***planar*** **valence isomers of [n]annulenes having** ***exactly*** **β double bonds**

β \ n	4	6	8	10	12
0	1	1	3	9	32
1	0	1	4	16	75
2	1	2	5	22	112
3	—	1	4	16	86
4	—	—	1	7	41
5	—	—	—	1	10
6	—	—	—	—	1
Total	2	5	17	71	537

Table 3

Number of ***planar*** **valence isomers of [n] annulenes having** ***at least*** **β double bonds**

β \ n	4	6	8	10	12
0	2	5	17	71	357
1	1	4	14	62	325
2	1	3	10	46	250
3	—	1	5	24	138
4	—		1	8	52
5	—	—	—	1	11
6	—	—	—	—	1

All multigraphs with 2 or 3 double bonds and n = 4 or 6 points have equivalent double bonds. However, for n ⩾ 8 there exist multigraphs with two or more non-equivalent double bonds, so that in these cases one cubic multigraph gives rise to more than one mono- or poly-benzoderivative.

As notation for the benzoderivatives we shall use the notation of the valence isomers of annulenes * preceded by the symbol bB_i (or $bB_i{}^*$ for *o*-quinonoid structures), where b indicates the number of annelated benzenoid rings, B stands for benzo, and i is absent when there exists only one polybenzoderivative (i. e. when all double bonds to be annelated are equivalent), but is a serial index starting with 1 when one cubic multigraph gives rise to more than one polybenzoderivative. The order in which the polybenzoderivatives, resulted by annelation at non-equivalent bonds, are assigned serial indices i = 1, 2, ... is given by the following rules :

(i) *o*-Quinonoid structures follow all structures which are not *o*-quinonoid but are derived by annelation of the same valence isomer of an annulene.

(ii) When the annelated double bond is not involved in a ring, the serial index is lower than when it is involved in a ring.

(iii) The smaller is the smallest ring in which the annelated double bond is involved, the smaller is the serial index.

(iv) When all previous rules fail to provide a precedence criterion for mono- or polybenzoderivatives derived from annulene valence isomers with several double bonds in larger rings, then double bonds to be annelated with precedence are those closer to a smaller ring.

(v) When all previous rules fail to provide a precedence criterion for polybenzoderivatives this is done on the basis of the shortest path between the double bonds to be annelated : the longer this path (or sum of paths), the smaller is the serial index.

Thus, according to the above rules, acyclic double bonds to be annelated take precedence over cyclic ones, double bonds in smaller rings take precedence over those in larger rings, non-*o*-quinonoid structures take precedence over *o*-quinonoid ones, and annelation of clustered double bonds takes precedence over annelation of remote double bonds.

The application of all above ideas can be seen in table 4 (presenting all possible valence isomers of polybenzo-[n]annulenes with n = 4, 6 and 8) and in table 5 (for n = 10).

---

* This notation consists of a string of five numbers separated by hyphens indicating in turn the numbers of :

— points (CH groups), i.e. the order of the graph, n

— double bonds, i.e. circuits with two points, β

— circuits with three points, t

— circuits with four points, q

— a serial number s which starts with 1 and is larger only when n, β, t and q have the same values for more than one graph ; the order in which graphs are assigned s = 1, 2, ... is that of increasing number of circuits with 5,6 ... points. Thus, a wholly convention-free notation can be designed. Notations of ref. 3, 4 and 6 did not observe this last criterion for s, but in the present paper this has been done.

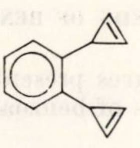
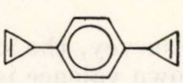
It can be seen that in table 4 biphenylene appears as dibenzocyclobutadiene (2B—4—2—0—1—1) and dihydrobiphenylene as a monobenzoderivative of a valence isomer of cyclooctatetraene ($1B_1$—8—3—0——1—1). This is a general feature of tables 4 and 5, where phenanthrene $2B_1$—6—3—0—1—1 and anthracene $2B_2^*$—6—3—0—1—1 appear as dibenzo-[6]annulenes, and their dihydroderivatives as monobenzo-[10] annulene valence isomers $1B_1$—10—4—0—0—2 and $1B_2^*$—10—4—0—0—2, respectively.

The numbers of possible valence isomers of benzoannulenes are given in table 6.

At first sight it seems rather queer to treat structures like XII as valence isomers of benzoannulenes, because chemically they differ little from their *para*-isomers XIII which are not included in tables 4 — 6. However, this is in keeping with the definitions of valence isomerism and of annelation to benzoderivatives.



XII



XIII

Table 6

The number of planar valence isomers of [b]benzo[n]annulenes[a,b]

n / b	4	6	8	10
1	1(0)	4(0)	21(3)	113(17)
2	1(0)	4(1)	17(3)	102(23)
3	—	1(0)	6(1)	44(11)
4	—	—	1(0)	10(2)
5	—	—	—	1(0)
Total	2(0)	9(1)	45(7)	270(53)

[a] The figures for b = 0 can be found in table 2 in the line "total".

[b] The number of *o*-quinonoid structures is given in brackets; the number of non-*o*-quinonoid structures results by difference.

Of course, in appropriate cases, when the geometry is favourable, a dibenzoderivative can be further bridged, leading to interesting structures. Thus, taking dibenzoderivatives of cyclooctatetraene as examples, they

can lead to such structures as XIV (x = 1 or 2), XV or XVI (x = 3 or 4)* which can be built strain-free from molecular models.

SURVEY OF KNOWN VALENCE ISOMERS OF BENZOANNULENES

In the following survey, the structures presented in tables 4 and 5 are correlated with known valence isomers of benzoannulenes. The survey is illustrative rather than exhaustive.

Both valence isomers of [b]benzo-[4]annulene are known. Benzocyclobutadiene 1B—4—2—0—1—1 (I) is a short-lived species which dimerizes [10] rapidly to $2B_1$—8—3—0—1—1 (II); in the presence of nickel tetracarbonyl catalyst, however, [11] another dimer is formed, namely 2B—8—2—0—3—1, which goes easily into dibenzo[*a*, *e*]cyclooctatetraene $2B_1$—8—4—0—0—1; in the presence of silver ions, a third dimer results, [14] namely 2B—8—2—1—0—1; this was explained by a different ring-opening of the Diels-Alder adduct from two molecules of benzocyclobutadiene leading, in the presence of silver ions, to the intermediate formation of the elusive dibenzo[*a*, *e*]cyclooctatetraene $2B_3^*$ 8—4—0—0—1. Dibenzocyclobutadiene (biphenylene)[9,15] is a stable hydrocarbon.

From the nine possible [b]benzo-[6] annulenes, six are known; naphthalene 1B—6—3—0—1—1, phenanthrene $2B_1$—6—3—0—1—1, anthracene $2B_2^*$—6—3—0—1—1 and triphenylene 3B—6—3—0—1—1 are too well-known benzenoid aromatic hydrocarbons [13] to warrant more than a cursory mention. It is noteworthy that anthracene is the only stable *o*-quinonoid valence isomer of a benzoannulene known so far: in other cases the presence of such a structural feature gives too unstable *o*-xylylenic structures. Substituted [16] and unsubstituted [17] hemi-Dewar-naphthalenes (benzobicyclo[2.2.0] hexa-2,5-diene, 1B—6—2—0—2—1) were prepared recently and are appreciably more stable than Dewar-benzene. A derivative of Dewar-anthracene (dibenzo-Dewar-benzene 2B—6—2—0—2—

—1) is also known,[18] in 9,10-dehydro-dianthracene, and like the previous monobenzo-Dewar-benzene, it is a stable substance.

From the 45 possible constitutionally different valence isomers of [*b*]benzo-[8]annulene, 15 are known as stable compounds (chart 1*). The reaction of cyclobutadiene with benzocyclobutadiene[14] affords 1B—8—2—0—3—1, which can ring-open to benzocyclooctatetraene slowly by a thermal, symmetry-forbidden reaction, and rapidly in the presence of silver ions,[19] passing through an unstable *o*-quinonoid valence isomer 1B$_3^*$— — 8 — 3 — 0 — 1 — 1 which could be trapped by dienophiles. Benzosemibullvalene 1B—8—2—1—0—1 (benzo[*c*] tricyclo-[3.3.0.0.^{2,8}] octa-3,6-diene) was prepared photochemically from benzobarrelene 1B—8—3—0—0—1, along with benzocyclooctatetraene.[20] Benzosemibullvalene or its substituted derivatives,[21] unlike semibullvalene which gives a degenerate rearrangement evidenced by its NMR spectrum, does not fluctuate. A substituted benzo[b]-bicyclo [4.2.0]octa-2,4, 7-triene, 1B$_2$ — 8 — 3— 0— 1 — — 1, isomerizes to the corresponding benzocyclooctatetraene but much more slowly than the non-annelated compound.[21] Benzobarrelene is, along with benzocyclooctatetraene, one of the reaction products from benzene and benzyne. Benzocyclooctatetraene 1B—8—4—0—0—1 was mentioned repeatedly above.[14,20–24] The three dibenzo-$(CH)_8$ structures obtained by the dimerization of benzocyclobutadiene under different conditions were mentioned above : 2B — 8 — 2— 0 — 3 — 1,[11,19] 2B$_1$ — 8 — 3 — 0 — 1— — 1,[10] and 2B — 8 — 2 — 1 — 0 — 1.[14] In the opening of the first transannular bond of 2B — 8 — 2 — 0 — 3 — 1, the *o*-quinonoid valence isomer 2B$_3^*$ — 8 — 3— 0— 1— 1 appears as an unstable intermediate which can be trapped by dienophiles and which rapidly valence isomerizes to dibenzo [*a*, *e*] cyclooctatraene.[19] Dibenzosemibullvalene[25] 2B — 8 — 2 — 1 — — 0 — 1 or its substituted derivatives[26] can be also obtained photochemically from dibenzobarrelene 2B — 8 — 3 — 0 — 0 — 1. The preparation of the latter hydrocarbon and its derivatives was described earlier.[27–33]

From the three possible dibenzocyclooctatetraenes, only the non-*o*-quinonoid are stable, whereas the *o*-quinonoid dibenzo[*a*, *d*]cyclooctatetraene $2B_3^* - 8 - 4 - 0 - 0 - 1$ was discussed as an unstable intermediate in the $Ag^{\oplus}$-catalyzed formation of dibenzosemibullvalene from benzocyclobutadiene.[14] Dibenzo[*a*, *c*]cyclooctatetraene $2B_2 - 8 - 4 - 0 - 0 - 1$ valence isomerizes to dibenzo[*b*, *d*]bicyclo[4.2.0]octa-2,4,7-triene $2B_2 - 8 - 3 - 0 - 1 - 1$ photochemically, whereas the reverse thermal reaction requires very high temperatures (350°)[34]; this evidences how drastic the effect of the annelation is on the tautomeric equilibrium between cyclooctatetraene and bicyclo [4.2.0] octa-2,4,7-triene.[35] Dibenzo-[*a*, *e*]cyclooctatetraene $2B_1 - 8 - 4 - 0 - 0 - 1$ was mentioned above.[11,19,24,31] Its preparation is of earlier date.[36-42] Tribenzobarrelene is the well-known triptycene[43] $3B - 8 - 3 - 0 - 0 - 1$. Tribenzocyclooctatetraene $3B - 8 - 4 - 0 - 0 - 1$ is known.[44] Tetrabenzocyclooctatetraene or tetraphenylene[41,44-46] $4B - 8 - 4 - 0 - 0 - 1$ can be obtained from *o,o'*-dilithiobiphenyl by oxidation with transition metal halides[47] along with bi- and hexaphenylene.

From the 270 possible constitutionally different valence isomers of [b]benzo-[10]annulene (disregarding stereoisomerism which gives a larger number of possible structures), 21 are known as stable compounds (chart 2).

Benzobasketene[48,49] $1B - 10 - 1 - 0 - 4 - 1$ is obtained photochemically, along with $1B_2 - 10 - 2 - 1 - 1 - 3$,[48,49] from the *anti*-benzo-Nenitzescu hydrocarbon $1B_2 - 10 - 3 - 0 - 1 - 1$ which is available by cycloaddition of benzene to 7,8-dichlorobicyclo [4. 2. 0] octa-2,4-diene[48] or to cyclooctatetraene.[50] The *syn*-isomer of $1B_2 - 10 - 3 - 0 - 1 - 1$ is also known.[51] The *anti*-benzo[*g*] tricyclo [4.2.2.0 ^{2,5}] deca-3,7,9-

triene $1B_2 - 10 - 3 - 0 - 1 - 1$ [52-54] rearranges thermally to *cis*-4*b*, 8*a*-dihydrophenanthrene $1B_1 - 10 - 4 - 0 - 0 - 2$ [48, 53, 54]; in this reaction, $1B_1 - 10 - 4 - 0 - 0 - 1$ is an isolable intermediate. [53]

Benzobasketene rearranges under the influence of silver ions to benzosnoutene $1B - 10 - 1 - 2 - 0 - 1$. [48] In the addition of benzyne to cyclooctatetraene, [50] silver ions influence the proportion of reaction products: absence of metal favours $1B_2 - 10 - 3 - 0 - 1 - 1$, whereas $Ag^{\oplus}$ causes the predominant formation of $1B_1 - 10 - 3 - 1 - 0 - 2$; a third product is $1B_1 - 10 - 4 - 0 - 0 - 1$.[52] From the three non-*o*-quinonoid benzo-lumibullvalenes, $1B_3 - 10 - 3 - 1 - 0 - 2$ is unstable because of a Cope rearrangement which converts it into $1B_1 - 10 - 3 - 0 - 0 - 1$, [55] which also results by thermal rearrangements from the other two benzo-lumibullvalenes, $1B_1 - 1 - 0 - 3 - 10 - 2$ and $1B_2 - 10 - 3 - 1 - 0 - 2$ [55]; both these isomers result together by thermolysis of $1B_2 - 10 - 2 - 1 - 1 - 3$. [48] An anionic rearrangement under the influence of organolithium reagents converts $1B_2 - 10 - 3 - 1 - 0 - 2$ into $1B_2 - 10 - 2 - 1 - 0 - 1$. [56] Photolysis of the dihydrophenanthrene $1B_1 - 10 - 4 - 0 - 0 - 2$ gives benzo[*g*]-bicyclo[4.2.2]deca-2,4,7,9-tetraene $1B_2 - 10 - 4 - 0 - 0 - 1$, [48] which on irradiation in acetone gives $1B_1 - 10 - 3 - 0 - 0 - 1$. [48]

A recent paper[57] reports the preparation of benzobullvalene $1B - 10 - 3 - 1 - 0 - 1$, whose topomerization only involves the homotropylidene moiety. A substituted benzobullvalene had been known for several years. [58]

Monobenzo-$(CH)_{10}$ valence isomers which were discussed as unstable reaction intermediates or alternative structures are $1B_2 - 10 - 3 - 0 - 2 - 2$, [53] $1B_2 - 10 - 4 - 0 - 1 - 1$, [48,53] $1B_2 - 10 - 3 - 0 - 1 - 2$,[55] $1B_1 - 10 - 3 - 0 - 1 - 2$, [48] $1B - 10 - 3 - 0 - 0 - 2$, [48] and $1B_3 - 10 - 3 - 1 - 0 - 2$. [48,55]

From the dibenzo-$(CH)_{10}$ valence isomers, dibenzo[*g, h*]tricyclo-[4.2.2.0 ^{2,5}] deca-3,7,9-triene $2B_2 - 10 - 3 - 0 - 1 - 1$, [51,59] and *syn*-dibenzo[*c, g*]-tricyclo[4.2.2.0 ^{2,5}] deca-3,7,9-triene $2B_1 - 10 - 3 - 0 - 1 - 1$, [60] are both annelated derivatives of the Nenitzescu hydrocarbon $(CH)_{10}$. Dibenzobullvalene $2B - 10 - 3 - 1 - 0 - 1$ was obtained together with $2B_1 - 10 - 4 - 0 - 0 - 1$; the latter is thermally stable (and is formed by pyrolysis of $2B_2 - 10 - 3 - 0 - 1 - 1$), but is converted on photolysis into dibenzobullvalene, [61a] Pyrolysis of dibenzobullvalene affords dibenzo[*b*, *i*]-tricyclo [5.3.0.0 ^{4,8}] deca-2,5,9-triene $2B_2 - 10 - 3 - 0 - 0 - 1$,[61] together with $2B_1 - 10 - 3 - 0 - 0 - 1$.[61b] At higher temperatures, tetraphene and chrysene are formed, presumably *via* the dihydrotetraphene $2B_4^* - 10 - 4 - 0 - 0 - 2$.[61b]

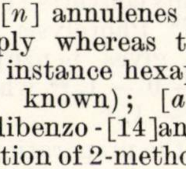
Another dibenzo-$(CH)_{10}$ valence isomer, $2B - 10 - 2 - 1 - 0 - 1$, was obtained from benzene and benzyne,[23] and its structure was established by electron diffraction.

trans-[*a*, *c*, *g*] Tribenzo-[10]annulene, $3B_1 - 10 - 5 - 0 - 1 - 1$, is a stable hydrocarbon, unlike the non-annelated [10] annulene, since it cannot give an intramolecular ring closure to a 9,10-dihydronaphthalene derivative.[62]

From this survey of known valence isomers of [*b*]benzo-[n]annulenes with n = 4, 6, 8 and 10, one can conclude that with the exception of anthracene, *o*-quinonoid valence isomers of benzoannulenes tend to be unstable, and that so far no molecule with a benzocyclopropene moiety is known. This reduces somewhat the numbers of possible valence isomers in table 6.

For benzoderivatives of [*n*] annulenes with n >10, the numbers of possible isomers increase sharply whereas the number of known compounds is at present small. For instance hexaphenylene is hexabenzo-[12]-annulene (two isomers are known); [*a*, *e*, *i*] tribenzo-[12]annulene has also been prepared[63,64]; a dibenzo-[14]annulene valence isomer (XVII) is also known.[65] Photodimerization of 2-methoxynaphthalene yields several dibenzo-$(CH)_{12}$ valence isomers.[66]



XVII

Owing to these reasons, the tables of valence isomers of [b] benzo-[n]annulenes were restricted to n = 4 – 10, but they can be expanded to n >10 when need arises.

INVESTIGATIONS IN THE CYCLOBUTANE SERIES. XXXIII.[1]

SYNTHESIS OF *syn*-DIBENZO [*c*, *g*] TRICYCLO [4.2.2.0 ^{2,5}] DECA-3, 7, 9-TRIENE. A NEW DIBENZO $(CH)_{10}$ HYDROCARBON

ILIE G. DINULESCU, MIRCEA POP, FILIP CHIRALEU, MARGARETA AVRAM and COSTIN D. NENITZESCU *

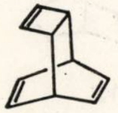
Institute of Organic Chemistry, Spl. Independenţei 202 B, Bucharest, Romania

Received February 6, 1974

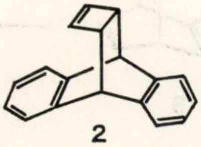
The synthesis of the dibenzo $(CH)_{10}$ hydrocarbon **3** is described.

Considering the particular interest raised by the chemistry of $(CH)_0$ hydrocarbons, [2] the investigation of the dibenzo-derivatives of $(CH)_{10}$ Nenitzescu hydrocarbon (**1**) [3] seemed appropriate.

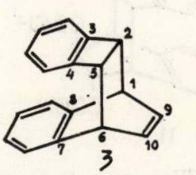
In the course of previous studies, the synthesis [4] and the thermal behaviour [5] of isomer **2** were described.



1



2



3

In this work we report the synthesis of a new isomer in the same series : *syn*-dibenzo[*c*, *g*] tricyclo[4.2.2.0 ^{2,5}]deca-3,7,9-triene (**3**).

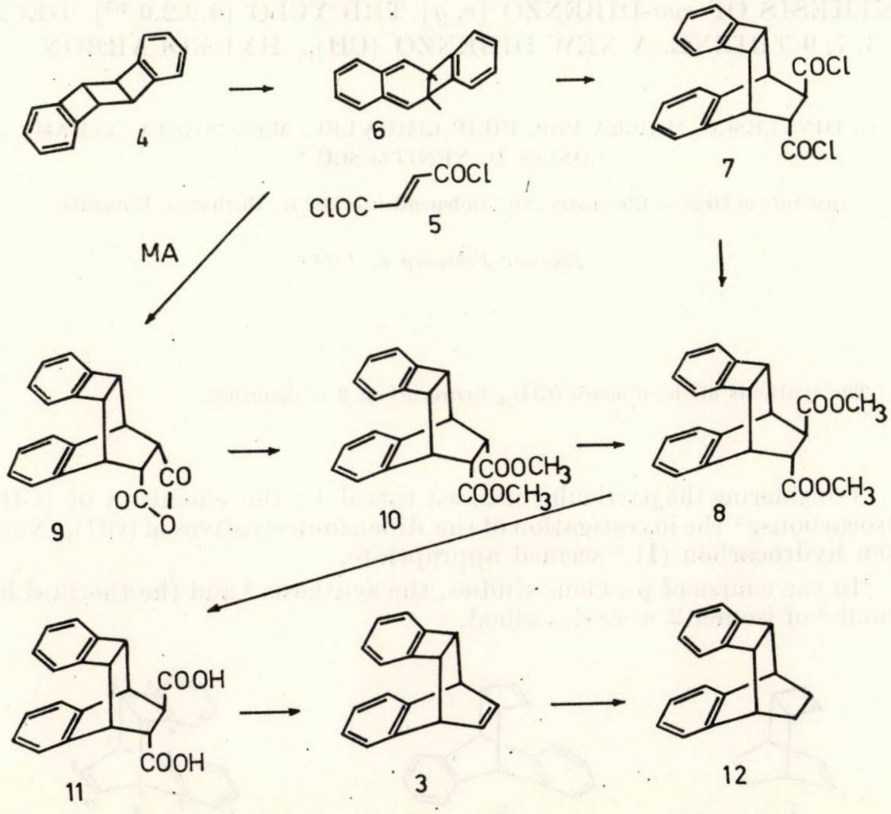
By gradual heating (1°/min) to 120° of stoechiometrical amounts of dibenzo [*c*, *g*] tricyclo [4.2.0.0 ^{2,5}] octa-3,7-diene (**4**)[6] and fumaryl chloride (**5**) in xylene, the adduct **7** results by a Diels-Alder reaction of the *ortho*-quinonoid hydrocarbon **6** generated *in situ* from the hydrocarbon **4**.

Refluxing of **7** in methanol afforded (69% yield calcd. on **4**) the *trans*-ester **8**, colourless crystals with m.p. 180° (from methanol).



The structure and stereochemistry of compounds **7** and **8** are evident from their method of synthesis and examination of their NMR spectra.

The NMR spectrum of **8** ($CDCl_3$, δ, ppm) exhibits the following signals: 6.65 — 7.00 (m, 8H, aromatics), 3.65 — 3.95 (m, 4H, H-1, H-2, H-5, H-6), 3.26 and 3.53 (splitted AB system, J = 6 and 2.5 Hz, H-9, H-10), 3.85 (s, 3H from *exo*-carbomethoxy group), 3.60 (s, 3H from *endo*-carbomethoxy group); IR (CCl_4) : ν_{CO} 1734 cm^{-1}.

The same *trans*-ester **8** was obtained also from the earlier described[7,8]. anhydride **9**. Hydrolysis of the latter and treatment of the resulted *cis*-acid with an ethereal solution of diazomethane afforded the *cis*-ester **10**, m.p. 155° (from methanol) ; NMR ($CDCl_3$, δ, ppm) : 6.60 – 7.00 (m, 8H, aromatics), 3.65 (s, 4H, H-1, H-2, H-5, H-6), 3.40 (s, 6H from carbomethoxy groups), 3.15 (s, 2H, H-9, H-10) ; IR (CCl_4) : ν_{co} 1751 cm^{-1}.

[7] M. Avram, I. G. Dinulescu, D. Dinu, G. Mateescu and C. D. Nenizescu, *Tetrahedron*, **19**, 309 (1963).

[8] M. P. Cava and R. Pohlke, *J. Org. Chem.*, **28**, 1012 (1963); W. Merk and R. Pettit, *J. Amer. Chem. Soc.*, **89**, 4788 (1967).

Heating of the *cis*-ester **10** in methanol with catalytic quantities of sodium methoxide gave rise to the *trans*-ester **8** in 84 % yield.

Alkaline hydrolysis of ester **8** led to the *trans*-acid **11**, m.p. 264° (from 50 % aqueous methanol), NMR ($CDCl_3$+$(CD_3)_2SO$, δ, ppm) : 6.60 - 7.00 (m, 8H, aromatics), 3.65-3.85 (m, 4H, H-1, H-2, H-5, H-6), 3.11 and 3.41 (splitted AB system, J = 6 and 2.5 Hz, H - 9, H-10).

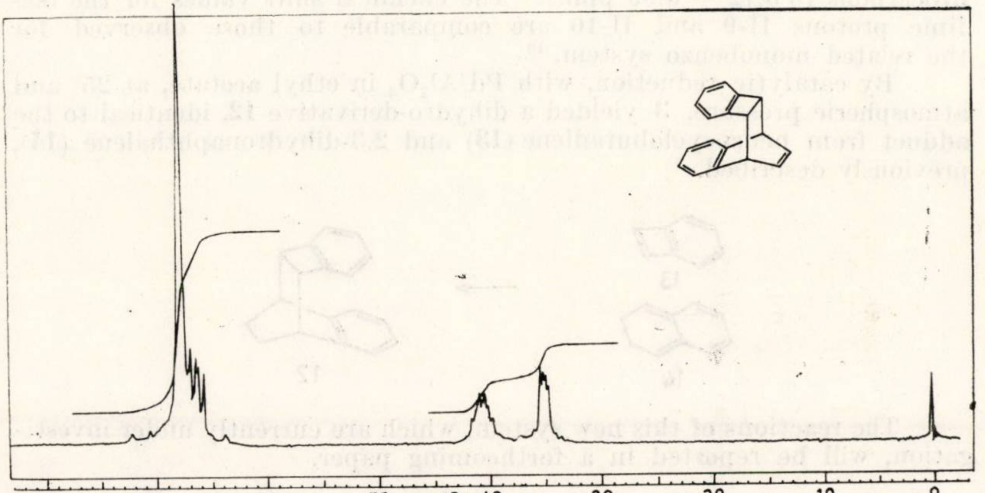

Fig. 1. — NMR spectra of the olefins **2** and **3**.

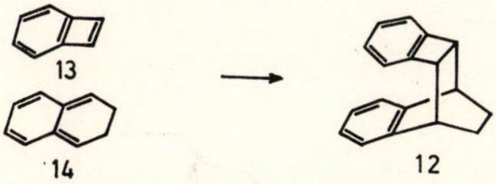
The acid **11**, on treatment with 3 moles lead tetraacetate, in pyridine solution, after extraction with petroleum ether, afforded olefin **3** in 47% yield, as colourless crystals with m.p. 132°. The NMR spectrum of olefin **3** in $CDCl_3$ shows the following signals (δ, ppm) : 6.75 (broad s, 8H, aromatics), 6.64 (m, 2 olefinic H, H-9, H-10, a part of an A_2X_2 system), 4.04 (m, 2H, H-1, H-6), 3.48 (m, 2H, H-2, H-5). UV (ethanol) : λ_{max} (log ε) : 262.8 nm (3.328), 268.4 (3.436), 275.1 (3.410).

The *syn* orientation of both aromatic rings is reflected in the value of aromatic protons which is shifted toward higher field, namely with 0.25 ppm, as compared with **2** (δ arom. 6.95 – 7.30 ppm) ; this value is also in good agreement with the chemical shift of some tribenzo $(CH)_{10}$ hydrocarbons (δ 6.12 – 6.90 ppm). [9] The chemical shift values for the olefinic protons H-9 and H-10 are comparable to those observed for the related monobenzo system. [10]

By catalytic reduction, with Pd/Al_2O_3 in ethyl acetate, at 25° and atmospheric pressure, **3** yielded a dihydro-derivative **12**, identical to the adduct from benzocyclobutadiene (**13**) and 2.3-dihydronaphthalene (**14**), previously described. [7]



The reactions of this new system, which are currently under investigation, will be reported in a forthcoming paper.

EXPERIMENTAL

Microanalyses were performed by Miss Elvira Sliam and Mrs. Violeta Daniel. IR and NMR spectra were recorded using a Jena UR-20 spectrophotometer and a Varian A-60A spectrometer, respectively.

Dimethyl dibenzo [c, g] tricyclo [4.2.2.0^{2,5}] deca-3, 7-dien-*trans*-9, 10-dicarboxylate (8)

A well stirred mixture of 1.02 g (5 mmoles) *anti*-dibenzo[*c*, *g*] tricyclo [4.2.0.0^{2,5}] octa-3,7-diene (**4**), 0.80 g (0.57 ml ; 5 mmoles) fumaryl chloride (**5**) and 2.5 ml xylene was gradually heated (1°/min) until the temperature reached 120° ; this temperature was maintained for 1 hour. After evaporation *in vacuo* of the solvent and unreacted **5**, the oily residue (crude dichloride **7**) was treated with 25 ml methanol and was boiled for 5 hours. After cooling, the crystals which separated were filtered, yielding 1.2 g (69%) **8**, m.p. 185° (from methanol).

Isomerization of *cis* ester 10 to *trans* ester 8

A solution of 0.1 g (43.5 mmoles) sodium in 30 ml anhydrous methanol was treated with 0.30 g (0.86 mmoles) *cis*-ester **10**, and the mixture was boiled for 7 hours. After evaporation of the solvent, 20 ml water were added and the crystals were filtered, yielding 0.25 g (84%) *trans*-ester **8**, identical (m. p., mixed m.p., IR and NMR spectra) with the above described product.

Dibenzo [e, g] tricyclo [4.2.2.0^{2,5}] deca- 3, 7-dien- *trans*-9, 10- dicarboxilic acid (11)

a. *By hydrolysis of the trans-ester* **8**. A solution of 0.50 g (9 mmoles) potassium hydroxide in 10 ml methanol was heated with 0.50 g (1.44 mmoles) *trans*-ester **8** and the mixture was boiled for 6 hours. The solvent was then distilled, the residue was dissolved in 12 ml hot water, the solution was filtered and acidified, yielding 0.30 g (60%) *trans*-acid **11**, m.p. 264° (from 50% aqueous methanol).

$C_{20}H_{14}O_4$	*Calcd.* :	C, 74.98 ; H, 5.04
	Found :	C, 74.24 ; H, 5.30

b. *Preparative method for the trans-acid* **11** *starting from* **4**. A well stirred mixture of 6.12 g (30 mmoles) **4**, 5.6 g (35 mmoles ; 4.0 ml) fumaryl chloride (**5**) and 15 ml xylene was gradually heated (1°/min) until the temperature reached 120°, and this temperature was maintained for 1 hour. After evaporation *in vacuo* of the solvent and the unreacted **5** the oily residue was boiled with 110 ml methanol for 4 hours. The solvent was removed by distillation and the oily residue was treated with a solution of 7.5 g potassium hydroxide in 120 ml methanol and refluxed for 6 hours. After evaporation of the solvent, the residue was stirred for 15 min with 185 ml hot water, the coled solution was filtered and acidified under cooling with concentrated hydrochloric acid. By filtration, 5.25 g (55%) practically pure *trans*-acid **11** were obtained, which can be used further without purification.

syn- Dibenzo [e, g] tricyclo [4.2.2.0^{2,5}] deca- 3, 7, 9 - triene (3)

A solution of 5.0 g (15.6 mmoles) *trans*-acid **11** in 92 ml anydrous pyridine was treated, at 30—i35°, with 20.2 g (45 mmoles) lead tetraacetate, and the mixture was vigorously stirred until the evolution of carbon dioxide aceased. The reaction mixture was extracted with petroleum ether (b. p. 28–32°) and the resulted solution was washed several times with 2% hydrochloric acid, until all pyridine was removed. After washing with water and drying, the petroleum ether was removed by distillation and the crude crystalline residue was purified by chromatography on aluminium oxide with petroleum ether, yielding 1.7 g (47%) **3**, mp. 132°.

$C_{18}H_{14}$ *Calcd.*: C, 93.87; H, 6.13
Found: C, 93.59; H, 6.37

syn-Dibenzo [e, g] tricyclo [4.2.2.0^{2,5}] deca-3,7-diene (12)

A solution of 0.3 g olefin **3** in 15 ml ethyl acetate was stirred in hydrogen atmosphere with a small quantity of Pd/C, until the absorption ceased. The catalyst was filtered, the solvent was evaporated *in vacuo* and the residue was recrystalized from methanol yielding 0.25 g (13%) **12**, identical (m.p., IR and NMR spectra) with the previously described [7] adduct of benzocyclobutadiene with 2.3-dihydronaphthalene.

INCHAIN-EPOXIDES OF CAROTENOIDS. IV[1]

METAL-CHLORIDE COMPLEXES OF CANTHAXANTHIN INCHAIN-EPOXIDES

DOINA OŞIANU, ELENA NICOARĂ and C. BODEA

Institute of Agronomy "Dr. Petru Groza", Department of Chemistry and Biochemistry,
str. Mănăştur 3, Cluj, Romania

Received November 13, 1973

Canthaxanthin mono and di-inchain-epoxides form coloured complexes with $AlCl_3$ and $FeCl_3$. These complexes have characteristic electronic spectra which can be used for the identification of inchain-epoxides. The complexes are instable in the presence of acetone, being converted into a mixture of canthaxanthin and initial epoxide.

Acting with perbenzoic acid on canthaxanthin we have obtained so far two mono-inchain-epoxides, 9,10- and 13,-14-epoxy-canthaxanthin [2] and a diepoxide, 9, 10, 9′, 10′-diepoxy-canthaxanthin.[3]

As we have shown in a previous paper, [1] canthaxanthin inchain-epoxides form green complexes with $HgCl_2$ differing by their weak stability from the $HgCl_2$ complexes of 5,6- and 5, 8-epoxy-carotenoids obtained by Yamamoto et al. [4] The $HgCl_2$ complexes of the inchain-epoxides are sufficiently stable in benzene to allow the electronic spectra to be recorded. The electronic spectra of these mercury-chloride complexes show a sharp maximum at 700–750 nm.

Monties and Costes [5] have mentioned a colour reaction for 5,6- and 5,8-epoxy-carotenoids with aluminium chloride.

We have obtained colour reactions for inchain-epoxides of canthaxanthin by using ferric chloride and aluminium chloride.

The ferric-chloride complexes were obtained by treating the benzenic solution of the inchain-epoxides with a benzenic solution of the anhydrous $FeCl_3$.

The complexes of inchain-epoxides of canthaxantin with aluminium chloride can be obtained in benzenic as well as in ethereal solution. The ethereal solutions being however more stable, they were prefered for the recording of the electronic spectra.

[1] D. Oşianu, E. Nicoară and C. Bodea, *Rev. Roumaine Chim.*, **16**, 765 (1971).

[2] E. Nicoară, D. Oşianu and C. Bodea, *Rev. Roumaine Chim.*, **15**, 1965 (1970).

[3] D. Oşianu, E. Nicoară and C. Bodea, *Rev. Roumaine Chim.*, **16**, 925 (1971).

[4] H. I. Yamamoto, C. O. Chichester and T.O.M. Nakayama, *Analyt. Chem.*, **33**, 1792 (1961).

[5] B. Monties and C. Costes, *Compt. rend. Ser. C.*, **266**, 481 (1968).

The colour of the metal-chloride complexes of inchain-epoxides is blue-green for $FeCl_3$ and violet for $AlCl_3$.

The attempt to separate from solution the pure $FeCl_3$ and $AlCl_3$ complexes, respectively, failed.

The electronic spectra of the complexes are shown in figures 1 and 2.

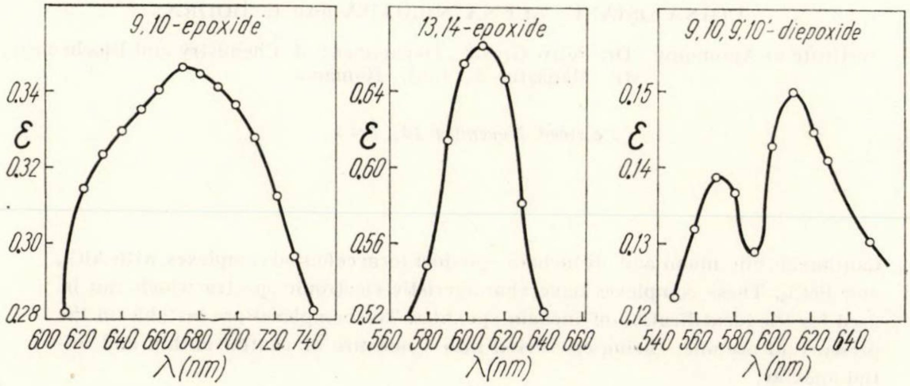

Fig. 1.—Visible light absorption spectra of $FeCl_3$ complexes of canthaxanthin inchain-epoxides.

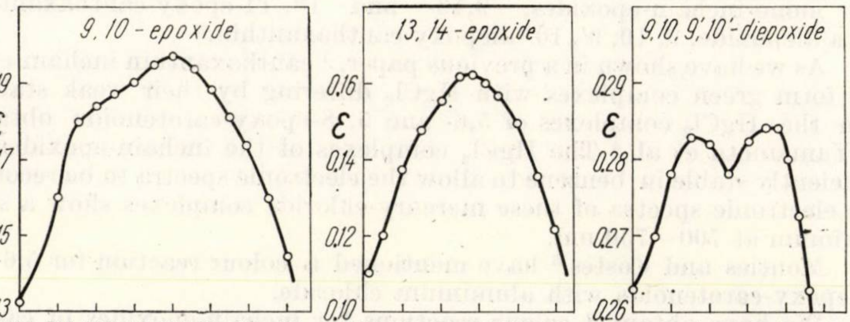

Fig. 2.—Visible light absorption spectra of $AlCl_3$ complexes of canthaxanthin inchain-epoxides.

As the inchain-epoxides have the chromophoric system shortened and show the electronic spectra at low wave lengths, the complexation reaction with metal chlorides is useful for their identification.

The absorption maxima of the inchain-epoxides and their complexes with $FeCl_3$ and $AlCl_3$, as well as with $HgCl_2$, are shown in table 1. As it is seen, the mercury-chloride complexes present the highest and the aluminium-chloride complexes the lowest absorption.

For the identification of the inchain-epoxides the complexation reaction with ferric chloride and aluminium chloride is recommended because it can be carried out in the solution without any difficulty.

Table 1

Visible light absorption maxima of metal-chloride complexes of canthaxanthin inchain epoxides

	Solvent	λ_{max} (nm)		
		9,10-epoxide	13,14-epoxide	9,10,9′, 10′-diepoxide
Initial epoxide	benzene	434	376	344
$HgCl_2$-complexes	benzene	754	700	754
$FeCl_3$-complexes	benzene	670	610	600 ;570
$AlCl_3$-complexes	diethyl ether	555	515	470 ;430

Under the action of acetone the $FeCl_3$ and $AlCl_3$ complexes are split into a mixture of canthaxanthin, initial epoxide and metal chloride. This behaviour is similar to that shown by the HCl[2,3] and $HgCl_2$ [1] complexes.

Thus, the decomposition reaction followed by partial deepoxidation is characteristic of the metal-chloride complexes of inchain-epoxides. Under the same conditions the decomposition of the 5,6-epoxy-complexes is associated with the isomerization in the corresponding 5,8-epoxide.

EXPERIMENTAL

Materials and apparatus

All the reagents and solvents were of analytical grade. Diethyl ether and benzene were dried over Na prior to use.

Electronic spectra were recorded with a Zeiss-Jena V.S.U.1 Universal spectrophotometer.

Methods

The canthaxanthin inchain-epoxides were prepared as described in previous papers, [2,3] by acting with perbenzoic acid upon canthaxanthin.

The $FeCl_3$ and $AlCl_3$ contents of the solutions were established by the chloride ion contents determined according to Morhr's method commonly used.

Canthaxanthin inchain-epoxy-$FeCl_3$ complexes

A ferric chloride solution in benzene was obtained by shaking a few minutes the anhydrous salt (in excess) with the solvent. The concentration of the solution determined according to the content of chloride ions was 10^{-3} M.

The $FeCl_3$ reagent was added dropwise to the epoxide solution until the formation of a soluble complex showing an intense green colour in the case of 9,10 epoxide ($\lambda_{max}=670$ nm), a blue colour for the 13,14-epoxide($\lambda_{max}=610$nm)and a green colour for 9.10,9',10'-diepoxide(λ_{max} = 600 and 570 nm). The absorption maxima were performed 15—30 minutes after the formation of the complex, using the initial solution diluted beforehand with the same solvent. The molar ratio inchain-epoxide : $FeCl_3$ of the complexes in solution was 2 :1. The attempt to isolate the complexes by thin layer chromatography on MgO or silicagel and by paper chromatography failed.

Through acetonolysis the complexes result in the formation of canthaxanthin and the initial epoxide. Compounds formed through acetonolysis were identified by cochromatography using authentic samples.

Canthaxanthin inchain-epoxy-$AlCl_3$ complexes

An aluminium chloride solution 10^{-2}M in diethyl ether was obtained by shaking a few minutes anhydrous salt (in excess) with the solvent.

The inchain-epoxide solutions, obtained as above with diethyl ether, were treated with the $AlCl_3$ reagent, dropwise, until the formation of a soluble complex showing an intense violet colour for 9,10 -epoxide ($\lambda_{max}=555$ nm), a violet colour for 13,14-epoxide($\lambda_{max}=515$ nm), and a red colour for 9,10,9', 10'-diepoxide ($\lambda_{max}=470$ and 430 nm). The absorption maxima were recorded not later than 20 minutes after preparation.

The molar ratio inchain-epoxide : $AlCl_3$ of the complexes in the ethereal solution was 1 : 1.

The $AlCl_3$ reagent as well as the complexes can be prepared also in benzene, but the obtained complexes are less stable than in the ethereal solution.

The $AlCl_3$ complexes of canthaxanthin epoxides show on acetonolysis and chromatography the same behaviour as the $FeCl_3$ complexes.

Revue Roumaine de Chimie, 19, 7, 1207–1219 (1974)

FORMATION D'ISOMÈRES DANS LES RÉACTIONS DE CYCLOHEXYLATION CATALYTIQUE DE BENZÈNE*

M. IOVU et ECATERINA TUDOR

Faculté de chimie, Université de Bucarest, Splaiul Independenţei 89, Bucarest

Reçu le 4 avril 1973

Dans les nombreux travaux effectués jusqu'à présent, concernant la cyclohexylation du benzène avec chlorure de cyclohexyle, cyclohexène ou cyclohexanol, en présence d'acides Lewis ou Brönsted, les auteurs considèrent le cyclohexylbenzène comme unique produit de réaction avec C_{12}. Compte tenu que le cyclohexène subit la polymérisation en présence des acides Lewis ou Brönsted et que le cyclohexane peut subir un rétrécissement du noyau, en présence des acides Lewis, nous avons estimé que telles réactions conduiraient aussi à la formation d'autres hydrocarbures avec du C_{12}, outre le cyclohexylbenzène, en pourcentages fonction de la méthode de synthèse du cyclohexylbenzène. Par l'application des voies de synthèse employées de plus couramment, et en respectant les conditions de réaction mentionnées par leurs auteurs, nous avons constaté que, sauf le cas où l'on utilise du chlorure de cyclohexyle comme agent de cyclohexylation, en présence de chlorure d'aluminium comme catalyseur, quand le cyclohexylbenzène résulté dépasse 99,5 %, dans les autres cas, outre le cyclohexylbenzène apparaissent également des bicycloalkyls, (méthylcyclopentyle) cyclohexane, hydrocarbures non saturés, isomères du (méthylcyclopentyl) benzène et cyclopentyl-phénylméthane. Les produits secondaires de réaction ont été mis en évidence par chromatographie.

INTRODUCTION

Les hydrocarbures cycloalkyl-aromatiques, intéressants comme « hydrocarbures modèles » du pétrole, sont employés à l'obtention d'initiateurs de polymérisation, comme matières premières pour la préparation de certains combustibles spéciaux et dernièrement on a étudié l'oxydation du cyclohexylbenzène au phénol et au cyclohexanone, matières premières importantes pour la préparation du caprolactame.

Les auteurs qui ont effectué les réactions de cycloalkylation des hydrocarbures aromatiques ne se sont pas posé le problème d'un rétrécissement de cycle avant ou après alkylation, notamment dans les conditions de réaction de type Friedel-Crafts.

---

* Travail présenté à la IIIe Conférence de Chimie Physique Générale et Appliquée — Bucarest, 4 — 7 septembre 1972.

Il est bien connu le fait que le cyclohexane en présence d'$AlCl_3$ humide passe en methylcyclopentane [1,2]. A 80° il atteint un équilibre[3] où méthylcyclopentane se trouve en proportion de 25%. Le méthylcyclohexane, de même, subit l'isomérisation, mais dans une moindre mesure (à l'équilibre existent 3% d'éthylcyclopentane et des diméthylcyclopentanes seulement[4]).

D'autre part, en cherchant d'obtenir du 1,4-dicyclohexylbenzène par cyclohexylation du benzène, ou a constaté que celui-ci résulte dans des proportions différentes par rapport à 1,2-et 1,3-dicyclohexylbenzène, en fonction du catalyseur et de l'agent de cyclohexylation utilisé. Ce fait pourrait être dû à certains rétrécissements du noyau saturé de 6 atomes de carbone, ce qui conduirait à la perte de la symétrie, dont la conséquence est la baisse de la température de fusion et la diminution du rendement en 1,4-dicyclohexylbenzène.

Pour vérifier si l'on peut obtenir du cyclohexylbenzène pur par cyclohexylation du benzène, on a passé à la cyclohexylation de celui-ci selon les conditions mentionnées dans la littérature, en selectionnant les catalyseurs et les procédés les plus indiqués. Les procédés de cyclohexylation peuvent être répartis selon les agents de cyclohexylation employés, notamment: chlorure de cyclohexyle, cyclohexène et cyclohexanol. Les catalyseurs sont soit des acides Lewis, tels que l'$AlCl_3$ et le $TiCl_4$ qui peuvent être employés

pour tous les agents de cyclohexylation, soit des acides Brönsted, tels que le H_2SO_4 utilisés pour le cyclohexène et le cyclohexanol seulement.

Dans les synthèses effectuées par nous on a maintenu les différents rapports moléculaires : benzène : agent de cyclohexylation : catalyseur (tableaux 1, 2, 3) indiqués par la littérature, puisque le rapport benzène : agent de cyclohexylation influence seulement le rapport entre monoalkylat et polyalkylats, ce qui ne présente pas d'intérêt dans le présent ouvrage. Nous avons maintenu cependant la température constante, 25°, qui pourrait influencer l'équilibre entre les molécules au cycle de 6 et de 5 atomes de carbone.

Bien que la cyclohexylation du benzène avec du chlorure de cyclohexyle en présence de $AlCl_3$[5] et de $TiCl_4$[6] a été récemment effectuée, ses auteurs n'ont pas posé le problème d'une éventuelle obtention d'un mélange d'isomères.

La cyclohexylation du benzène avec du cyclohexène[7–10], en présence de $AlCl_3$ anhydre, a été effectuée à un moment où les moyens techniques de mise en évidence des isomères résultés de la réaction n'étaient pas encore connus. Plus tard, au lieu de $AlCl_3$, nous avons utilisé comme catalyseur le sesquichlorure d'éthylaluminium l'$AlEt_2Cl$. $AlEtCl_2$[11], mais nous n'avons pas étudié la formation des isomères.

Dans cet ouvrage nous consignons également les résultats de la cyclohexylation du benzène avec du cyclohexène en présence de $AlCl_3$ hydraté (cas qui n'est pas encore mentionné par la littérature), afin de voir si celui-ci a une action différente du chlorure d'aluminium anhydre.

Pojeau [6] utilise le $TiCl_4$, partiellement décomposé dans l'eau, à la cyclohexylation du benzène avec du cyclohexène.

Tous les auteurs, [9,12–16] qui effectuent la cyclohexylation du benzène avec du cyclohexène, en présence d'acide sulfurique considèrent le cyclohexylbenzène comme unique produit de 12 atomes de carbone, quoiqu'on puisse s'attendre à l'apparition d'un nombre plus grand de produits, compte tenu que l'acide sulfurique catalyse la réaction de polymérisation du cyclohexène.

La cyclohexylation avec du cyclohexanol en présence de $AlCl_3$ est attribuée à Tsukervanic [17] qui, plus tard, relève la commodité de cette méthode [18] par rapport aux cyclohexylations avec du chlorure de cyclohexyle et cyclohexène, matières premières que l'on doit synthétiser en partant du cyclohexanol. L'auteur cité ne met pas en évidence l'existence de certains isomères. De même, Lipovich [19], en répétant cette synthèse et en utilisant le cyclohexanol à carbone marqué, souligne que les bons rendements obtenus s'expliquent par l'absence de l'isomérisation du cycle de 6 atomes de carbone.

Pojeau [6] effectue la cyclohexylation du benzène avec du cyclohexanol aussi en présence de $TiCl_4$ et mentionne également que l'emploi du cyclohexanol est avantageux en comparaison d'autres agents de cyclohexylation, synthétisés en partant du cyclohexanol.

La cyclohexylation du benzène avec du cyclohexanol en présence de H_2SO_4 a été réalisée plus tard par Zavgorodnyi et ses collaborateurs [20] qui, bien qu'employant la chromatographie des produits obtenus, ne mettent pas en évidence la formation simultanée du cyclohexylbenzène et des méthylcyclopentylbenzènes ou des hydrocarbures cycliques saturés.

Comme agent de cyclohexylation on a utilisé le plus couramment le cyclohexène.

Corson et Ipatieff[21] par le traitement de grandes quantités de cyclohexylbenzène (825 g) à l'$AlCl_3$, à 80°, mettent en évidence la formation des dicyclohexylbenzène, diphénylcyclohexane, benzène, cyclohexane et methylcyclopentane, mais sans observer la formation de (méthyl-cyclopentyle) benzènes.

De même, en 1944, Nenitzescu [22] montrait qu'à la distillation du cyclohexylbenzène en présence d'$AlCl_3$ humide, une décomposition a lieu avec formation de benzène, de cyclohexane et de méthylcyclopentane. Aucune isomérisation du phénylcyclohexane n'est enregistrée.

RÉSULTATS ET DISCUSSIONS

Dans les tableaux 1—3 on a reporté, en pour cent, les différents produits à C_{12}, résultés de la cyclohexylation du benzène analysés par chromatographie, après une séparation préalable, par distillation en atmosphère et sous vide, du benzène pris à l'excès et des produits plus lourds de cyclohexylation ou de polymérisation.

Les données des tableaux révèlent que, dans la majorité des cas, outre le produit principal — le cyclohexylbenzène — des produits secondaires apparaissent aussi à la cyclohexylation du benzène, notamment :

Bicycloalkyls, tels que : *bi* (*méthyl-cyclopentyle*), *bicyclohexyle* et (*methyl-cyclopentyle*) *cyclohexane*. L'apparition de ces produits est plus facile à comprende lorsqu'on utilise comme agent de cyclohexylation le cyclohexène qui peut aussi subir des réactions de dimérisation, trimerisation,

etc.[23]. Le dimère qui doit être non saturé et qui se trouve en quantité appréciable au cas du catalyseur H_2SO_4 peut être transformé en produit saturé après les processus de transfert d'hydrogène [24].

Hydrocarbures non saturés constitués de deux noyaux à 5 ou 6 atomes de carbone dont l'un non saturé, qui n'ont pas subi des processus de disproportionnation, mais qui ont pu subir un rétrécissement de cycle.

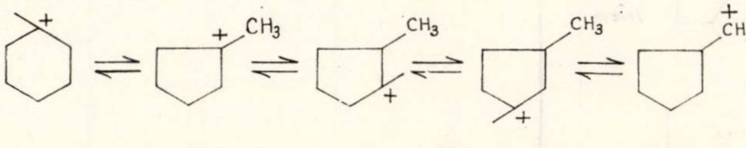
Isomères du (méthylcyclopentyl) benzène et le cyclopentyl-phenylmethane, résultés soit par un rétrécissement de cycle de l'agent d'alkylation soit par une isomérisation ultérieure du cyclohexylbenzène.

Cyclohexylation du benzène avec du chlorocyclohexane

On suppose que la réaction du chlorure de cyclohexyle avec le benzène, en présence d'acides Lewis, compte tenu des données de la littérature concernant la cinétique de certaines réactions similaires [25], a lieu par l'attaque électrophile du benzène par l'ion de carbone qui apparaît à la complexation du chlorure de cyclohexyle, par exemple avec le $AlCl_3$, avec la formation d'un complexe qui se décompose conduisant au cyclohexylbenzène

$$C_6H_{11}Cl + AlCl_3 \rightleftharpoons C_6H_{11}^+ + AlCl_4^-$$

La formation des ions de carbonium, même si l'équilibre est fortement déplacé à gauche, dû à l'impossibilité de la solvatation des ions dans le solvant non polaire (benzène), pourrait aussi être suivie de leur transposition par le transfert intramoléculaire d'un ion d'hydrure



Les deux ions $C_6H_{11}^+$ et $AlCl_4^-$ restent cependant réunis par une attraction électrostatique sous forme d'une paire d'ions qui se trouve, selon Nenitzescu, [25] dans une « Cage de dissolvant ». L'ion de carbonium réagit avec le benzène sans se détacher de l'anion

[23] R. Sperlyng, *J. Chem. Soc.*, **1949**, 1928.

[24] S. S. Nametkin et M. G. Rudenko, *Zhur org. Khim.*, **7**, 763 (1937) ; Chem. Abstr. **31**, 5750 (1937).

[25] C. D. Nenițescu, *Studii și Cercetări Chimice. București*. **12**, 5 (1964).

La formation du cyclohexylbenzène qui dépasse 99,5% (tableau 1) est en accord avec l'hypothèse de l'existence des paires d'ions ; l'apparition de certains ions de carbonium libres aurait mené à leur transposition et ensuite à l'attaque électrophile du benzène par les nouveaux ions de carbonium, avec formation de (méthylcyclopentyle) benzènes et cyclopentylphénylméthane en proportions fonction de la stabilité des différents ions de carbonium. Le pourcentage réduit d'isomères du cyclohexylbenzène, 0,41%, (0,08 + 0,32 + 0,01), atteste que dans les conditions de travail utilisées (25°), ce processus est très réduit, et cela sans tenir compte qu'une partie des isomères du cyclohexylbenzène serait due aux impuretés du chlorure de cyclohexyle utilisé (1,81% cyclohexanol).

L'addition d'eau au chlorure d'aluminium n'influence pratiquement pas les résultats (tabl. 1), ce qui montre que la cyclohexylation avec du chlorure de cyclohexyle ne subit pas de catalyse par l'acide $H^+(AlCl_3OH)^-$.

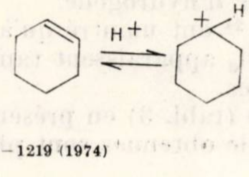
De même, le fait que le pourcentage d'isomères du cyclohexylbenzène ne s'élève pas (il est par contre moindre), par l'emploi du chlorure d'aluminium hydraté, en comparaison du cas où l'on utilise du chlorure d'aluminium anhydre, démontre que, au moins à 25°, le $H^+ (AlCl_3OH)^-$ ne réussit pas à arracher un ion d'hydrure du cyclohexylbenzène une fois formé pour le transformer ensuite en un ion de carbonium qui subisse par la suite la transposition.

En présence du tétrachlorure de titane (catalyseur plus faible que l'$AlCl_3$) la cyclohexylation du benzène avec du chlorure de cyclohexyle conduit à des quantités appréciables de cyclopentylphenylmethane(1,05%) en comparaison des cas où l'on utilise le chlorure d'aluminium. Le cyclopentylphénylméthane est probablement l'isomère thermodynamiquement le plus stable. La formation de l'isomère le plus escompté issu d'un ion de carbonium secondaire a été aussi rencontrée au cas d'autres hydrocarbures alkylaromatiques [25].

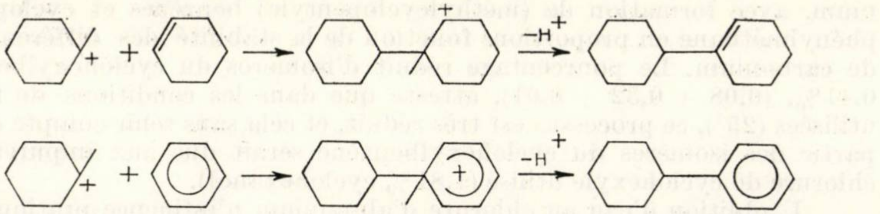
Cyclohexylation du benzène avec du cyclohexène

Un grand groupe d'impuretés dans le produit principal le cyclohexylbenzène, est formé de bicycloalkyls et cycloalkylcyclènes, qui sont présents si l'on utilise comme matières premières le cyclohexène et le cyclohexanol et sont pratiquement absents au cas du chlorure de cyclohexyle.

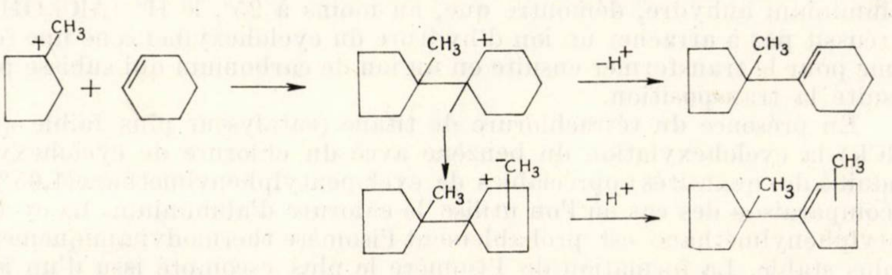
L'acide sulfurique (acide Brönsted) comme le chlorure d'aluminium et le chlorure de titane (acides Lewis) en présence de l'eau catalyseur, lorsqu'on forme par exemple le $H^+AlCl_3OH^-$, peuvent protonner le cyclohexène en créant un ion de carbonium : ensuite les réactants nucléophiles du milieu de réaction, le cyclohexène et le benzène, subissent l'attaque électrophile de l'ion de carbonium

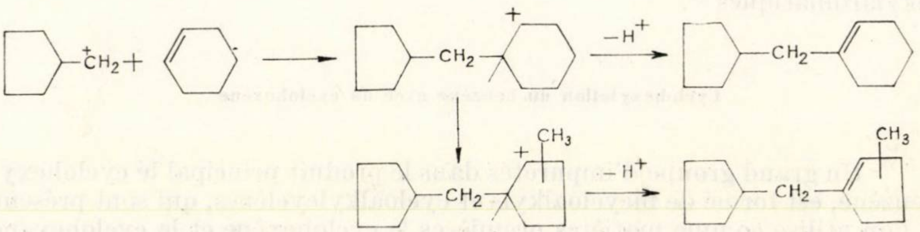


Le pourcentage très élevé de cyclohexylbenzène est dû d'une part au caractère nucléophile plus accusé du benzène par rapport au cyclohexène, et d'autre part à sa quantité à l'excès.



Du fait que l'ion de carbonium subit la transposition à l'attaque électrophile du cyclohexène par l'un des nouveaux ions de carbonium, il résulte un nouvel ion de carbonium qui peut expulser un proton ou peut subir une transposition suivie de l'expulsion du proton, comme par exemple :



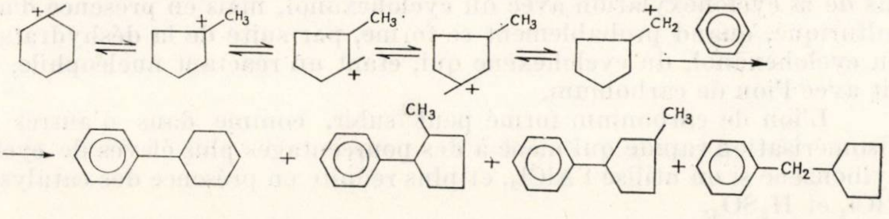


Conformément à ce mécanisme il faudrait q'il résulte des hydrocarbures dicycliques non saturés. Ces hydrocarbures sont présents en quantité accrue surtout lorsqu'on travaille en présence d'acide sulfurique (tabl. 2,3), mais de plus, on a mis en évidence également des hydrocarbures dicycliques saturés comme résultat de l'hydrogénation des dicyclènes simultanément avec la déshydrogénation de certains noyaux jusqu'au benzène par un processus de transfer d'hydrogène.

Nametkin et Rudenko [24] ont montré qu'à la polymérisation du cyclohexène en présence d'$AlCl_3$ apparaissent tant d'hydrocarbures saturés que de cycloalkyl-aromatiques.

Au cas du cyclohexène (tabl. 3) en présence des catalyseurs Lewis, les quantités de bicyclohexyle obtenues sont plus élevées, tandis que, en présence de l'acide sulfurique, les hydrocarbures non saturés sont prédominants.

A l'attaque électrophile du benzène par les ions de carbonium, il résulte les isomères suivants, sans tenir compte des isomères de conformation.



Le chlorure d'aluminium humide conduit à la formation d'une quantité double d'isomères cycloalkylbenzéniques par rapport au chlorure d'aluminium anhydre. Le fait s'explique par la production de l'acide $H^{+}(AlCl_3OH^{-})$ qui protonne le cyclohexène et qui détermine la formation de produits secondaires en proportions plus proches de celles obtenues par l'emploi de H_2SO_4 que par l'$AlCl_3$ anhydre (tableau 2).

Le tétrachlorure de titane, étant utilisé à l'état d'hydrat seulement, exerce, lui aussi, une action similaire à celle de l'acide sulfurique.

Lebedev [26] étudiant la cinétique de la réaction de cyclohexylation du benzène avec du cyclohexène en présence de $AlCl_3$ montre que l'agent d'alkylation est le chlorure de cyclohexyle formé par l'addition d'acide chlorhydrique (provenu de l'hydrolyse d'$AlCl_3$ avec les traces inhérentes d'eau) au cyclohexène. Ce fait concorde avec le rapprochement des résultats obtenus à la cycloalkylation du benzène avec cyclohexylchlorure et cyclohexène, en présence d'$AlCl_3$ anhydre (tabl. 1,2).

Cyclohexylation du benzène avec du cyclohexanol

A la cycloalkylation du benzène avec du chlorure de cyclohexyle et cyclohexène, l'$AlCl_3$ est nécessaire en quantités catalytiques seulement, tandis qu'à la cyclohexylation avec du cyclohexanol la quantité d'$AlCl_3$ est considérablement plus élevée (tableau 3), dû à la réaction.

$$C_6H_{11}OH + AlCl_3 \longrightarrow C_6H_{11}^{+}\ OHCl_3^{-} \longrightarrow$$

$$\begin{tikzcd}[column sep=small] \longrightarrow C_6H_{11}^{+} + & {[HOAlCl_3]^{-}} \arrow[dl] \arrow[dr] & \\ HO^{-} + AlCl_3 & & Al(OH)Cl_2 + Cl^{-} \end{tikzcd}$$

L'ion de carbonium attaque de façon électrophile l'unique réactant nucléophile présent, le benzène, formant le cycloalkylbenzène, ce qui explique le pour cent réduit de dicycloalkyls (0,03 %) au cas des catalyseurs $AlCl_3$ et $TiCl_4$ (tabl. 3), en comparaison de la cycloalkylation avec du cyclohexène (tabl. 2), en présence des mêmes catalyseurs où, par exemple, le bicyclohexyle se trouve en proportion de 0,45 %.

---

[26] N. N. Lebedev, *Zhur. obshchei Khim.*, **10**, 1782 (1954).

La quantité de bicycloalkyl est de même plus grande aussi dans le cas de la cyclohexylation avec du cyclohexanol, mais en présence d'acide sulfurique, quand probablement se forme, par suite de la déshydratation du cyclohexanol, du cyclohexène qui, étant un réactant nucléophile, réagit avec l'ion de carbonium.

L'ion de carbonium formé peut subir, comme dans d'autres cas, l'isomérisation rapide qui mène à des pourcentages plus élevés de cycloalkylbenzène si on utilise l'$AlCl_3$, et plus réduite en présence des catalyseurs $TiCl_4$ et H_2SO_4.

De même, les ions de carbonium peuvent réagir avec les ions de chlore résultés de la décomposition de l'ion complexe $(HOAlCl_3)^-$, avec la formation de chlorure de cyclohexyle, dont la présence a été d'ailleurs mise en évidence par chromatographie.

Les isomères formés à la cyclohexylation du benzène avec du cyclohexanol en présence de H_2SO_4 comme catalyseur (tableau 3) sont également dus, aussi dans ce cas, à la formation de l'ion de carbonium qui est isomérisé.

$$C_6H_{11}OH + H_2SO_4 \longrightarrow C_6H_{11}OSO_2 + H_2O$$

$$C_6H_{11}OSO_2OH \rightleftharpoons C_6H_{11}^+ + HSO_4^-$$

PARTIE EXPÉRIMENTALE

Le benzène utilisé a été un produit commercial Reactivul séché sur au sodium et dont la pureté a été vérifiée par chromatographie.

Le chlorure de cyclohexyle a été obtenu du cyclohexanol et de l'acide chlorhydrique et purifié par rectification, à la chromatographie le produit purifié contenait 97,65 % chlorure de cyclohexyle, 1,81 % cyclohexanol, 0,16 % cyclohexanone et 0,25 % benzène, la reste constituant des impuretés indéterminées.

Le cyclohexène a été obtenu par déshydratation du cyclohexanol, avec de l'acide phosphorique comme cataylseur [28], son analyse chromatographique révèlent une pureté de 99,8 %.

Le cyclohexanol, produit Reactivul, analysé par chromathographie, avait une pureté de 97,6 % les impuretés principales étant le cyclohexanone 0,7 % et l'eau 1 %.

L'$AlCl_3$ a été un produit commercial Merck (sublimiert zur synthese).

Le $TiCl_4$ — un produit commercial Fluka.

Le H_2SO_4 — un produit commercial *p.a.*

La cyclohexylation du benzène a été realisée dans un ballon de 250 ml, à quatre cols muni d'un agitateur, réfrigérant ascendant, d'un tube de $CaCl_2$, d'un thermomètre et d'un entonnoir compte gouttes. Dans le ballon est d'abord introduit le benzène et le catalyseur, et ensuite graduellement l'agent d'alkylation, de façon que la température ne dépasse pas 20° (le ballon était refroidi dans un bain d'eau). Au cas de la cyclohexylation de benzène avec du cyclohexène et du

[27] H. Pines, W. D. Huntsman et V. N. Ipatieff, *J. Amer. Chem. Soc.*, **73**, 4343 (1951).

[28] W. M. Dehn et K. E. Jackson, *J. Amer. Chem. Soc.*, **55**, 4285 (1933).

chlorure de cyclohexyle en présence de $TiCl_4$, sur les réactants et le catalyseur on a ajouté de l'eau en portions réduits, tenant compte que la réaction du $TiCl_4$ avec l'eau est violente.

Les produits de réaction ont été traités, au cas où l'on utilise les acides Lewis, comme catalyseurs, avec une solution de HCl pour la solubilisation du catalyseur et au cas de H_2SO_4 on a éliminé le goudron formé. Les produits de réaction sont ensuite lavés à l'eau à une solution de $NaHCO_3$ 10% et de nouveau à l'eau. On sèche sur chlorure de calcium et, ensuite, par distillation à pression normale, le benzène à l'excès est écarté ; le reste est distillé *in vacuum* (12mm Hg). On a séparé la fraction correspondant aux hydrocarbures à C_{12}.

L'analyse chromatographique a été effectuée à l'aide d'un chromatographe Carlo Erba modèle G.T. —200 à double détecteur de conductibilité thermique et à gaz porteur hydrogène, à savoir.

Pour les matières premières — sur une colonne à carbowax 20 M, 20% sur chromosorb W 60/80 msh, $l = 2{,}5$ m, $\varnothing = 2$ mm, respectivement à 50° pour le cyclohexène et à 110° pour le chlorure de cyclohexyle et cyclohexanol ; la pureté du cyclohexanol a été aussi vérifiée a une température plus élevée de la colonne (150°).

Pour la composition de la fraction C_{12}, l'identification, et la séparation ont été effectuées conformément aux procédés décrits dans un travail précédent.[29]

Les résultats quantitatifs sont exprimés en % aires.

CONCLUSIONS

On a analysé pour la première fois, par la méthode chromatographique des gaz les produits de cyclohexylation à C_{12} du benzène.

La cyclohexylation du benzène avec du chlorure de cyclohexyle en présence d'$AlCl_3$ anhydre ou hydraté conduit au produit le plus pur, du cyclohexylbenzène au-dessus de 99,5%. Des dimères du cyclohexène n'apparaissent pas, l'ion de carbonium intermédiaire ne trouvant pas autre réactant nucléophile dans le milieu de réaction en dehors du benzène. Le rétrécissement du noyau de 6 atomes de carbone du radical cyclohexyle se produit en petite mesure.

La cyclohexylation du benzène avec du cyclohexène mène à la formation de bicycloalkyls par suite des réactions de dimérisation et de transfert d'hydrogène, en présence de $AlCl_3$ (anhydre et hydraté), de $TiCl_1$(hydraté) et de H_2SO_4, catalyseurs, ainsi qu'à la formation d'hydrocarbures non saturés en présence de H_2SO_4, ce qui est possible dû à l'attaque électrophile des ions de carbonium intermédiaires non seulement contre le benzène, mais aussi contre le cyclohexène.

La cyclohexylation du benzène du cyclohexanol, recommandée par certains auteurs comme la voie la plus commode d'obtention du cyclohexylbenzène (vu que le chlorure de cyclohexyle et le cyclohexène sont préparés en partant du cyclohexanol) n'est pas indiquée, celle-ci menant à des produits secondaires toujours avec du C_{12}, impossibles à séparer par les méthodes courantes, en proportion de 2 à 4%.

THE SYNTHESIS OF 2,6-DICHLOROBENZALDOXIME FROM 4-NITROTOLUENE

P. BUCHWALD and F. DOMNARIU

Chemical-Pharmaceutical Research Institute, str. Fabricii 126, Cluj, Romania

Received July 17, 1971

Revised text received October 5, 1973

The synthesis of 2,6-dichlorobenzaldehyde and the respective 2,6-dichlorobenzaldoxime from 4-nitrotoluene by successive nucleus and side-chain chlorination is described. It is shown that by nucleus chlorination, besides 2-chloro-4-nitrotoluene and 2,6-dichloro-4-nitrotoluene, the derivative chlorinated in 2, 3, 6 positions is also produced. In side-chain chlorination of 2,6-dichlorotoluene under free radical conditions, the products containing one, two and three chlorine atoms in their side chain are also resulting. A convenient chemical method for their separation is described.

According to the literature the 3(2,6-dichlorophenyl)-5-methylisoxazole-4-carboxylic acid—the principal intermediate in dicloxacilline synthesis — usually is obtained from 2,6-dichlorobenzaldehyde.

Our principal aim being the synthesis of this semisynthetic penicilline, as a first step in our investigation we proposed to find a method for the preparation of the 2,6-dichlorobenzaldehyde and the respective 2,6-dichlorobenzaldoxime from a convenient starting material.

It was shown [1] that the 2,6-dichlorobenzaldehyde has been obtained by the hydrolysis of the 2,6-dichlorobenzal chloride. The latter has been prepared by the chlorination of the 2-nitro-6-chlorotoluene, when besides the side-chain chlorination, the nitro group was also substituted with chlorine atom. [2]

We have considered as a first step for the synthesis of 2,6-dichlorobenzaldehyde the preparation of 2,6-dichlorotoluene because of its easy conversion into 2,6-dichlorobenzal chloride, under the side-chain chlorination conditions.

It is well known [3] that the direct nucleus chlorination of the toluene is not selective, for it leads to a complex mixture of the positional isomers of the chlorotoluenes. From this the isolation of 2,6-dichlorotoluene is very difficult.

Since the separation of the positional isomers of dichlorotoluene is more difficult than the isolation of mono-, di-, and trichlorotoluenes, we intended to chlorinate in nucleus a toluene derivative in which the 3, 4 and 5 positions were protected by a convenient group which was easy to eliminate after chlorination.

Although it seemed that 4-aminotoluene was a convenient starting material in this direction, the method which involved the treatment of the acetyl derivative of *p*-toluidine was not really satisfactory, for it led to a very crude amine, with a low yield.[4]

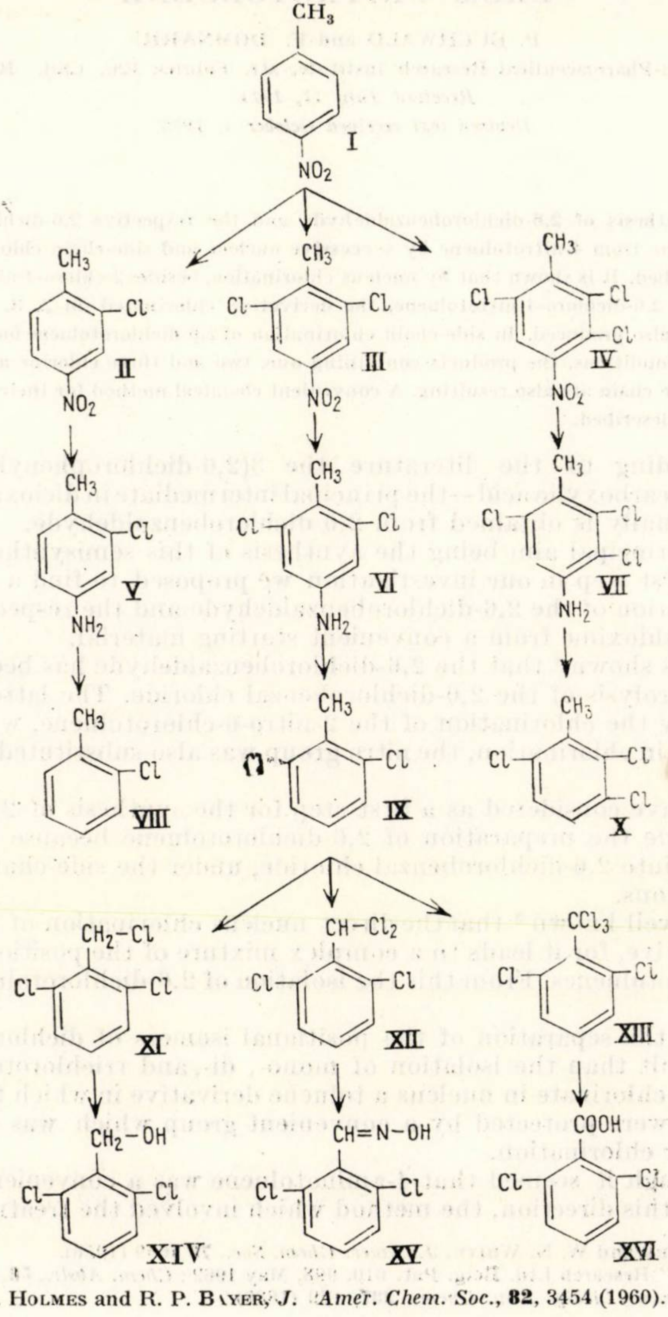
Thus, to obtain 2,6-dichlorobenzaldoxime we used as starting material the 4-nitrotoluene, the synthesis involving the following steps (see scheme):



---

[4] R. R. Holmes and R. P. Bayer, *J. Amer. Chem. Soc.*, **82**, 3454 (1960).

Naturally, we supposed that in this case the nitro group would protect the 3, 4, and 5 positions from chlorination.

However, when the chlorination of 4-nitrotoluene (I) was effected by Davies' method [5] at 65 – 75° with chlorine in the presence of antimony pentachloride, until the reaction mixture increased in weight corresponding to two chlorine atoms, besides 2-chloro-4-nitrotoluene (II) and 2,6-dichloro-4-nitrotoluene (III) the 2, 3, 6-trichloro-4-nitro-compound (IV) was also produced. This was confirmed by the isolation of 2-chloro-4-aminotoluene (V), 2,6-dichloro-4-aminotoluene (VI), and 2,3,6-trichloro-4-aminotoluene (VII) from the reaction mixture obtained by reduction of the corresponding nitro compounds by Béchamp's method (iron filings, acetic acid in aqueous solution). These were separated by fractionated distillation under reduced pressure and were characterized by their acetyl derivatives' melting points.

The replacement of the amino group by hydrogen was carried out by a modification of Coleman and Talbot's method [6] for the preparation of sym.-tribrombenzene from 2, 4, 6-tribromoaniline. In this way, working at 70 – 80° in benzene-ethanol (1 : 3) solution in the presence of concentrated sulphuric acid, and using crystalline sodium nitrite we succeeded to synthesize 2,6-dichlorotoluene (IX) with an 80 % yield as referred to (III).

By the side-chain chlorination of 2,6-dichlorotoluene (IX) under free radical conditions (at 180° with UV source, or at 90 – 110° in the presence of 2,2′-azo-bis-isobutyronitrile [7]) there resulted also the entrance of one, two and three chlorine atoms in the side chain. Although their isolation is possible by fractionated distillation, the boiling points being very close an efficient fractionating column must be used. In order to avoid these inconveniences and the inevitable loss of compounds owing to the fractionated distillation, we proposed to use for the separation a chemical method. Thus, by hydrolysing together the side-chain chlorinated derivatives of 2,6-dichlorotoluene (XI – XIII) with concentrated sulphuric acid (90 – 94 %) in the presence of hydroxylamine hydrochloride, followed by transfer of the reaction mixture in water-ice, in the hydrolysate there will be obtained : 2,6-dichlorobenzylic alcohol (XIV) (formed by hydrolysis of (XI)), 2,6-dichlorobenzaldoxime (XV) (from (XII)), and 2,6-dichlorobenzoic acid (XVI) (from (XIII)). When the hydrolysate is extracted with an organic solvent (it has been proved that the most convenient is the butyl acetate) the products of hydrolysis pass into the organic phase. After washing the organic layer with water (to eliminate the inorganic acid traces) the butyl acetate solution is treated with saturated sodium bicarbonate solution. Thus, the 2,6-dichlorobenzoic acid passes into the aqueous phase as sodium salt. From this, after treatment with dilute hydrochloric acid, the pure (XVI) is obtained. Melting point : 143 – 145° (141 – 142° [1]).

By repeated extractions with diluted sodium hydroxide (10 %) from the organic layer the 2,6-dichlorobenzaldoxime, as sodium salt, passes into the aqueous alkaline phase, from which the almost pure (XV) is precipitated by acidulation. Melting point : 149° (133–137°[2]; 147 – 148°[8]).

---

[5] W. Davies, *J. Chem. Soc.*, **121**, 812 (1922).

[6] G. H. Coleman and W. F. Talbot, "Organic Syntheses", Coll. Vol. 2, New York, 1948, p. 592.

[7] "Shell" Research Ltd. Fr. Pat. 1, 343, 178 Dec. 12, 1962 ; *Chem. Abstr.*, **60**, 9208 (1964).

The 2,6-dichlorobenzylic alcohol (XIV) and other by-products without an acid character remain in the organic layer. Thus, the quantitative isolation of the side-chain chlorinated compounds, respectively their hydrolysis products, is possible.

By hydrolysis of 2,6-dichlorobenzaldoxime, followed by steam distillation, the 2,6-dichlorobenzaldehyde may be obtained in a good yield. Since the first step in the 3 (2,6-dichlorophenyl)-5-methyl-isoxazole-4-carboxylic acid synthesis is just the preparation of dichlorobenzaldoxime from 2,6-dichlorobenzaldehyde, it was not necessary to accomplish the hydrolysis of (XV).

EXPERIMENTAL

Melting points are uncorrected.

1. The nucleus chlorination of 4-nitrotoluene

548 g (4 moles) of 4-nitrotoluene were chlorinated by barbotage of chlorine at 70–80° in the presence of antimony pentachloride (20 g) in about 5 hours, until the reaction mixture increased in weight 270–280 g. The reaction mixture was poured into about 4 l cold water, the lower oil layer was separated and washed with dilute sodium hydroxide and water successively.

The resulted crude chlorinated 4-nitrotoluene (containing (II), (III), and (IV) weighed 768 g and was used as such for the preparation of the chlorinated 4-aminotoluene.

2. The reduction of nitro group

A mixture of the above obtained crude chlorinated 4-nitrotoluene (768 g), grease-free iron filings (500 g) — previously activated by washing with dilute hydrochloric acid, - ammonium chloride (17 g), acetic acid (15 ml), and water (about 1 l), was heated gently at 80–90° and maintained at this temperature under vigorous stirring, by alternate heating and cooling, for two –three hours. When the exotherm reaction was finished, the reaction mixture was heated on a water bath under stirring for another 10 hours, in order to complete the reaction. After cooling, the amine separated as an oil, the iron residues were filtered off and washed with benzene. The filtrate was separated, the solvent was removed and then distilled at reduced pressure. The mixture of mono-, di-, and trichloro-4-aminotoluene (V – VII) distils at 105–141° /4–5 mm.

529 g (400 ml) chlorinated 4-aminotoluene derivatives were obtained.

3. The replacement of the amino group by hydrogen

The chlorinated 4-aminotoluene (529 g) was dissolved in an ethanol (4 l)–benzene (1.5 l) mixture, and was treated under stirring with concentrated sulphuric acid (300 ml). To the hot solution at 70–72° the powdered sodium nitrite was added in three portions (3 × 100 g).

---

[8] "Bristol-Myers Co." U.S.A.Pat. 6, 603, 496, Sept. 19, 1966 ; *Chem. Abstr.*, **63**, 15390 (1965).

The reaction heat and nitrogen evolution led to a vigorous boiling of the solution. After the boiling slowed down, the reaction mixture was heated on a boiling water bath as long as gas was evolved (about 2–3 hours), and then was distilled in steam until no more oil passed over (about 5 l distillate). The distillate was separated , washed successively with sodium hydroxide solution (10%) and water, the solvent was removed and the halogenated toluene derivatives were fractionated at reduced pressure. At 5 mm :

between 43–45° there were distilled 113 g of 2-chlorotoluene (VIII)
61–64° ,, 117 g of 2,6-dichlorotoluene (IX)
87–100° ,, 90 g of 2, 3, 6 – trichlorotoluene (X)

4. The side-chain chlorination of 2,6-dichlorotoluene

Dry chlorine gas was bubbled in 2,6-dichlorotoluene (117 g) at 90–100° in the presence of 2,2′-azo-bis-isobutyronitrile (5g), until the reaction mixture increased in weight with 51–52 g (corresponding to the obtaining of 2,6-dichlorobenzal chloride). The cooled reaction mixture was poured into water, the lower oil layer was extracted with benzene (500 ml) and after separation dried on calcium chloride. After this, the solvent was removed and the obtained crude mixture of 2,6-dichlorobenzyl chloride (XI), 2,6-dichlorobenzal chloride (XII) and 2,6-dichlorobenzenyl chloride (XIII) was hydrolysed as such.

5. The obtaining and isolation of 2,6-dichlorobenzaldoxime

The crude mixture of chlorinated 2,6-dichlorotoluene was mixed with concentrated sulphuric acid (200 ml) and then treated under stirring with hydroxylamine hydrochloride (50 g) in portions (vigorous hydrogen and azote gas evolution !). After the hydroxylamine hydrochloride was introduced, the mixture was stirred for three hours at 55–60°, then poured into an ice-water mixture. The separated crystals were extracted with butyl acetate (500 ml). The organic layer was washed with water and then extracted three times with saturated sodium bicarbonate solution (3 × 200 ml). From the acidulated aqueous solution the crystalline 2,6-dichlorobenzoic acid (XVI) (6.5 g) with m.p. 143 – 145° was obtained. After recrystallization from ethanol-water (1 :1), the melting point rised at 149–150° (141–142° [1]).

The 2,6-dichlorobenzaldoxime (XV) was extracted from butyl acetate solution with dilute sodium hydroxide (10%) solution (6 × 100 ml). When the aqueous alkaline solution was acidulated to pH = 1, the crystalline (XV) separated and was filtered off. After washing with water and drying, 80 g 2,6-dichlorobenzaldoxime (XV) with m.p. 139–143° resulted. After recrystallization from ethanol-water (1 : 1), the melting point rised at 149° (147° [8]).

The yield of 2,6-dichlorobenzaldoxime calculated on 4-nitrotoluene is 12.5%.

The reaction heat and nitrogen evolution led to a vigorous boiling of the solution. After the boiling slowed down, the reaction mixture was heated on a boiling water bath as long as gas was evolved (about 2 - 3 hours), and then was distilled in steam until no more oil passed over (about 5 l distillate). The distillate was separated, washed successively with sodium hydroxide solution (15%) and water, the solvent was removed and the halogenated toluene derivatives were fractionated at reduced pressure. At 5 mm:

between 50 - 60° there were distilled 113 g of 2-chlorotoluene (VIII)
61 - 84° 117 g of 2,6-dichlorotoluene (IX)
87 - 110° 90 g of 2,3,6 - trichlorotoluene (X)

4. The side-chain chlorination of 2,6-dichlorotoluene

Dry chlorine gas was bubbled in 2,6-dichlorotoluene (117 g) at 160 - 180° in the presence of 2,2'-azodi-isobutyronitrile (1g), until the reaction mixture increased in weight with 51 - 52 g corresponding to the obtaining of 2,6-dichlorobenzal chloride. The cooled reaction mixture was poured into water. The lower oil layer was extracted with benzene (500 ml) and after separation dried on calcium chloride. After this, the solvent was removed and the obtained crude mixture of 2,6-dichlorobenzyl chloride (XI), 2,6-dichlorobenzal chloride (XII) and 2,6-dichlorobenzotrichloride (XIII) was hydrolysed as such.

5. The hydrolysing and oximation of 2,6-dichlorobenzalchlorides

The crude mixture of chlorinated 2,6-dichlorotoluene was mixed with concentrated sulphuric acid (200 ml) and then heated under stirring with hydroxylamine hydrochloride (41 g) in portions. Vigorous hydrogen chloride gas evolution. After the hydroxylamine hydrochloride was introduced, the mixture was stirred for three hours at 55 - 60°, then poured into an ice-water mixture. The separated crystals were extracted with butyl acetate (500 ml). The organic layer was washed with water and then extracted three times with saturated sodium bicarbonate solution (3 x 200 ml). From the acidulated aqueous solution the crystalline 2,6-dichlorobenzoic acid (XIV) (5.5 g) with m.p. 140 - 142° was obtained. After recrystallization from diluted ethanol (1:1), the melting point rose to 148 - 150° (141 - 142° [1]).

The 2,6-dichlorobenzaldoxime (XV) was extracted from butyl acetate solution with diluted sodium hydroxide (10%) solution (3 x 150 ml). When the aqueous alkaline solution was acidulated to pH = 1, the crystalline (XV) separated and was filtered off. After washing with water and drying, 50 g 2,6-dichlorobenzaldoxime (XV) with m.p. 139 - 141° resulted. After recrystallization from ethanol-water (1 : 1), the melting point fixed at 149 (149° [2]).

The yield of 2,6-dichlorobenzaldoxime calculated on 4-nitrotoluene is 12.7%.

RADICAL-IONS. II[1]

NITROPHENOTHIAZINE RADICAL-IONS

MIHAELA HILLEBRAND[a] and M. RĂILEANU[b]

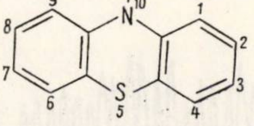
[a] University of Bucharest, Department of Physical Chemistry, B-dul Republicii 13

[b] University of Craiova, Department of Organic Chemistry, Str. Alex. I. Cuza 13

Received October 31, 1973

ESR spectra of the positive and negative radical-ions of some nitrophenothiazines are presented and discussed. The hyperfine splitting constants point out an essential change of the spin density pattern for the two radical species.

Three radical species, the radical-cation, the neutral free radical and the nitroxide radical, were previously described for phenothiazine and some of its N-substituted derivatives, [1–11] but no data on the negative radical-ions are available. * As nitrophenothiazines connect the donor character of the phenothiazinic cycle with the electronegative property of the nitro group it was expected to obtain from them both positive and negative radical-ions. It is the aim of this paper to report the ESR spectra of both kinds of radicals prepared from some nitro-substituted pheno-



---

* The paper of Bruin et al.[12] claiming the formation of negative ions from some phenothiazine derivatives is not very conclusive, as the hyperfine splittings reported are more consistent with the neutral free radicals in spite of the experimental technique used.

thiazines and phenothiazine-5-oxides, and to reveal their completely different spin density pattern.

EXPERIMENTAL

The 3-nitro- and 3,7-dinitrophenothiazine radical-cations were obtained by solving the parent compound[13] or the correspondent sulphoxides [14] in concentrated sulphuric and perchloric acids .[4] Due to the strong effect of the four nitro groups on the donor properties of phenothiazine, the preparation of the radical-cation from 1, 3, 7, 9-tetranitrophenothiazine [15] failed.

The negative radical-ions from the same compounds were electrolytically generated in dimethylformamide (DMF). In order to verify some assumptions on the nautre of the negative species obtained, the radical-ion of the sodium salt of 1,3,7,9-tetranitrophenothiazine-5-oxide was also prepared.

The ESR spectra were registered on a JES—3B spectrometer in the X band frequency at room temperature. The spectra were interpreted following the technique described by Balaban[16] and simulated using the QCPE—83 simulation program adapted for an IMB—360 computer.

RESULTS AND DISCUSSION

The low resolution spectra of 3-nitro- and 3,7-dinitro-phenothiazine radical-cations exhibit the general pattern of the phenothiazinic radical-cation, that is four lines with the intensities 1 : 2 : 2 : 1, due to the quasi-equivalent coupling of the heterocyclic nitrogen and the iminic proton. At higher resolution the hyperfine interaction with the other nuclei was also evidenced (figs. 1 and 2), but only the spectrum of the 3,7-dinitrophenothiazine cation-radical was completely interpreted. Owing to the high viscosity of the solvents and to the *g* factor anisotropy,[17] the spectra present important line-width effects, that render their analysis more difficult and intro-

duce some uncertainty in the estimation of the a_N, a_H splittings. The hyperfine splitting constants are listed in table 1.

Table 1

Hyperfine splittings of nitrophenothiazine radical-ions

Parent compound	Radical species	Hyperfine splittings (Gauss)			
		a_N	a_H^{NH}	a_{NO_2}	Ring proton splittings
3-Nitrophenothiazine	Positive ion	6.30	7.03		
3,7-Dinitrophenothiazine	Positive ion	6.22	6.95	0.59	0.30(2) ; 1.18(2)
3-Nitrophenothiazine-5-oxide	Negative ion	—	—	11.50	1.11 ; 2.22 ; 4.74
3,7-Dinitrophenothiazine-5-oxide	Negative ion	1.18	—	4.59	0.78(2) ;1.96(4)
1,3,7,9-Tetranitrophenothiazine-5-oxide	Negative ion	1.48	—	1.48 2.70	—
3,7-Dinitrophenothiazine	Negative ion	1.92	—	4.22	0.96(2) ; 1.92(2) ; 4.22(2)

The unpaired electron is mainly localized on the heterocyclic nitrogen, the nitro group splitting being unsignificant, although the 3,7 positions are characterized by a high spin density in the unsubstituted phenothiazine radical-cation.

The spectra of the negative species obtained for the nitrophenothiazine-5-oxides are presented in figs. 3—5, the constants being also listed in table 1.

The presence of several nitro groups enhanced the delocalization of the unpaired electron on the whole molecule, the nitro group splitting decreasing from 11.50G (the mononitroderivative) to 2.70G (the tetranitroderivative). Simultaneously, the heterocyclic nitrogen splitting is fairly increased, its greatest value being reached for 1,3,7,9-tetranitrophenothiazine-5-oxide, where the nitrogen atom is situated in the environment of two nitro groups. As the total length of the spectrum is also stronly diminuted, a great amount of spin density is probably transferred to the carbon positions not experimentally measurable and to the sulphoxidic group.

The differences found between the spectra of 3,7-dinitrophenothiazine-5-oxide and 3,7-dinitrophenothiazine negative ions (fig. 6 ; table 1), that is the decrease of some splitting constants for the former, are in agreement with the electronegative effect of the sulphoxidic group on the spin density distribution.[18]

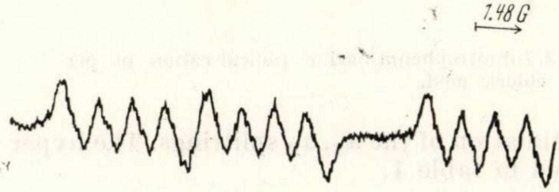

Fig. 3. — Low field half of the ESR spectrum of the 3-nitrophenothiazine-5-oxide negative ion.

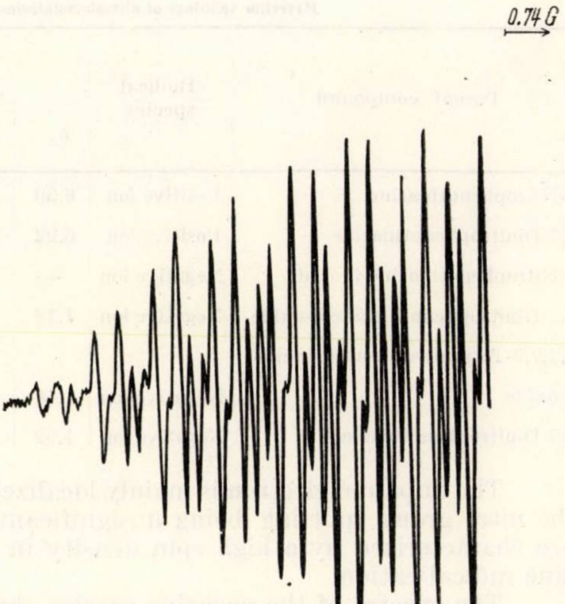

Fig. 4. — Low field half of the ESR spectrum of the 3,7-dinitrophenothiazine-5-oxide negative ion.

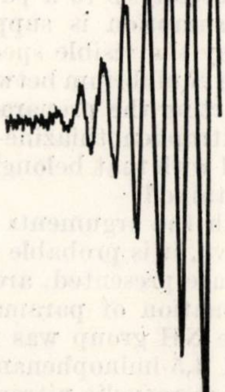
---

[18] E. T. Kaiser and D. H. Eargle, *Proc. Chem. Soc.*, **1964**, 22.

Fig. 5. — High field half of the ESR spectrum of the 1, 3, 7, 9-tetranitrophenothiazine-5-oxide negative ion.



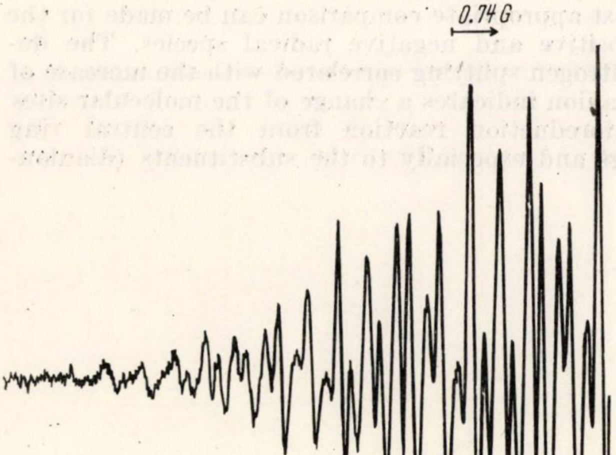


Fig. 6. — Low field half of the ESR spectrum of the 3,7-dinitrophenothiazine negative ion.

In none of the ESR spectra of the negative ions the iminic proton splitting was observed. Although for 3-nitrophenothiazine-5-oxide this could be due to the lack of a total resolution, in the other cases it is unlikely, as the heterocyclic nitrogen has a measurable splitting. The absence of the iminic proton could be explained by a previous dissociation of the parent compound, the nitrophenothiazinic anion being further reduced during the electrolysis to a paramagnetic dianion-radical.

This assumption is supported for the 1,3,7,9-tetranitrophenothiazine-5-oxide by the visible spectrum in the same solvent (DMF), [19] which agrees with an equilibrium between the dissociated and undissociated forms. Secondly, starting the preparation of the radical from the sodium salt of 1,3,7,9-tetranitrophenothiazine-5-oxide, completely dissociated, a spectrum identical with that belonging to the 1,3,7,9-tetranitrophenothiazine-5-oxide was obtained.

Although the arguments hitherto presented refer only to the tetranitro derivative, it is probable that in all cases the negative species whose ESR spectra are presented, are paramagnetic dianion-radicals.

The formation of paramagnetic dianion-radicals from heterocycles containing the NH group was previously reported by Janzen et al. [20] for carbazole and 4,5-iminophenanthrene. Their result concerning the small value of the heterocyclic nitrogen splitting is consistent with ours and it is probably characteristic of this kind of radicals.

The hyperfine splitting constants from table 1 reveal the important differences in the spin density distribution between the positive and negative radicals-ion. The most appropriate comparison can be made for the 3,7-dinitrophenothiazine positive and negative radical species. The decrease of the heterocyclic nitrogen splitting correlated with the increase of the NO_2 splitting for the dianion indicates a change of the molecular sites mainly implied in the oxidoreduction reaction from the central ring (cations) to the lateral rings and especially to the substituents (dianion-radicals).

MATHEMATISCHE DARSTELLUNG DER HOMOLOGIE UND DER HOMOLOGEN SERIEN. I

ÜBER DIE BESCHREIBUG DER CHEMISCHEN SYSTEME MIT HILFE DER be-MATRIZEN

IOAN MOŢOC

Fakultät für Industriechemie, Polytechnisches Institut „Traian Vuia“ Timişoara

Eingegangen am 8. Mai 1973

Diese Arbeit versucht zu dem Bergriff der von I.Ugi und P. P. Gillespie vorgeschlagenen be-Matrizen, durch ein konstruktives Verfahren, das auf Operationen in einem Ring fußt, zu gelangen. Gleichfalls werden einige Zusätze zu obengenannter Arbeit gebracht. Es wird eine neue Erläuterung des Begriffs der chemischen Reaktion vorgeschlagen.

1. EINLEITUNG

In ihrer Arbeit „Beschreibung chemischer Systeme und ihrer Umwandlungen durch be-Matrizen und ihre Transformationseigenschaften“ [1] schlagen die Autoren die Verwendung der be-Matrizen vor, als vorteilhafte Möglichkeit der Beschreibung chemischer Systeme.

Eine Familie isomerer Ensembles von Molekülen (FIEM) wird als Menge der Ensembles von Molekülen, die aus demselben Satz (A) abgeleitet werden, definiert. Also:

$$\mathrm{FIEM} = \{\mathrm{EM}_0, \mathrm{EM}_1, \ldots, \mathrm{EM}_f\} \tag{1}$$

Im allgemeinen kann man beweisen, daß der Rang der Menge (1) gleich ist mit:

$$|\mathrm{FIEM}| \leqslant (2N)!/2^T \cdot (2N - T)! \tag{2}$$

wobei N die Gesamtanzahl der im Grundzustand besetzten AO und der ICAO-MO darstellt. T stellt die Anzahl der Valenzelektronen in A dar.

Wenn der Rang der Menge A gleich $|A| = n$ ist, dann wird die M_j zugeordnete Matrix vom Typ $n \times n$ sein, für jedwelches $\mathrm{EM}_j \in \mathrm{FIEM}$, $j = 1 \div f$.

---

[1] I. Ugi u. P. Gillespie, *Angew. Chem.*, **23**, 980 (1971).

Dies ist im Grunde genommen der wichtigste Vorteil, den man durch die Einführung des Begriffes FIEM erzielt : Alle Matrizen, mit welchen man im Rahmen eines FIEM operiert, werden dieselben Dimensionen besitzen.

Die be-Matrizen werden als $Mn \times n$ Matrizen wie folgt definiert :

$$M = [m_{ij}], \quad i = 1 \div n \,; \; j = 1 \div n \,; \tag{3}$$

wobei die Elemente :

m_{jj} für $i > j$ als $m_{ij} = b_{ij}$ bezeichnet werden. Die Menge der Elemente b_{ij} bilden die b-Zone der Matrix.

m_{ij} für $i < j$, werden mit $m_{ij} = i_{ij}$ bezeichnet. Die Menge der Elemente i_{ij} bilden die i-Zone der Matrix.

m_{ij}, für $i = j$ bezeichnet man mit $m_{ij} = \mathrm{e}_{\lambda = ii = jj}$.

2. ÜBER DIE M-MATRIZEN

Was diese Arbeit Neues gegenüber der angeführten Arbeit bringt, ist die Eingliederung dieses Formalismus in die Theorie der Kategorien, was zu einem höheren Abstraktisierungsgrad führt.

Gegeben sei die Kategorie $C \in U - A$, so daß :

$$\mathrm{Ob\,C} = M \tag{4}$$

M definiert man :

$M : R \in U$-Ens, wobei R die Menge der reellen Zahlen darstellt M stellen die der FIEM zugeordneten b-Matrizen dar, wobei $|A| = n$, mit F wurde die Menge $\{M_0, M_1, \ldots, M_f\}$ bezeichnet.

Die Menge $\mathscr{F}$ der Matrizen $n \times n$ kann mit der Addition $(+)$ und dem direkten Produkt $(\times)$ als Verknüpfungsgesetz ausgestattet werden. Also erhält man in Wirklichkeit ein Objekt aus $U - A$. Selbstverständlich $F \subset \mathscr{F}$.

Ein EM$\in$FIEM kam durch ein symmetrisches Graph $G = (X, \Gamma)$ dargestellt werden, was die Gleichheit $g_{ij} = g_{ji}$ in der Einfallsmatrix $\mathscr{G}$ bestimmt. G wird im allgemeinen mehrere konexe Komponenten (selbstverständlich nicht stark konexe) besitzen. Die Anzahl dieser konexen Komponenten ist gleich mit der Anzahl der Moleküle, die das EM bilden.

Das Vorhandensein mehrerer konexer Komponenten führt zur Tatsache, daß wenigstens eine Indexierung der Eckpunkte des Graphes existenzfähig ist, für welchen die Einfallsmatrix in blockierter Form erscheint.

Die Einfallsmatrix baut man auf, indem man als Element g_{ij} die formale Ordnung der Bindung zwischen den Atomen i und j setzt. Es ist offensichtlich, daß man so eine Matrix $[b_{ij}]$ erhält.

Um eine be-Matrix zu erhalten, kann man wie folgt vorgehn :

$$[b_{ij}] \times [\lambda_{ij}] \tag{5}$$

wobei :

$$\lambda_{ij} = \begin{cases} 0, & i < j \\ 1, & i > j \end{cases}$$

Die Matrix (5) enthält die b-Zone, der Rest der Elemente ist gleich mit Null.
Weiterhin :

$$[b_{ij}] \times [\lambda_{ij}] + [\delta_{ij} \cdot e_{ij}] \tag{6}$$

Wobei :

$$\delta_{ij} = \begin{cases} 0, & i \neq j \\ 1, & i = j \end{cases}$$

Die Matrix (6) enthält auch die Elemente $e_{\lambda=ii=ji}$.

Die Matrix (7) ist eine be-Matrix :

$$[b_{ij}] \times [\lambda_{ij}] + [\delta_{ij} \cdot e_{ij}] + [i_{ij} \cdot \lambda'_{ij}] \tag{7}$$

wobei :

$$\lambda'_{ij} = \begin{cases} 0, & i > j \\ 1, & i < j \end{cases}$$

Die Beziehung (7) zeigt an,daß die Informationen bezüglich der Eigenschaften $L_1 \ldots, L_l$ der Paare A_i, A_j nur so angeordnet sein müssen, wie es die Regeln $\mathfrak{L}_1, \ldots, \mathfrak{L}_l$ erfordern.

$\mathfrak{L}_j$ können matriziell dargestellt werden. Z. B. : Wenn L_1 sich auf die Valenzelektronen bezieht, so hat $\mathfrak{L}_1$ die Form :

$$\mathfrak{L}_1 \sim [\delta_{ij}]$$

BEMERKUNGEN

In der gewöhnlichen Schreibweise :

$$A_1 + A_2 + \ldots \rightleftharpoons B_1 + B_2 + \ldots \tag{8}$$

hat das Zeichen ,, + “nicht den Sinn eines Verknüpfungsgesetzes in der additiven Notierung. Man könnte ein solches Verknüpfungsgesetz nicht einmal definieren, ,, + “ besitzt den Sinn einer Vereinigung.

Heute ist die Schreibweise :

$$A_1UA_2U \ldots \rightleftharpoons B_1UB_2U \ldots \tag{9}$$

nicht mehr üblich, obzwar sie dem von der Beziehung (8) ausgedrückten Sinn näher ist. Die be-Matrizen führen zu einer der Beziehung (9) analogen Darstellung der Reaktion.

Eine be-Matrix enthält mehrere Informationen als eine gewöhnliche chemische Formel. Die in den chemischen Formeln enthaltenen Informationen befinden sich in der b-Zone der Matrix. Nach Durchführung der Operation (5) stehen $n^2 - n(n+1)/2$ Stellungen der Einfallsmatrizen zur

Verfügung, in welchen die in den *i*- und *e*-Zonen der be-Matrizen enthaltenen Informationen verstanden werden.

3. ÜBER DEN R_ρ OPERATOR

In der Arbeit[1] wird der R_ρ Operator im Rahmen einer FIEM wie folgt definiert :

$$\mathrm{EM}_\Phi \rightarrow R_\rho \cdot \mathrm{EM}_\psi \tag{10}$$

wobei EM_Φ, $\mathrm{EM}_\psi \in \mathrm{FIEM}$.

R_ρ stellt den chemischen Prozeß dar, der die Umwandlung der Reaktanten EM_Φ in die Produkte EM_ψ bewirkt. Die Definitionsbeziehung (10) verfügt über den Vorteil, daß der Operator R eine matrizielle From annehmen kann.

Es sei nun : $M_\Phi = [\Phi_{ij}]$ die EM_Φ zugeordnete Matrix, $M_\psi = [\psi_{ij}]$ die EM_ψ zugeordnete Matrix und $R = [r_{ij}]$ die R zugeordnete Matrix.

Die Beziehung (10) wird nun zu :

$$[\Phi_{ij}] = [r_{ij}] \times [\psi_{ij}] \tag{11}$$

Aus (11) folgt unmittelbar, daß :

$$\Phi_{ij}/\psi_{ij} = r_{ij} \tag{12}$$

Selbstverständlich wird $\psi_{ij} \neq 0$ vorausgesetzt. Wenn $\psi_{ij} = 0$, kann man $\psi_{ij} = \varepsilon$ setzen, wobei ε willkürlich klein ist. So hat die Beziehnung (12) immer einen Sinn und also auch die folgende Interpretierung für R : R mißt die Veränderung der Eigenschaften (die im gegebenen Fall interessieren) bei der der Umwandlung $\mathrm{EM}_\Phi \xrightarrow{R_\rho} \mathrm{EM}_\psi$.
Aber R kann auch (und im allgemeinen ist es auch natürlich so) durch folgende Beziehung definiert werden :

$$R = [r_{ij}(t)] \tag{13}$$

Also sind die Elemente der Matrix von der Zeit abhänging.

DISKUSSIONEN

Wir glauben, daß es noch eine Möglichkeit der Interpretierung für eine chemische Umwandlung (chemische Reaktion) gibt, und zwar, eine chemische Reaktion ist ein Funktor. Diese Interpretierung könnte sich nützlicher als jene von I. Ugi und P. P. Gillespie mit Hilfe von R_ρ erweisen, aber die Entwicklung eines, für alle von der Chemie studierten Beziehungen, allgemeinen und abstrakten funktoriellen Formalismus setzt unbedingt eine feste Basis für die Chemie in der Mengenlehre voraus.

Man kann voraussehen, daß eine Anpassung der organischen Chemie an den Formalismus der Mengenlehre leichter sein wird, als im Falle der anorganischen Chemie.

Umso mehr könnte ein Formalismus in der Mengenlehre für die organische Chemie zu einem einheitlichen Standpunkt in bezug auf die wichtigen, mit Hilfe der Graphen [2] und der algebraischen Methoden [3] erzielten Ergebnisse führen.

MATHEMATISCHE DARSTELLUNG DER HOMOLOGIE UND DER HOMOLOGEN SERIEN. II[1]

BEHANDLUNG IN KATEGORIEN

IOAN MOŢOC
Fakultät für Industriechemie
Polytechnisches Institut „Traian Vuia“
Timişoara

Eingegangen am 8. Mai 1973

Diese Arbeit versucht eine neue Festlegung im Zusammenhang mit dem Begriff der Homologie und der homologen Serien. Der Unterschied zwischen diesen beiden Begriffen wird gleichfalls hervorgehoben. Einige unmittelbare Folgen unserer in der vorhergehenden Arbeit[1] ausgesagten Standpunkte werden ebenfalls behandelt.

1. EINLEITUNG

Für jedwelches $j = 1 \div \ldots$, hat S_j folgende Eigenschaften :

i) wenn $s_{ji} \in S_j$, dann ist $\{s_{ij}\} \in S_j$

ii) wenn $s_{ji} \in X$, $X \in S_j$, dann gehört $s_{ij} \in S_j$

iii) wenn $X \in S_j$, dann gehört die Menge der Teile $P(X) \in S_j$

iv) wenn $(X_i)_{i \in I}$ eine Mengenfamilie $X_i \in S_j$ ist und wenn $I \in S_j$, dann ist $\bigcup\limits_{i \in I} X_i \in S_j$

v) die Dublette $(s_{jp}, s_{jq}) \in S_j$, wenn und nur wenn s_{jp} und $s_{jq} \in S_j$, also ist die Menge S_j eine Univers-Menge.

Die Gesamtheit der homologen Serien $(S_j)_{j \in J}$ ist eine Familie von Universen.

$\bigcap\limits_{i \in J} S_j$ wird als leeres Universum bezeichnet.

Folgendes Axiom wird als erfüllt vorausgesetzt :

Für jedwelche Menge A gibt es ein Universum $\mathcal{U}$, welches A als Element enthält. In dieser Arbeit ist es vorteilhaft $S_j, j \in J$ anstelle von A und $\bigcup\limits_{j \in J} S_j$ als Menge $\mathcal{U}$ zu betrachten. Laut Definition wird die Beziehung angenommen :

$$\bigcap_{j \in J} S_j \in \mathcal{U} \tag{1}$$

---

[1] I. Moţoc, *Rev. Roumaine Chim.*, **18**, 1419 (1973).

2. KATEGORIEN

Man kann zeigen, daß die Menge $\mathcal{U} = \bigcup_{j \in J} S_j$ eine Kategorie $\mathcal{C}$ ist [2]. Dadurch erzielt man die Möglichkeit einer eleganten und kurzgefaßten Behandlung des Homologie- und homologen-Problems. Man kan feststellen, daß sich in Wirklichkeit folgende Eigenschaften als richtig erweisen:

i) es gibt eine Menge Ob$\mathcal{C}$, deren Elemente Objekte von $\mathcal{C}$ genannt werden, u. zw.: Ob$\mathcal{C}$ ist $S_j, j \in J$

ii) für jedwelches S_p, S_q $\in$ Ob $\mathcal{C}$ existiert eine Menge HOM$_{\mathcal{C}}$ (S_p, S_q), deren Elemente Morphismen genannt werden.

iii) für S_x, S_y $S_z \in$ Ob$\mathcal{C}$ existiert:

$$\text{HOM}_{\mathcal{C}}\ (S_x, S_y) \times \text{HOM}_{\mathcal{C}}\ (S_y, S_z) \rightarrow \text{HOM}_{\mathcal{C}}\ (S_x, S_z)$$

Die Morphismen erfüllen folgende Axiome:

1. Für jedwelches $S_j \in$ Ob $\mathcal{C}$, existiert ein Morphismus 1 $S_j \in \text{HOM}_{\mathcal{C}}(S_j, S_j)$, der als Identität von S_j bezeichnet wird.
2. Die Zusammensetzung der Morphismen ist assoziativ.
3. Die Mengen HOM$_{\mathcal{C}}$ (S_p, S_q) sind jede mit jeder disjunkt.

Daraus ist ersichtlich, daß $P(\mathcal{U})$, d.h. die Menge der Teile von $\mathcal{U}$, zusammen mit den Einschlußbeziehungen, eine Kategorie bilden.

Man kann feststellen daß, falls S_p, S_q $P(\quad)$:

$$\text{HOM}\ (S_p, S_q) = \Phi \tag{2}$$

da:

$$S_p \not\subset S_q,\ \forall\ p, q \in J \tag{3}$$

Mit den Beziehungen (1) und (2) kann man leicht die Wahrheit des folgenden Satzes beweisen:

Satz 1: Die Kategorie $\mathcal{C}$ ist eine $\mathcal{U}$-Kategorie.

Folgende Beziehung:

$$\text{Ob}\ \mathcal{C} \in \mathcal{U} \tag{4}$$

beweist den

Satz 2: Die Kategorie $\mathcal{C}$ ist eine kleine $\mathcal{U}$-Kategorie.

Diese erzielten Ergebnisse ermöglichen die in der früheren Arbeit [1] gegebene Definition 2 wie folgt zu vervollständigen:

Definition 1: Die unäre Beziehung $S_j \in S\ (= \mathcal{U})$ besitzt die Eigenschaft: $S_j \in$ Ob ($\mathcal{U}$-Ens)

Eine homologe Serie ist also eine amorphe Menge, laut Definition.

Die Homologiebeziehung ($\wedge$) ist eine Abbildung der Menge:

$$\wedge\ :\{s_{ji}\}\ U\ S_0 \rightarrow \mathrm{S}_j$$

Die in der Arbeit [1] angeführte Definition 3 wird wie folgt vervollständigt:

Definition 2. Die binäre Beziehung $\wedge$ besitzt folgende Eigenschaft: $\wedge \in$ Ob($\mathcal{U}$-Ens)

---

[2] C. A. CAZACU, A. DELEANU, M. JURCHESCU, „Topologie, categorii, suprafeţe riemanniene", Ed. Academiei, Bukarest, 1966.

Der Begriff der Homologie und der homologen Serien (nur als Sammlung von Homologen betrachtet) sind Objekte in $\mathcal{U}$-Ens.

Es ist leicht ersichtlich, daß obige Betrachtungen ohne Schwierigkeit auch auf polymerhomologe Serien ausgedehnt werden können.

Die Kardinalzahlen der Menge N der natürlichen Zahlen wird mit $\# N = \aleph$ bezeichnet.

Die Beziehung (12) aus der Arbeit [1] führt unmittelbar zum Beweis folgenden Satzes :

Satz 3 : Für jedwelches $p, q \in J$ besteht die Beziehung :

$$\# S_p = \# S_q = \aleph \tag{5}$$

Tatsächlich können für $p, q \in$ J, folgende eineindeutige Beziehungen festgelegt werden :

$$\begin{gathered} s_{p1} \in S_p \to 1 \in N \\ s_{p\lambda} \in S_p \to \lambda \in N, \quad \lambda \geqslant 2 \\ s_{q1} \in S_q \to 1 \in N \\ s_{q\lambda} \in S_q \to \lambda \in N, \quad \lambda \geqslant 2 \end{gathered} \tag{6}$$

Die Beziehungen (6) beweisen die Behauptung (5).

Stellt man der Beziehung (7) aus der Arbeit [1] die Bedingung $p - n \leqslant -1$, gelangt man zu folgendem Ergebnis : Man baut schrittweise eine neue Menge auf :

$$\{s_{p0}, s_{j,-1}, s_{j,-2}, \ldots, s_{j,-n}, \ldots\} = S_j^- \tag{7}$$

die den gleichen Sinn wie Menge S_j hat, aber einer anderen formellen Situation entspricht, u. zw. :

$$s_{jp} \wedge ns_1 \to s_{j,p+n} \quad \text{für } S_j \tag{8}$$

$$s_{j,p+n} \leftarrow s_{jp} \wedge ns_j \quad \text{für } S_j \tag{8a}$$

Man bemerkt, daß in den Beziehungen (8) und (8a) die Richtung der Pfeile entgegengesetzt ist. Die Situationen (8) und (8a) können auf Grund ihres Vergleichens unterschieden werden. Diese Tatsache wird in folgenden Beziehungen widerspiegelt :

$$\{-1\} \cdot S_j = S_j^- \tag{9}$$

$$\{-1\} \cdot S_j^- = S_j \tag{9a}$$

Die Beziehungen (9) und (9a) können schrittweise abgeleitet werden. Das Ergebnis des schrittweisen Aufbauverfahrens wurde als direktes Produkt zwischen den Mengen (9) bezeichnet. Die Menge der pseudoskalaren Eigenschaften, die dem Element s_{ji} zugeordnet werden, bezeichnet man mit $\bar{s}_{ji}$. Mit $\bar{S}_j$ bezeichnet man die Menge $\{\bar{s}_{j0}, \bar{s}_{j1}, \ldots\}$

Die Beziehung (10) ist offensichtlich :

$$\# S_j = \# S_j^- = \delta \tag{10}$$

S_j^- kann also S_j in den Beziehungen (9) ersetzen :

$$\{-1\}\ S_j = S_j^- \tag{11}$$

$$\{-1\}\ S^- = S_j \tag{11a}$$

Mit den Beziehungen (11) wurde ein interessantes Ergebnis wiederentdeckt, u. zw. das in der physikalischen Chemie verwendete Verfahren zum Berechnen einiger pseudoskalaren Eigenschaften der Moleküle (z. B. die Berechnung der Reaktionsentalpien).

Es ist bemerkenswert, daß eine Grundlage aus der Mengenlehre für die organische Chemie äußerst nützlich wäre. Die Mengenlehre stellt einen ausreichlich abstrakten Formalismus dar und es hat sich erwiesen, daß dieser Formalismus sich einer Anwendung in der organischen Chemie nicht widersetzt.

Herzlichen Dank schulde ich Herrn Professor A.T. BALABAN für die mir zuteil gewordenen Ratschläge, die zur vorliegenden Arbeit führten.

CHAIN TRANSFER IN EMULSION POLYMERIZATION OF VINYL ACETATE

D. DONESCU, C. HAGIOPOL, MARIANA MUNTEANU, VICTORIA DIMONIE
and I. GAVĂT

"P. Poni" Institute of Macromolecular Chemistry, Section of Polymerization Processes,
str. Dumbrava Roșie 18, Bucharest

Received January 10, 1974

Studies have been made on the influence of aromatic hydrocarbons and allyl derivatives as chain transfer agents, on the emulsion polymerization of vinyl acetate (VAc) in the presence of polyvinyl alcohol (PVA). The dependence of the polymerization rate and of the polymer structure on the concentration of the above-mentioned substances was determined. The activity as transfer agents increases for aromatic hydrocarbons in the order: toluene, ethyl benzene, isopropyl benzene, tetraline, while for allyl derivatives: allyl alcohol, allyl acetate, diallyl ether, allyl bromide.

1. INTRODUCTION

Vinyl acetate polymerization is characterized by a high reactivity of the increasing macroradical. This reactivity is revealed by its sensitivity to substances capable of releasing a hydrogen atom by chain transfer. [1] A comparative study both of propagation rate constants (k_p) in homopolymerization and of chain transfer constants (C) for VA and for styrene [2] shows an increased reactivity of poly(vinyl acetate) macroradical (PVAc) ($k_{p\,\mathrm{VAc}} \approx 1500\ k_{p\,\mathrm{St}},\ C_{\mathrm{VAc}} \approx 100\ C_{\mathrm{St}}$).

The previous study [3] regarding VAc emulsion polymerization in the presence of polyvinyl alcohol as an emulsifier focussed on the effects of transfer reactions on the polymerization kinetics and also on the structure of the formed polymer. Strong transfer reactions occur in the mentioned system to emulsifier (PVA), polymer (PVAc) and to other substances additionally introduced and capable of participating in such reactions (diallyl ether).

This transfer reaction causes the occurrence of PVAc graft copolymers on PVA and PVAc branched polymers.

To eliminate the appearance of PVAc branched polymers, it is necessary to find some more active compounds in chain transfer processes than the above-mentioned homopolymer and emulgator. Data provided by the literature show that aromatic hydrocarbons [1,2,4-6] and allyl derivatives[7-9] were chosen as transfer agents, being known as active factors in vinyl polymerizations with free radicals.

The above-mentioned substances are known as active agents also in other homolytic reactions of the same type : autooxidation [10-13] and hydrogen atom extraction by the free radicals of a small molecular mass. [14-21]

The present paper is concerned with the influence of these substances on the reaction rate and on the structure of polymers obtained by emulsion polymerization of VAc in the presence of PVA.

2. EXPERIMENTAL

Materials. Conditions for the purification of materials and for the preparation of the emulgator solution are similar to those reported in the previous paper.[3]

The transfer agents, p.a. products, were subjected to an extra purification on a highly efficient column.

Polymerization procedure. The apparatus involved and the working procedure were reported to be identical with those presented in the previous paper. [3] The concentrations of reactants (except for transfer agents) were kept constant : $[\mathrm{VAc}]_0 = 2.72$ mole/l, $[\mathrm{PVA}]_0 = 25.4$ g/l, $[\text{peroxide of hydrogen}]_0 = 3.10^{-3}$ mole/l, $[\mathrm{FeSO_4}]_0 = 3.85.10^{-5}$ mole/l. Transfer agents were added to the monomer before placing it in the reactor.

Analyses of polymer. The succession of operations for the determination of solubilities and of K values of polymers was identical with that previously mentioned.

3. RESULTS AND DISCUSSION

3.1. Effects of aromatic hydrocarbons on VAc emulsion polymerization

A systematic study of the relationship between the structure of the aromatic hydrocarbon and its reactivity to free radicals shows the following order : toluene< ethyl benzene< isopropyl benzene. At the same time 1,2,3,4-tetrahydronaphthaline, tetraline, was found to display a surprisingly high reactivity in the above-mentioned reactions. [21–23]

The use of the above-mentioned aromatic hydrocarbons as chain transfer agents results in a decrease of the polymerization rate (R) of VAc relative to the polymerization rate in their absence (R_0).

Fig. 1 illustrates the influence of the concentration of various transfer agents on the polymerization rate of VAc.

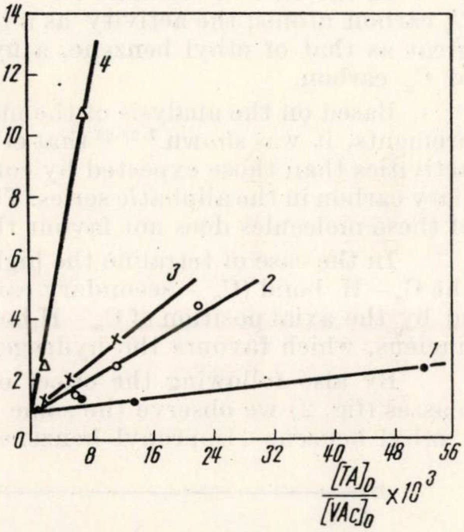

Fig. 1. — Influence of the transfer agent/ monomer ratio on the polymerization rate : *1*, toluene; *2*, ethyl benzene; *3*, isopropyl benzene; *4*, tetraline.

A dependence has been found in the case of all used aromatic hydrocarbons between the polymerization rate R and the concentration of the respective transfer agent, similar to that established by Allen et al. [24] for VAc polymerization in solution

$$\frac{R_0}{R} = 1 + A\,\frac{[TA]_0}{[\mathrm{VAc}]_0}$$

where

$[TA]_0$ = initial concentration of the transfer agent
A = characteristic constant for each transfer agent.

[22] E. C. KOOYMAN, *Tetrahedron*, **19**, 415(1963).

[23] A. E. EACHUS, J. A. MEYER, J. PEARSON and M. SZWARC, *J. Amer. Chem. Soc.*, **90**, 3646(1968).

[24] P. W. ALLEN, F. M. MERRETT and J. SCANLEN, *Trans. Faraday Soc.*, **51**, 95(1955).

The values of constant A characterize the capability of the aromatic hydrocarbon in question to slow down the polymerization rate of VAc in emulsion. A comparison of these values shows a similar succession of the activity (toluene $<$ ethyl benzene $<$ isopropyl benzene $<$ tetraline) to that reported in papers dealing with homolytic reactions. [5,7,12–16,18,19,21–23]

This reactivity order is due to the different capacity of extracting a hydrogen atom from the position relative to benzene nucleus (C_α carbon).

The lability of the C—H bond depends on a multitude of factors: degree of substitution of C_α carbon (primary carbon $<$ secondary carbon $<$ tertiary carbon), mobility of $C_\alpha—C_\beta$ bond, position of hydrogen atoms in C_α carbon with respect to the plane of benzene nucleus, interaction of hydrogen atoms in C_β carbon with the hydrogen atom in the *ortho* position of the nucleus. [7,21–23]

In the case of tetraline ($A = 1480$), a hydrocarbon with secondary C_α carbon atoms, the activity as a transfer agent is roughly nine times as great as that of ethyl benzene, a hydrocarbon with similar substitution of C_α carbon.

Based on the analysis of the molecular structure and of kinetic measurements, it was shown [7,22,23] that ethyl benzene and cumene have smaller activities than those expected by comparison with the secondary and tertiary carbon in the aliphatic series. This is due to the fact that the structure of these molecules does not favour the extraction of the hydrogen atom. [7]

In the case of tetraline the higher reactivity similar to that found for the $C_\alpha—H$ bond (C_α — secondary carbon) of the aliphatic series is explained by the axial position of $C_\alpha—H$ bond relative to the plane of the benzene nucleus, which favours the hydrogen extraction by a free radical.

By also following the effect of these substances on the molecular masses (fig. 2) we observe the same succession of the efficiency toluene $<$ $<$ ethyl benzene $<$ isopropyl benzene $<$ tetraline.

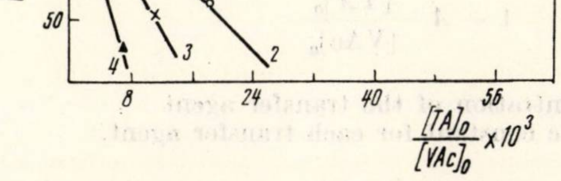

Fig. 2. — Modification of the K value of the benzene-soluble fraction as a function of the transfer agent/monomer ratio: *1*, toluene; *2*, ethyl benzene; *3*, isopropyl benzene; *4*, tetraline.

The increase of the molar ratio $\frac{[TA]_0}{[VAc]_0}$ determines a decrease of K value for the fraction of benzene-soluble polymer.

The presence of transfer agents of the aromatic series diminishes the chain transfer to PVA, VAc and PVAc which corresponds to a decrease in the weight of the water- and benzene gel-insoluble polymer and to an increase in the weight of the benzene-soluble polymer (table 1).

Table 1

Decrease of the amount of benzene-insoluble polymer and increase of the amount of benzene-soluble polymer as a function of the molar ratio $\frac{[TA]_0}{[VAc]_0}$ ($[VAc]_0$ = 2.72 mole/l, $[PVA]_0$ = 25.4 g/l, $[H_2O_2]_0 = 3.10^{-3}$ mole/l, $[FeSO_4]_0 = 3.85.10^{-5}$ mole/l, t = 63°)

Chain transfer agent	$\frac{[TA_c]_0}{[VA_c]_0} \cdot 10^3$ mole/mole	Benzene-insoluble polymer mass %	Benzene-soluble polymer mass %
—	0	38.5	50
Toluene	3.3	25.5	61.2
	6.6	24.6	63.5
	13.2	21.4	65.8
	53.5	15.25	68.5
Ethyl benzene	5.36	16.5	62.0
	10.72	16.2	66.8
	21.44	11.55	68.5
Isopropyl benzene	1.1	39.2	60.3
	2.2	23	62.8
	5.5	14.5	71.3
	11.0	11.3	72.2
Tetraline	1.37	15.9	67.3
	6.85	4.95	32.6

3.2. Effect of allyl compounds on VAc emulsion polymerization

Compared to aromatic hydrocarbons analyzed above, allyl compounds display a higher reactivity as to the transfer of a hydrogen atom to a free radical. [7,25]

Allyl derivatives studied in the present work are allyl acetate, allyl alcohol, diallyl ether and allyl bromide. The ratio between allyl compounds and VAc was chosen so as to practically eliminate the possibility of copolymerization. [26]

In fig. 3 and table 2 we may observe the decrease of K value of the benzene-soluble fraction and of water- and benzene-insoluble fraction, respectively, with the increase in the amount of transfer agent.

The activity as a transfer agent presents a gradual increase in the order allyl acetate < allyl alcohol < diallyl ether < allyl bromide.

[25] G. M. Bristow, *Trans. Faraday Soc.*, **54**, 1239(1958).

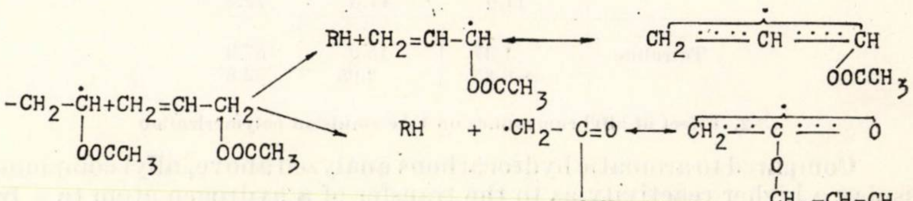
[26] E. Y. C. Chang and C. C. Price, *J. Amer. Chem. Soc.*, **83**, 4650(1961).

Table 2

Decrease of the amount of benzene- and water-insoluble polymer as a function of the nature and the concentration of the molar ratio $[TA]_0$ $[VAc]_0 = 2.72$ mole/l, $[PVA]_0 = 25.4$g/l $[H_2O_2]_0 = 3.10^{-3}$ mole/l, $[FeSO_4]_0 = 3.85.10^{-5}$ mole/l, t = 63°)

Chain transfer agent	$\frac{[TA]_0}{[VAc]_0} . 10^3$ mole/mole	Benzene- and water-insoluble polymer mass %
—	0	38.5
Ethyl acetate	18.9	37
Allyl bromide	2.5	7
	5.0	4.46
Allyl alcohol	3.42	19.5
	17.1	4.4
Allyl acetate	3.42	34.6
	11.3	15.5
	18.9	7.6
Diallyl ether	2.3	11.2
	3.45	19.6
	4.93	12.6

The transfer of the radicalic species may take place at the allyl group[27,28] or at the acetate group [29] in the case of allyl acetate :



The abstraction of hydrogen atom from the allyl group has a much greater role. [27-31] Our experimental results with ethyl acetate confirm this fact (fig. 3, fig. 4 and table 2). The higher reactivity of allyl acetate was explained by the existence of an axial configuration [7] of the C—H bond of the carbon in α relative position to the carbon—carbon double bond.

[28] P. D. Bartlett and F. A. Tati, *J. Amer. Chem. Soc.*, **75**, 91(1953).

[29] N. G. Gaylord, *J. Polymer Sci.*, **22**, 71 (1956).

[30] M. Litt and F. R. Eirich, *J. Polymer Sci.*, **45**, 379(1960).

[31] N. G. Gaylord and F. R. Eirich, *J. Amer. Chem. Soc.*, **74**, 337(1952).

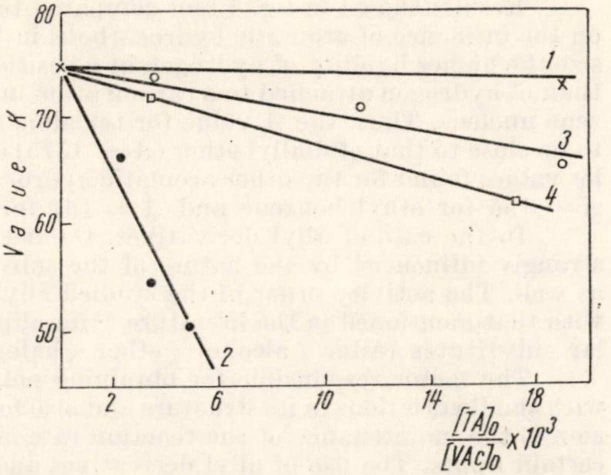

Fig. 3. — Influence of the transfer agent/monomer molar ratio on the K value of the benzene-soluble polymer fraction :

1, ethyl acetate; 2, diallyl ether; 3, allyl acetate; 4, allyl alcohol.

The freshly formed allyl radical has a lower reactivity but it may participate in a new initiation reaction.[28] This lower reactivity due to the interaction of the odd electron orbital with the π electrons of the double bond, determines the decrease of the all polymerization rate.

The behaviour of these allyl compounds is controlled by the same laws as those applying for aromatic hydrocarbons (fig. 4).

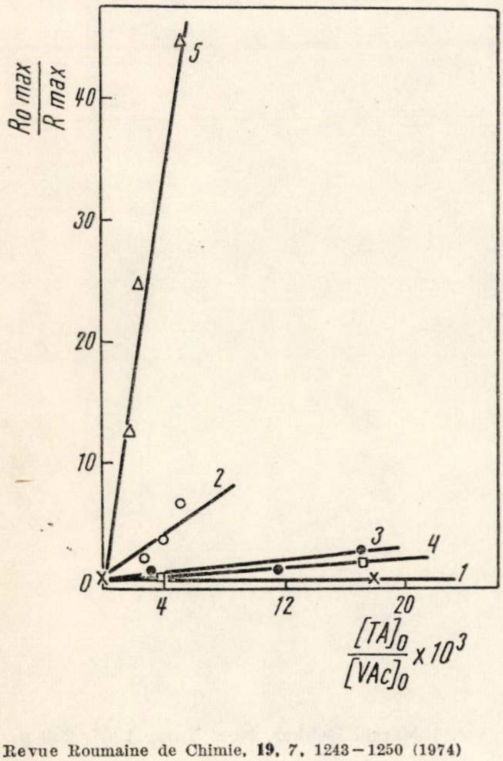

Fig. 4. — Dependence of the polymerization rate on the transfer agent/monomer molar ratio :

1, ethyl acetate; 2, diallyl ether; [3, allyl acetate; 4, allyl alcohol; 5, 'allyl bromide.

Results shown in fig. 4 and compared to the kinetic determinations on the influence of aromatic hydrocarbons in VAc polymerization emphasize the higher liability of hydrogen in α position relative to a double bond than of hydrogen attached to a carbon atom in position α relative to a benzene nucleus. Thus, the A value for tetraline ($A = 1430$) is also observed to be close to that of diallyl ether ($A = 1575$) compared to the much smaller values found for the other aromatic hydrocarbons ($A = 29$ for toluene, $A = 156$ for ethyl benzene and $A = 187$ for isopropyl benzene).

In the case of allyl derivatives, the activity as a transfer agent is strongly influenced by the nature of the substitute in the allyl grouping as well. The activity order of the studied allyl compounds compares well with that mentioned in the literature [32] for aliphatic derivatives with similar substitutes (ester $<$ alcohol $<$ ether $<$ halogenated derivative).

The factor responsible for obtaining poly(vinyl acetate) in emulsion with small variations in its structure and also for the properties of the emulsion is the maintenance of the reaction rate and of gel proportion within certain limits. The use of allyl derivatives and of aromatic hydrocarbons provides the possibility of controlling the mentioned factors, an essential condition for the completion of the emulsion polymerization of vinyl acetate without a strong exothermal reaction.

**Research Department of the Synthetic Fiber Plant Săvineşti, Romania.

Received September 13/1973

The binary copolymerizations of N-vinylcaprolactam (I) with 2-vinylpyridine (II), 4-vinylpyridine (III) and 2-methyl-5-vinylpyridine (IV) were studied in solution at 70°. The reactivity ratios of these pairs of monomers were determined, the following values being obtained:

$$r_1^{\mathrm{I}} = 0.123 \qquad r_1^{\mathrm{I}} = 0.096 \qquad r_1^{\mathrm{I}} = 0.037$$

$$r_2^{\mathrm{II}} = 4.35 \qquad r_2^{\mathrm{III}} = 4.43 \qquad r_2^{\mathrm{IV}} = 11.58$$

The average values of the Q and e parameters are the following:

$$Q_{\mathrm{I}} = 0.169 \qquad e_{\mathrm{I}} = -1.26$$

1. INTRODUCTION

Data concerning free radical copolymerization of N-vinylcaprolactam (NVC) are still scarce. The reactivity ratios for the binary copolymerization of NVC with phenyl vinyl ether (PVE), [1] butylmethacrylate, [2] vinyl acetate (AV), [3] acrylonitrile (AN), methylmethacrylate (MMA) and styrene (ST)[4] have been determined.

The average values of the Q_{NVC} and e_{NVC} parameters (0.116 and −1.1, respectively) determined from the binary copolymerization with AN, MMA, and ST[4] are in good agreement with the parameters Q and e of the N-vinylpyrolidone, obtained by Alfrey.[5] These parameters anticipate the fact that the radical reactivity of NVC is higher than that of AV($Q_{AV} = 0.02$; $e_{AV} = -0.56$[6]).

The average value $e_{NVC} = -1.1$ shows a lower donor effect of the substituent of this vinylic monomer than that assumed in the copolymerization with PVE,[1] AV[3] and ST[4] and anticipates a relatively weak tendency of NVC toward cationic polymerization.

The observed values Q_{NVC} and e_{NVC} largely depend upon the nature of the comonomer in copolymerization. They increase with the increase in the acceptor effect of the comonomer.[4]

In order to obtain more accurate information regarding this latter aspect, this paper has studied the binary copolymerization of NVC with vinylpyridines (VPy).

2. EXPERIMENTAL

a. *Materials.* NVC was obtained and purified according to indications given in the literature.[7] The product, purified and encapsulated in an argon atmosphere, was redistilled under vacuum prior to use. The fraction used in the experiments had a refractive index, $n_D^{20} = 1.5135$.

2-Vinylpyridine (2VPy) was purified by distillation under vacuum (17 torr) at 60°. The product used in the experiments had a refractive index, $n_D^{20} = 1.5510$, according to the literature data.[8]

4-Vinylpyridine (4VPy) was purified by distillation under vacuum (15 torr) at 65°. The fraction used had a refractive index, $n_D^{20} = 1.5499$.[8]

2-Methyl-5-vinylpyridine (2M5VPy) was purfied by distillation under vacuum (15 torr) at 76°. The freshly distilled fraction used in the experiments had a refractive index, $n_D^{20} = 1.5454$.[9]

The commercial α,α'-azobisisobutyronitrile (AIBN) was twice recrystallized from ethanol ($B_P = 102.5°$).

Dioxan as a pure solvent ($n_D^{20} = 1.4224$) was obtained by refluxing it on metallic sodium; it was then rectified using a twenty theoretical plates column.

b. *Polymerization procedure.* Copolymerization reactions for the determination of reactivity ratios and the calculation of parameters Q_{NVC} and e_{NVC} were carried out in two-arm glass ampoules.[10] The two monomers of the binary system under study were determined in the two arms of the ampoule. The initiator solution in dioxan was added in the arm containing NVC.

[10] T. Otsu and H. Inoue, *Makromol. Chem.*, **128**, 31 (1969).

After filling, one of the arms was stoppered, the content was frozen in liquid nitrogen, with air removal at 1...2.10^{-2} torr, introducing thereafter argon purified by water and oxygen and warming at 20°. This cycle (freezing , removal of gas, filling with argon and warming at 20°) was run three times. Finally, the ampoules, brought at normal pressure by introducing argon, were closed and the solution in the two arms of the ampoules were rapidly mixed at the reaction temperature.

After the established reaction time, the copolymerization reaction was stopped by abrupt freezing, and the polymers were isolated from solution by precipitating them with a nonsolvent, filtering, washing with the nonsolvent and drying under vacuum at 50 ... 60°. The nonsolvent used for the copolymer NVC—2M5VPy was ethyl ether and the nonsolvent used for the other copolymers was petroleum ether.

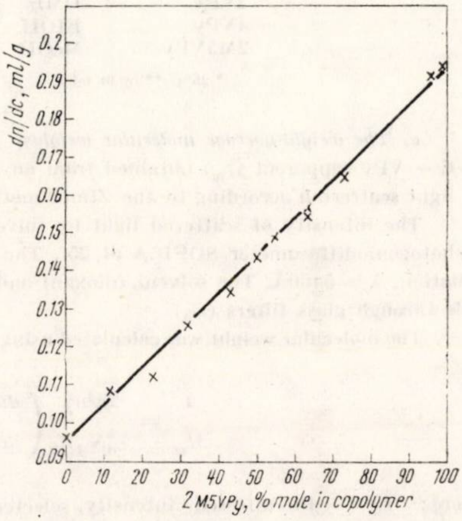

Fig. 1. — The calibrated curve $\frac{dn}{dc}$ upon the composition of homopolymer mixtures.

c. *Analyses of the copolymers.* For the composition determination of the copolymers NVC — 2M5VPy two methods were used, the analysis of carbon content and interferometry, the latter being based on the assumption of the additivity of refractive index increments of the components of the copolymer in a single solvent :

$$\left(\frac{dn}{dc}\right)_{12} = X_1 \left(\frac{dn}{dc}\right)_1 + (1 - X_1) \left(\frac{dn}{dc}\right)_2 \qquad (1)$$

The calibrated curve $\frac{dn}{dc} = f_{(X_1)}$ of mixtures of homopolymers (NVC and 2M5VPy) is presented in figure 1.

The measurements were made with a Zeiss — Jena interferometer at 25° and $\lambda = 5460$Å.

The composition of the copolymers NVC — 2VPy and NVC — 4VPy was determined by the Dumas classical micromethod.

d. *Viscosity measurements.* Intrinsic viscosities of copolymers were calculated by means of the following relationship [11]:

$$[\eta] = \eta^{sp}/C\ (1 + 0.333\ \eta sp),\ \text{ml/g} \qquad (2)$$

---

[11] O. F. Solomon and B. Gottesman, *Makromol. Chem.*, **104**, 177 (1967).

Viscometric determinations for diluted solutions (copolymer concentration less than 0.2 g/dl) were made with an Ubbelohde viscometer at 25° ± 0.05°. The molecular weights of homopolymers of 2VPy, 4VPy and 2M5VPy were estimated with the equation of table 1.

Table 1

The equations used for the calculation of molecular weights of homopolymers 2VPy, 4VPy and 2M5VPy [12,13]

Homopolymer of	Solvent *	Equation **
2VPy	DMF	$/\eta/ = 1.47 \cdot 10^{-2}\, M^{0.67}$
4VPy	EtOH	$/\eta/ = 2.5 \cdot 10^{-2}\, M^{0.68}$
2M5VPy	MeOH	$/\eta/ = 0.8 \cdot 10^{-2}\, M^{0.76}$

* 25°; ** $/\eta/$ in ml/g.

e. *The weight-average molecular weights*, $\overline{M_w}$, for homopolymer of NVC and copolymer NVC – VPy (apparent $\overline{M_W}$) obtained from an approximate equimolar feed were determined by light scattering according to the Zimm method. [14]

The intensity of scattered light by solvent and polymer particles was measured with a photogoniodiffusometer SOFICA at 25°. The light source was a mercury lamp of selected radiation, λ = 5460Å. The solvent (dioxan) and the polymer solutions were filtered into the cells through glass filters (G_5).

The molecular weight was calculated using the following relationship :

$$\frac{1}{M_w} = \frac{2\pi^2 n_B^2}{\lambda_0^4 N_A R_\theta}\left(\frac{dn}{dc}\right)^2 I_B \left(\frac{c}{I_{\mathrm{cor}}}\right)_{\theta=0}^{c=0} \tag{3}$$

where: I_β — the diffused intensity, selected for the standard benzene;

$$I_{\mathrm{cor}} - (I - I_0)\sin\theta/(1+\cos^2\theta) \tag{3a}$$

I — the scattered light intensity of the solution;

I_0 — the scattered light intensity of the solvent.

3. RESULTS AND DISCUSSION

3.1. The establishment of the optimum parameters for the copolymerization of NVC with VPy

Taking into account the activity of NVC as chain transfer agent,[4,15-17] and the fact that Mayo's differential equation [18]:

$$d[M_1]/d[M_2] = [M_1]\,(r_1[M_1] + [M_2])/[M_2]\,(r_2[M_2] + [M_1]) \tag{4}$$

is applied only to the copolymerization processes which give high polymers, preliminary tests were made to establish the monomer and initiator concentration so that the reaction product at 70° should have a molecular weight of scores and even hundreds of thousands.

The 70° temperature was chosen to compare Q_{NVC} and e_{NVC} constants with previously obtained[4] average values for Q and e.

The copolymerization process was carried out in the presence of small concentrations of dioxan, this solvent allowing a more precise and rapid dosing of the initiator.

In order to have a representation of the feed composition influence on the reaction kinetics, the AIBN was used as initiator (the substance whose splitting rate does not depend on the nature of the reaction medium[19]) in all the processes of the binary copolymerization NVC — VPy.

Anticipating a more pronounced chain transfer of 2M5VPy than that of the other VPy's, the copolymerizations of NVC with 2M5VPy were carried out with a lower concentration of AIBN than that used in the copolymerization processes of NVC — 2VPy and NVC — 4VPy, that is 0.873 mmole/l and respectively 1.17 mmole/l.

A homopolymer of NVC with an intrinsic viscosity similar to that of the copolymers obtained from the equimolecular feed of the two monomers (86 ml/g) was obtained in bulk at 50° with $[AIBN]_0 = 1.10^{-4}$ mole/l.

The Zimm plots were drawn with the values of light scattering intensity at different angles and polymer concentrations in dioxan.

Two of these plots are presented in Figs. 2 and 3.

As a result of double extrapolation the characteristic values $\left(\frac{c}{I_{cor}}\right)_{\theta=0}^{c=0}$, necessary to the calculation of the weight-average molecular weight, were obtained by means of the relationship (3). The obtained values are summarized in table 2.

Table 2

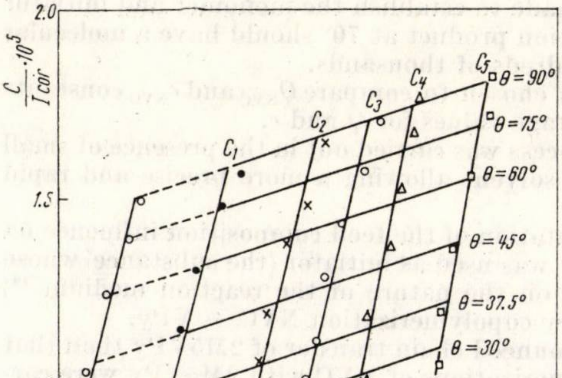

Fig. 2. — **Zimm plot for poly-NVC in dioxan at 25° :** $C_1 = 47.9.10^{-5}$; $C_2 = 95.8.10^{-5}$; $C_3 = 124.5\ 10^{-5}$; $C_4 = 153.3.10^{-5}$; $C_5 = 191.6.10^{-5}$.

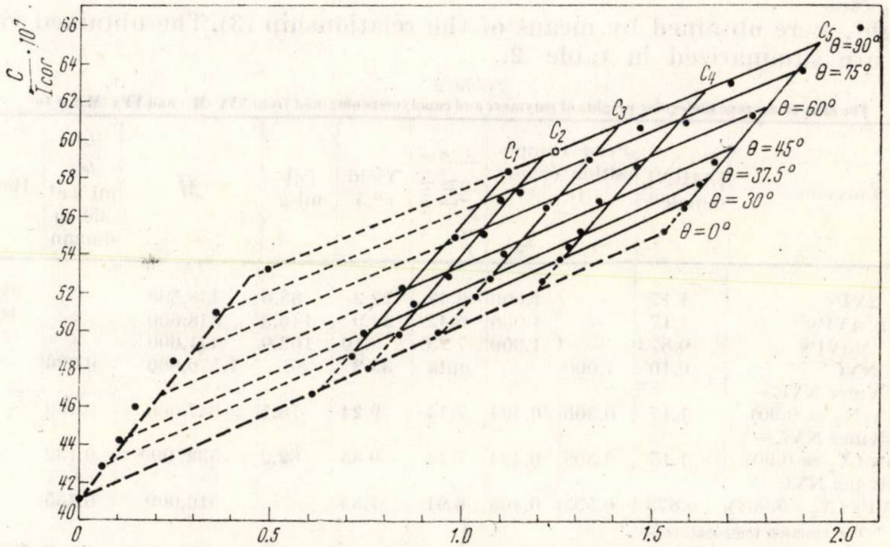

Fig. 3. — **Zimm plot for the copolymer NVC — 2M5VPy in dioxan at 25° :** $C_1 = 60.92.10^{-5}$; $C_2 = 79.62.10^{-5}$; $C_3 = 97.47.10^{-5}$; $C_4 = 121.84.10^{-5}$; $C_5 = 154.3.10^{-5}$.

It may be seen that in all these cases the weight-average molecular weights of polymers are high enough.

When comparing the molecular weights of the homopolymers of VPy with those of the copolymers obtained under the same conditions, it may be observed that the latter are higher.

The apparent molecular weight results from the light scattering data concerning the copolymer solutions with structural polydispersity (statistical, graft, bloc-copolymers :

$$M_{\text{ap}} = M_{\text{real}} + P\alpha + Q\alpha^2 \qquad (5)$$

where P and Q are constants,

$$\alpha = \left[\left(\frac{dn}{dc}\right)_1 - \left(\frac{dn}{dc}\right)_2\right] \Big/ \left(\frac{dn}{dc}\right)_{\text{cop}} \qquad (6)$$

and indexes 1 and 2 in equation (6) refer to the two homopolymers.

The theoretical basis of equation (5) was established by Stockmayer et al.,[20] Bushuk and Benoit,[21] Leng and Benoit[22] and others. The experimental test of this equation was made for many copolymers with structural polydispersity.[21-24] From the dependence of $\bar{M}_{\text{ap}}$ on the parameter α it may be observed that to establish $\bar{M}_{\text{real}}$ it is necessary to determine $\bar{M}_{\text{ap}}$ in different solvents or in the solvent in which α is very small so that $\bar{M}_{\text{ap}} \simeq \bar{M}_{\text{real}}$.

There are substantial differences between $\bar{M}_{\text{ap}}$ and $\bar{M}_{\text{real}}$ in the case of the copolymers NVC — VPy, because the parameter α is higher than 0.3 (table 2).

All the copolymerizations were carried out at the reaction times established, so that the copolymer yields did not exceed 3 %, except the copolymers for the average molecular weight establishment.

3.2. Some particular kinetic aspects

The binary copolymerization of NVC — VPy was in fact carried out in bulk, at different feed compositions. The determination of the copolymer composition led to the calculation of the reduced copolymerization rates. Some kinetic data regarding the dependence of the initial copolymerization rate on the feed composition are given in table 3 for a copolymerization process of NVC — 2M5VPy at 70°.

The values of the reduced copolymerization rates calculated from the copolymers composition determination by differential refractometry, correspond to those calculated from carbon analyses of the copolymers.

Figure 4 presents the dependence of the reduced copolymerization rate on the feed composition in the copolymerization of NVC with VPy.

* Calculated from the composition data of the copolymer established by carbon analysis, C%.

** Solvent $CHCl_3$, 25°.

*** $[AIBN]_0 = 1.591.10^{-3}$ mole/l.

It may be observed that, in all the cases, the copolymerization rate increases with the VPy molar fraction in the feed. The copolymerization rates of NVC with 2VPy and 4VPy are similar, which suggests the similarity in the two VPy reactivities.

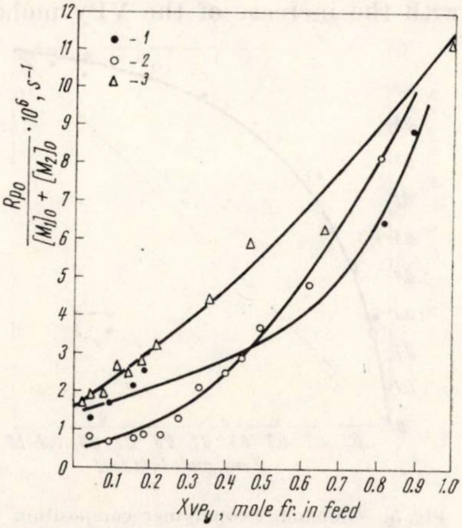

Fig. 4. — Copolymerization rate against composition feed for the NVC — VPy systems at 70°.
1, ●, 4VPy $[AIBN]_0 = 1.16.10^{-3}$ mole/l.
2, ○, 2VPy
3, Δ, 2M5VPy $[AIBN]_0 = 0.873.10^{-3}$ mole/l.

In the copolymerization reaction of NVC with 2VPy and 4VPy the reduced copolymerization rate shows a parabolic dependence on the molar feed composition. A quasi-parabolic dependence was found in the copolymerization reaction of NVC with 2M5VPy.

Although the AIBN concentration was lower in this process, the reduced copolymerization rate for the same composition of the feed was higher than that of the binary copolymerization of NVC with 2VPy and 4VPy respectively.

It is evident that, in all these copolymerization processes, the most reactive comonomer is the VPy.

In the reaction with NVC the reactivity series of the studied VPy is : 2M5VPy >2VPy ≃ 4VPy. This fact is also confirmed by the the monomer/copolymer composition curves representing the three binary systems, presented in figs 5 and 6.

The shape of these monomer/copolymer composition curves is particular for binary systems with $r_1 < 1$ and $r_2 > 1$, proving a higher reactivity of VPy in the reactions with both macroradicals of the system.

Another interesting kinetic aspect in these copolymerization processes is the dependence of the molecular weight on the feed composition.

It is rather difficult to establish this dependence. The chemical nature and the feed composition affect directly the average molecular weight by the chain transfer reactions and the kind of termination reaction.

Fig. 7 presents the dependence of the intrinsic viscosity on the composition of the copolymer.

Because the viscosity of the statistical copolymers depends on certain factors (the molecular weight, the chemical composition and the distribution of the structural unities in the copolymer), the influence of the feed composition on the molecular weight, established in this way, has only a qualitative value.

It may be seen that the intrinsic viscosity increases parabolically with the increase of the VPy molar fraction in the copolymer. This dependence points out a more pronounced chain transfer of NVC as compared with VPy. This fact corresponds to literature data.[4,15-17, 25-28]

3.3. Calculation of the reactivity ratios

The available literature mentions neither the reactivity ratios for these binary systems, nor the experimental data which can be used to calculate these reactivity ratios.

Two possibilities were used for the determination of the reactivity ratios r_1 and r_2 for these binary systems (in all the cases NVC was noted M_1) : the linearization of the differential composition equation of the copolymerization using Fineman-Ross' method[29] in both variants :

$$\frac{Ri}{\rho_i}(\rho_i - 1) = r_1 \cdot \frac{Ri^2}{\rho_i} - r_2 \tag{7}$$

and

$$\frac{\rho_i - 1}{R_i} = r_1 - r_2 \frac{\rho_i}{Ri^2} \tag{7'}$$

[29] M. Fineman and S. D. Ross, *J. Polymer Sci.*, **5**, 259 (1950).

and the least square method.[30]

For the latter case, the normal equations were :

$$\sum \frac{R_i}{\rho_i}(\rho i - 1) = r_1 \sum \frac{R_i^2}{\rho_i} - n r_2$$

$$\sum \frac{R_i^3}{\rho_i^2}(\rho i - 1) = r_1 \sum \frac{R_i^4}{\rho_i^2} - r_2 \sum \frac{R_i^2}{\rho_i} \qquad (8)$$

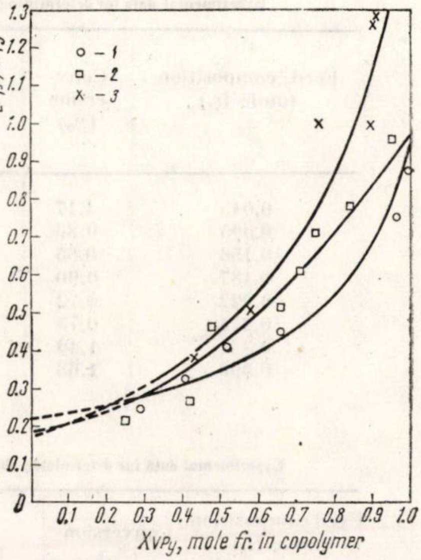

Fig. 7. — Dependence of the intrinsic viscosity upon the composition of copolymers : *1*, ○, 4 VPy; *2*, □, 2VPy; *3*, X, 2M5VPy.

where n = the number of feeds for which the copolymerization was made ; $R_i = \frac{x_{1i}}{x_{2i}}$ and $\rho_i = \frac{X_{1i}}{X_{2i}}$; x_i and X_i being the molar fraction of the monomer in the feed and respectively in the copolymer.

The necessary data for the determination of the reactivity ratios for the systems NVC — 2VPy and NVC — 4VPy are presented in tables 4 and 5, respectively. The experimental data necessary to the determination of the reactivity rations for the system NVC — 2M5VPy were presented in table 3.

As shown in the monomer/copolymer composition curves (figures 5 and 6), the variation of the composition of the copolymer obtained by the feed rich in M_2 takes place within very narrow ranges of the feed composition, while the variation at the feed poor in M_2 takes place within very wide ranges (the ascending slope of the monomer/copolymer curve).

The compositions of the copolymers affected by the highest errors correspond to the cases $x_2 > 0.6$.

Therefore, the contribution of the samples of copolymers obtained at the values of highest x_2 was diminished in the calculation of the reactivity ratios.

[30] L. M. Batuner and M. E. Pozin, "Mathematical Methods in Chemistry", translated into Romanian from Russian, 2nd edition, Bucharest, 1956, p. 480.

Some graphs regarding the linearization of the differential equation of the binary copolymers NVC − VPy by Fineman-Ross' method are presented in fig. 8, 9 and 10.

The values of the reactivity ratios for the three binary systems are summarized in table 6.

Table 4

Experimental data for determining the NVC (M_1) −2 VPy (M_2) system constants at 70°

Feed composition (mole fr.) x_2	Conversion (%)	N % Dumas	2VPy in copolymer (mole fr.) X_2	R_i	ρ_i

Table 5

Experimental data for determining the NVC (M_1) −4 VPy (M_2) system constants at 70°

Feed composition (mole fr.) x_2	Conversion (%)	N % Dumas	4VPy in copolymer (mole fr.) X_2	R_i	ρ_i
0.045	2.03	10.80	0.284	21.22	2.521
0.095	2.27	11.18	0.408	9.526	1.451
0.156	2.51	11.51	0.514	5.410	0.945
0.187	2.51	12.02	0.665	4.348	0.504
0.493	1.08	12.79	0.870	1.028	0.149
0.808	2.26	13.02	0.927	0.238	0.079
0.896	2.61	13.18	0.965	0.116	0.036

Table 6

Values of the copolymerization constants for the binary systems NVC (M_1) − VPy (M_2)

M_2	r_1		r_2	
	Least square method	Fineman-Ross method	Least square method	Fineman-Ross method
2VPy	0.123	0.10	4.35	3.7
4VPy	0.096±0.024	0.094	4.43±1.37	3.9
2M5VPy	0.037	0.04	11.58	10.70

As shown in this table, the values of the reactivity ratios obtained by Fineman-Ross' method and the least square method correspond to each other.

According to the kinetic determinations, the values of the reactivity ratios show that the best reactive monomers in these processes are the VPy.

It may be seen that the 2M5VPy reactivity and polarity are similar to those of ST ; this is based both on the values of the reactivity ratios of these monomers in their reactions with NVC[4] and on the binary copolymerization of ST with 2M5VPy.[31]

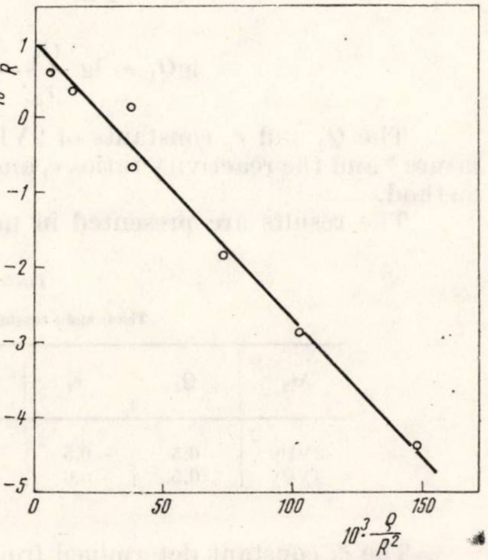

Fig. 8. — Graphic determination of the NVC — 2VPy system constants after Fineman-Ross.

3.4. Calculation of the Q and e constants

The Q_1 and e_1 constants for NVC were calculated by means of the equation derived from the Alfrey and Price's scheme [32] :

$$e_1 = e_2 \pm (-2.303 \ \lg \ r_1 r_2)^{1/2} \tag{9}$$

$$\lg Q_1 = \lg \frac{Q_2}{r_2} - \frac{e_2}{2.303}(e_2 - e_1) \tag{10}$$

The Q_2 and e_2 constants of 2VPy and 4VPy were found in the literature [8] and the reactivity ratios r_1 and r_2 were obtained by the least square method.

The results are presented in table 7.

Table 7

The Q and e constants for NVC (M_1)

M_2	Q_2	e_2	r_1	r_2	Q_1	e_1
2VPy	0.5	−0.5	0.123	4.35	0.171	−1.29
4VPy	0.5	−0.6	0.096	4.43	0.167	−1.22

The e_1 constant determined from these systems is intermediary between the values obtained in the copolymerization systems with ST ($e_{NVC} = -1.61$) and with MMA ($e_{NVC} = -0.96$). [4] At the same time, both the donor effect of the lactamic cycle and the significant dependence of the polar effect on the nature of the partner are confirmed.

The Q_1 and e_1 constants of NVC calculated from these copolymerization systems approach the average values obtained earlier, $\bar{Q}_1 = 0.116$; $\bar{e}_1 = -1.1$. [4]

LIQUID MEMBRANE-ELECTRODES. V*

ELECTRODIC BEHAVIOUR OF SODIUM TETRAPHENYLBORATE IN CYCLOHEXANONE TO CERTAIN MONOVALENT CATIONS

ELENA HOPÎRTEAN and EUGENIA ŞTEFĂNIGĂ

"Babeş-Bolyai" University, Department of Analytical Chemistry, Cluj, str. Arany Janos 11
Romania

Received October 29, 1973

The paper is concerned with obtaining and establishing the electrodic behaviour of a sodium tetraphenylborate liquid membrane dissolved in cyclohexanone. The electrodic behaviour to the following cations was studied : K^+, Cs^+, NH_4^+ and Ag^+. A good electrodic behaviour has particularly been observed to K^+ and Ag^+ both in the absence and in the presence of some interfering ions (Na^+, Ca^{2+}, Mg^{2+}).

1. INTRODUCTION

One of the liquid membrane-electrodes described in the speciality literature is that whose active electrodic component is sodium tetraphenylborate. The electrode accomplished by Scholer and Simon [1] has been obtained by evaporating tetrahydrofurane from the solution containing sodium tetraphenylborate, tenoyltrifluoracetone in *p*-nitrocymole and PVC in tetrahydrofurane. The resulting electrode was employed by the authors in the direct potentiometric determination of certain organic cations (ammonium quaternary salts) as well as of Cs^+ and K^+.

The present paper deals with a simpler approach for obtaining a liquid membrane-electrode with sodium tetraphenylborate as an active component and also tries to establish its behaviour to some monovalent cations : K^+, Cs^+, NH_4^+ and Ag^+.

2. EXPERIMENTAL SECTION

2.1. *Manner of obtaining the membrane-electrode.* The electrode body was achieved according to the chart in fig. 1. The active electrodic component (2) (sodium tetraphenylborate dissolved in cyclohexanone) is introduced into the space between the walls of the two concentric glass tubes having a glass frit G_4(1) fixed at their end. The central tube contains the internal solution (3) into which the internal reference electrode (5) (calomel saturated electrode) will be introduced by means of an electrolytic trap (4) (10^{-1}M $NaNO_3$+1 % agar-agar). The internal solutions used was the tested ion salt solution of a 10^{-4} M concentration.

2.2. *E-pM electrodic functions.* A MV—11 pH-meter was used for measuring the f.e.m. of the following electrolytic chain:

SCE | electrolytic trap | internal solution | membrane | external solution | electrolytic trap | SCE

Measurements were performed at room temperature under non-stirring conditions. A preliminary determination was made on the electrodic behaviour to K^+ of the liquid membrane with various proportions of sodium tetraphenylborate : 0.1 %, 0.25 %, 0.5 % and 1%, in view of establishing its optimum composition. A good electrodic behaviour was found in the case of the membrane having a 0.25 % $Na[B(C_6H_5)_4]$ content in cyclohexanone. All the results reported in this paper have been obtained with a membrane of this composition. The electrodic functions have been established both in the absence and in the presence of some interfering ions.

Fig. 2 presents the electrodic functions obtained for K^+ in presence of Na^+ having various concentrations, compared to the electrodic function obtained in the absence of the interfering ion. The electrodic functions shown in fig. 3 were obtained for K^+ in the presence of Mg^{2+}. Investigations were also made on the membrane electrodic behaviour to K^+ in the presence of ion Ca^{2+}. The results concerning the membrane electrodic behaviour to K^+ in the presence of interfering ions Na^+, Mg^{2+} and Ca^{2+} are presented in table. 1. Data in table 1 clearly illustrate that the concentration range in

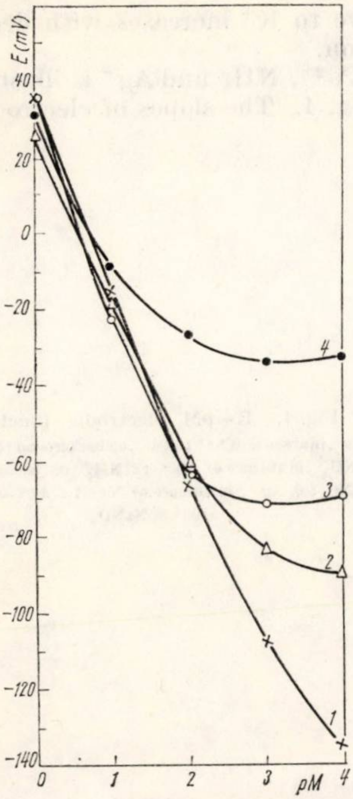

Fig. 2. — Electrodic functions for K$^+$:

Table 1

Electrode behaviour of the membrane to K$^+$

Interfering ion	Concentration of interfering ion	pK interval	Slope (mV)
—	—	0−3	48.0
Na$^+$	10^{-3} M	0−3	42.0
	10^{-2} M	0−2	41.0
	10^{-1} M	0−1.5	35.0
Ca^{2+}	10^{-2} M	0−2	44.0
	10^{-1} M	0−1.5	30.0
Mg^{2+}	10^{-3} M	0−3	48.0
	10^{-2} M	0−2	30.0
	10^{-1} M	0−2	30.0

which the membrane remains sensitive to K^+ increases with decrease in the concentration of the interfering ion.

The electrodic behaviour to ions Ca^{2+}, NH_4^+ and Ag^+ is illustrated by the electrodic functions presented in fig. 4. The slopes of electrodic functions obtained for these ions both in the absence and in the presence of ion Na^+ are plotted in table 2. The presence of ion Na^+ in solution hinders in particular the electrodic behaviour to NH_4^+. Emphasis is also laid on the super-Nernstian value of the electrodic function slope obtained for ion Ag^+ in the absence of the interfering ion.

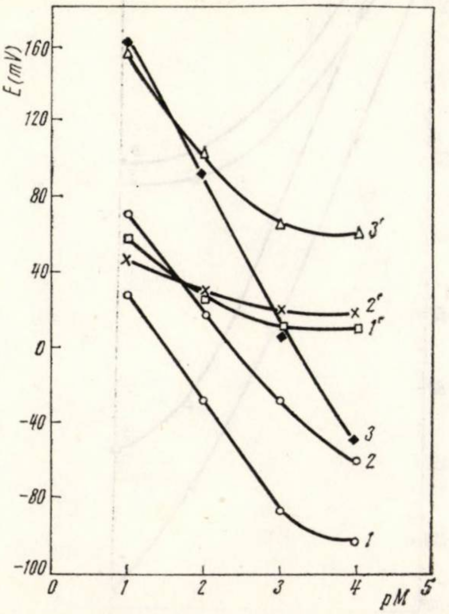

Fig. 4. — E — pM electrodic functions: 1, Cs^+, in absence of Na^+; 1, Cs^+, on background 10^{-1} M $NaNO_3$; 2, NH_4^+, in absence of Na^+; 2′ NH_4^+, on background 10^{-1} M $NaNO_3$; 3, Ag^+, in absence of Na^+; 3′ Ag^+ on background 10^{-1} M $NaNO_3$.

Table 2

Electrode behaviour of the membrane to Cs^+, NH_4^+ and Ag^+

Ion	In the absence of background		On background 10^{-1} M $NaNO_3$	
	pM interval	Slope (mV)	pM interval	Slope (mV)
Cs^+	1 – 3	49.5	1. – 2.5	24.0
NH_4^+	1 – 3	59.0	1 – 2.5	12.0
Ag^+	1 – 4	72.6	1 – 2.5	36.1

2.3. *Potentiometric titrations.* The membrane-electrode was used in the determination, by potentiometric titration, of tetraphenylborate with $AgNO_3$ and KCl, respectively, and also of KCl with sodium tetraphenylborate. The resulting titration curves are shown in fig. 5. As it was expected, a larger potential variation at equivalence has been found when using $AgNO_3$ as a titrant.

In conclusion, the liquid membrane-electrode obtained by impregnating the glass frit G_4 with a sodium tetraphenylborate solution in cyclohexanone revealed a good electrodic behaviour, particularly to K^+ and Ag^+. The electrode may be used both in direct determinations for Ag^+, K^+, Cs^+ and NH_4^+ and in the potentiometric titration of sodium tetraphenylborate (titrant $AgNO_3$ or KCl) and of KCl (titrant Na $[B(C_6H_5)_4]$.

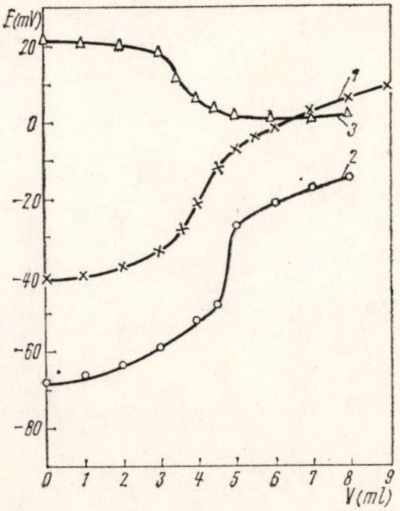

Fig. 5. – Potentiometric titrations : *1*, 2×10^{-2} M Na $[(B(C_6H_5)_4]$ with ~ 10^{-1} M $AgNO_3$; *2*, 2×10^{-2} M Na $[B(C_6H_5)_4]$ with ~ 10^{-1} M KCl ; *3*, 10^{-2} M KCl with ~ 5×10^{-2} M Na $[B(C_6H_5)_4]$.

CORRELATION OF THE POROUS STRUCTURE TO THE ACTIVITY AND SELECTIVITY OF SOME DEHYDROGENATION CATALYSTS

VLADIMIR MOCEAROV, GEORGETA CSOMONTANYI, CORNELIA CORICIUC
and ALEXANDRU PANOVICI

"I.C.P.R.P." Petroleum Refining and Petrochemistry Research and Design Institute, Ploieşti,
Bd. Republicii 291, Romania

Received November 7, 1972
Revised March 18, 1974

The possibilities of performing increased conversions in catalytic dehydrogenation of ethylbenzene, in an adiabatic reactor are analysed, based on theoretical considerations. A suitable catalyst is chosen for this purpose, according to its kinetic characteristics. Its porous structure is correlated to its activity and selectivity in the reaction studied. In order to eliminate the inner diffusional influences on the reaction rate, the porous structure of the catalyst was changed and the effect of this transformation on the catalyst performances was examined.

It is a well-known fact that the dehydrogenation of ethylbenzene to styrene is an equilibrium endothermal reaction which takes place with a volume increase.

Thermodynamic calculations enable us to establish the conditions favouring the progress of the reaction in the desired direction, namely towards :

a) temperatures over 550°, the upper limit being a function of kinetic features of the used catalysts, and of their selectivity at high temperatures ;

b) high dilutions of the reactant to lower its partial pressure. Generally, the dilution of hydrocarbon is achieved by steam, which, besides lowering the partial pressure of the hydrocarbon, plays also the role of heat carrier, and of regenerating agent of coke deposited on the surface of the catalyst.

The favourable effect of temperature and dilution on the dehydrogenation equilibrium of ethylbenzene is shown in figure 1.

Isobars 1 and 2 represent the variation of the conversion at equilibrium with the temperature, without dilution, and with molal dilution of 20 : I, respectively. Adiabatics 3, 4, 5, and 6, illustrate the decrease of temperature with the conversion, owing to the endothermic character of the reaction. For different values of the initial temperature – To, that is for 650°, 640°, 620°, and 580°C, under the conditions of the same conversion of about 65 mole per cent, effluent will leave the reaction zone with different temperatures, i. e. : 580°, 570°, 550° and 510°. An increase from 550° to 575° of the effluent temperature, at the outlet, displaces the equilibrium by approximately eight mole percent in favour of the formation of styrene (curve 2) so that, by reaching a 575° temperature at the bottom of an adiabatic styrene reactor, it becomes possible to perform conversions above 60 mole percent.

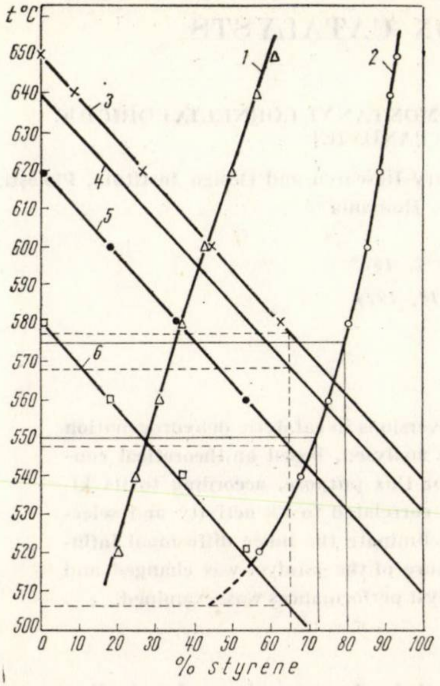

Fig. 1.— Conversion at equilibrium dependence on temperature, during dehydrogenation of ethylbenzene without dilution (1) and with dilution of 20 moles H_2O to one mole hydrocarbon (2). The adiabatics $\Delta T/\Delta x$ for different values T^0 (3, 4, 5, 6) dilution molal ratio 20 : I.

In modern styrene processes, such performances are obtained either in tubular polytropic reactors with outer heating or in a succession of several adiabatic reactors set in a series, with supplementary heating of the effluents from each reactor.[1-4]

The basic problem for achieving high conversions, on a single adiabatic reactor, consists in operating the latter in such a way as to have the effluent leaving the reactor at a temperature of about 575°. To achieve this, there are two possibilities namely :

— to obtain very high steam/hydrocarbon dilutions

[3] Hülls Chem. Werke, Brit. pat. 765025, 2 January, 1957;

[4] Monsanto, Chem. Co., Brit. pat. 966704, 12 August, 1964;

— to raise the temperature of the feed at the entrance of the reaction zone.

The reaction carried out at high dilutions in order to obtain the minimal values of the ratio $\Delta T/\Delta x$ (where T = the temperature in the reaction zone and x = conversion), may lead, theoretically, to the reduction of the temperature gradient on the catalytic layer at 45° for an approximate 65 mole per cent conversion.

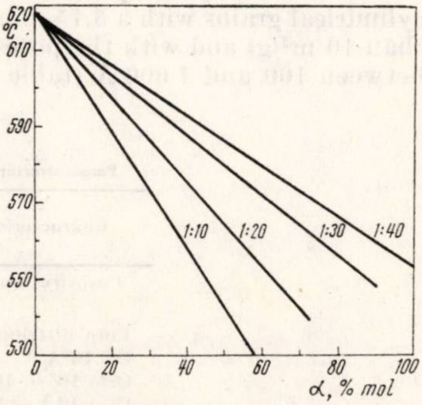

Fig. 2. — Decrease of the temperature with the degree of conversion in an adiabatic reactor, during dehydrogenation of ethylbenzene for different molal dilutions (T^o = 620°C).

As it results from figure 2, which shows the adiabatics of the temperature variation of different conversions for different dilutions, the above mentioned performances will be achieved, for instance, at a molal dilution of 40 : I if the entrance temperature of the stream on the catalytic layer is 620°. It is not profitable to obtain such high dilutions because this requires higher investments, owing to the large dimensions of the reactor, and to a supplementary energy consumption needed for the transport, evaporation and condensation of the diluent in excess.

The solution recommended to achieve higher conversions in the adiabatic styrene reactor, is to raise the temperature of the feed entering the reaction zone to approximately 640°, maintaining the molal dilution ratio at a value of 20 :1. At this temperature, the majority of catalysts involved in styrene process present low selectivities, either owing to their kinetic characteristics, or due to the shifting of the reaction into the diffusion rate controlled area.

EXPERIMENTAL

To obtain higher conversions in the adiabatic dehydrogenation reactor of ethylbenzene, we have recommended, as a result of our studies, the use of a catalyst based on iron oxides and additives differing from the variants of conventional catalysts by kinetic characteristics, namely : ability to work at high thermal level, possesing close values for the apparent activation energy of the main reaction and of the secondary reactions, i. e. the selectivity of the process is not significantly affected in the interval of 600 – 650°. This catalyst has been termed "catalyst *A*" in the present paper.

The kinetic characterization of "catalyst *A*" was carried out in a dynamic laboratory isothermal system, under kinetic conditions, the diffusional influences on the reaction rate being negligible.

The test reaction was the dehydrogenation of ethylbenzene in dilution with steam.

From a physical point of view, "catalyst *A*" occurs in the shape of cylindrical grains with a 3.75 mm diameter with a low specific surface (less than 10 m^2/g) and with the pores radia spread mainly in the field ranging between 100 and 1 000 Å (table 1).

Table 1

Porous structure of catalyst "A" and "B"

Characteristics	Catalysts "*A*"	Catalysts "*B*"
Porosity, $cm^3/100$ g	40.0	57.0
Pore distribution, %		
$Ø < 10^2$ Å	3.0	2.6
$Ø = 10^2 - 10^3$ Å	70.0	39.4
$Ø = 10^3 - 10^4$ Å	22.0	10.0
$Ø > 10^4$ Å	5.0	48.0

The study was further continued to establish the amount of inner and outer diffusion resistences. We have taken the partial pressure gradient of the reactant in the bulk gas phase and at the surface of the catalyst grain, as a measure of the external diffusion resistance.

Making use of the calculation relationship for the pressure gradient of the reactant, in the bulk gas phase and on the surface of the grain :

$(p_g - p_i) = \dfrac{N}{K_g}$, where : N = mass flow, moles/cm^2. sec.

K_g = mass transfer coefficient in the gaseous phase, moles/cm^2. atm. sec.

p_g = partial pressure of the reactant in the bulk gas phase, atm.

p_i = partial pressure of the reactant at the grain surface, atm.

Under hydrodynamic conditions favourable to the normal run of the process the values determined for $(p_g - p_i)$ were of the 10^{-2} atm order, a fact which entitled us to consider that outer diffusion does not control the process studied.

To evaluate the contribution of the inner diffusion on the dehydrogenation reaction rate in the presence of "catalyst *A*" we calculated the values of the dimensionless parameters γ and β determined by relationships :

$\gamma = \dfrac{E}{R \cdot T}$, where : E = activation energy, kcal/mol.

R = gas constant, kcal/mol. degree Kelvin

T = temperature, degree Kelvin

$\beta = \frac{\text{Co.H.Deff}}{K_{\min} \cdot T}$, where : C_0 = concentration of the reactant at the outside of the grain, mol/cm^3

H = reaction heat, kcal/mol.

Deff = effective diffusion coefficient, cm^2/sec.

K = thermal conductivity of the catalyst, kcal/cm. sec. degree Kelvin.

Using the values given in table 2, we calculated $\gamma = 19$ and, $\beta = 0.0038$ respectively. The very low value of parameter β leads us to the conclusion that no notable temperature decrease takes place inside the grain throughout reaction.

Table 2

Values for the calculation of parameters γ and β

Magnitude	Value
Apparent activation energy, E, kcal/mol	34,7
Gas constant, R, kcal/mol Kelvin degree	0,002
Temperature, T, Kelvin degree	913
Initial hydrocarbon concentration, C_0 mol/cc.	$6.75 \cdot 10^{-7}$
Reaction heat, H, kcal/mol	29.0
Grain thermal conductivity, kcal/ /cm.s°.K	$9 \cdot 10^{-8}$
Effective diffusion coefficient, cm^2/sec.	$1.59 \cdot 10^{-2}$
Dimensionless parameter γ	19
Dimensionless parameter β	0.0038

The calculus of the value of Thiele's modulus, by means of relations :

$\text{Ø} = R\sqrt{\frac{K}{\text{Deff}}}$, where : R = the effective grain radius, cm.

k = apparent rate constant, sec^{-1}.

Deff = effective diffusion coefficient, cm^2/sec.

in the case of "catalyst A" for a temperature of 640°C, based on the data of table 3, the module value of 6.04 was calculated.

Making use of the diagram representing the utilization factor η as a function of Thiele's modulus Ø, according to Weisz and Hicks[5] for $\gamma = 20$ (figure 3), we note that with "catalyst *A*", the utilization factor $\eta = 0,4$, what shows that the inner diffusion slows down the reaction rate.

---

[5] P. B. Weisz and J. S. Hicks, *Chem. Eng. Sci.*, **17** , 265 (1962).

Table 3

Values of Thiele's modulus for catalysts "A" and "B"

Catalyst	Rate constant k, $\sec^{-1}$	Effective grain radius cm	Ø
"*A*"	$2.95 \cdot 10^9 \exp\left(-\frac{34{,}700}{R.T}\right)$	0.187	6.04
"*B*"	$1.05 \cdot 10^9 \exp\left(-\frac{31{,}650}{R.T}\right)$	0.02	0.67

There are two means for eliminating this deficiency, namely : either to reduce the diameter of the catalyst grain, or to create, inside the grain, cavities in which the diffusion should take place, approximately according to the same laws as in the free intergranular space. Since the first solution implies an important pressure drop on the catalytic layer, we have chosen the second solution. Thus, acting on the porous structure of "catalyst *A*", by means of an original patented technique we created the catalyst, termed "catalyst *B*" in this paper.

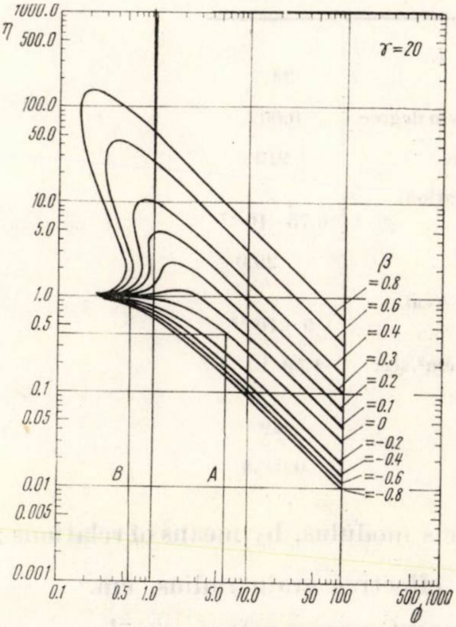

Fig. 3 — Utilization factor dependence on Thiele's modulus Ø, for the value $\gamma = 20$, in the case of catalysts "*A*" and "*B*".

From the texture point of view, "catalyst *B*" is characterized by a prevailing area of macropores, approximately 50 % of the pores having radia over 10.000 Å, the porosity being also higher than that of the "catalyst *A*" (table 1).

The kinetic characteristics of "catalyst *B*" are only slightly different from those of "catalyst *A*", and the differences between the values of dimensionless parameters γ and β are also very slight. According to the data presented in table 3, the marked differences in the value of the effective radii of the grains, as well as those of the effective diffusion coefficient, for "catalyst *B*", compared to "catalyst *A*", resulted in a 10 time smaller value of Thiele's modulus for "catalyst *B*", respectively 0.67 (table 3).

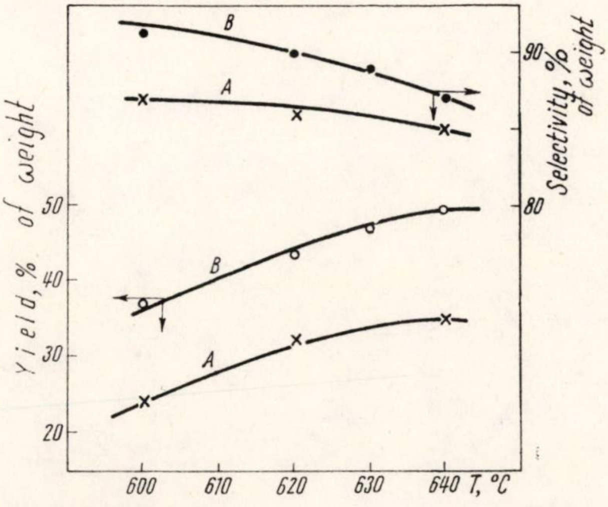

Fig. 4. — Yield (*R*) and selectivity (*S*) dependence on temperature, during dehydrogenation of ethylbenzene on catalysts "*A*" and "*B*".

According to the Weisz and Hicks diagram, for $\gamma = 20$, an utilization factor practically equal to I corresponds to a value 0.67 of Thiele's modulus, which means that the inner diffusion no longer bear any influence on the dehydrogenation rate (figure 3).

The effects of the change in the catalyst porous structure on its activity and selectivity in the dehydrogenation reaction of ethylbenzene are emphasized in the example given in figure 4.

By representing the variation of the yield and selectivity during the dehydrogenation of a steam diluted ethylbenzene (molal ratio water/ethylbenzene, 18 :I) one notices the superiority of the catalyst with modified porosity, "*B*", over "catalyst *A*" in yield as well as in selectivity.

To conclude, by combining harmoniously the kinetic properties and those of porous structure, we have obtained a catalyst with the desired qualities : high yields and selectivity at a high thermal working regime, without increasing the pressure drop on catalytic layer. The above performances were confirmed by a commercial practice.

Revue Roumaine de Chimie, **19**, 7, 1279–1282 (1974)

RARE EARTH ION EXCHANGE OF SYNTHETIC FAUJASITE SUBSTITUTED ISOMORPHOUSLY BY BORON

PETRU ONU and VASILE ABABI

Department of Chemical Technology, "Al. I. Cuza" University, Iași, Str. 23 August, nr. 11,
Romania.

Received May 25, 1973.

We studied the ion exchange capacity for europium and uranyl of synthetic faujasite zeolites, substituted isomorphously by boron. The ion exchange process is comparatively analysed relative to that involving X or Y type zeolites but without boron in their composition. Also, a few data about the thermal stability of the investigated samples are presented.

Faujasite zeolites have pores with a cross section of about 8 – 9 Å, which allow a great number of saturated and aromatic hydrocarbons to diffuse to the inside of the cavities. For this reason, these zeolites have important practical applications, among which their use in the different catalysis process is of great interest.

From the point of view of the catalytic activity, and their thermal stability, most important are faujasite zeolites in the alkaline earth metals form and especially those in the rare earth form.[1-3]

The latest investigations showed that besides zeolites with molecular sieve properties in the $Na_2O - Al_2O_3 - SiO_2 - H_2O$ system, it is also possible to form zeolites with aluminium and silicon, or only with one of these to be substituted isomorphously by other elements.[4]

This paper presents data concerning the ion exchange study with europium and uranyl on faujasite zeolites, substituted isomorphously by boron. This type of zeolites has been prepared hydrothermally by us, and the practical data with respect to their synthesis and structural adsorptive characterization was reported in a previous paper. [4]

From the cited literature it has resulted that no detailed study was reported up to now with regard to ion exchange with europium and uranyl on molecular sieves and especially on those substituted isomorphously by boron.

EXPERIMENTAL SECTION

For the determination of ion exchange capacity of the zeolites substituted by boron, we have chosen the samples number 43, 44 and 46,[4] comparatively with two reference samples without boron; one of Y type and the other of 13X type. The composition of these samples, expressed by the mole ratio between SiO_2, Al_2O_3 and B_2O_3 is presented in table 1.

Table 1

The chemical composition of the investigated zeolites

Sample	SiO_2/Al_2O_3	$SiO_2/Al_2O_3 + B_2O_3$
43	2.77	2.77
44	2.90	2.88
46	3.42	3.00
Y	4.40	
13X	2.70	—

For all determinations carried out by us, the reagents used were 0.3 N $EuCl_3.6H_2O$ and $(CH_3 - COO)_2UO_2$ solutions and the contact time and the ion exchange temperature were varied so as to obtain different degrees of exchange.

The variation of the exchange capacity for the UO_2^{2-} and Eu^{3+} ions, for all above mentioned samples is represented in figures 1 and 2.

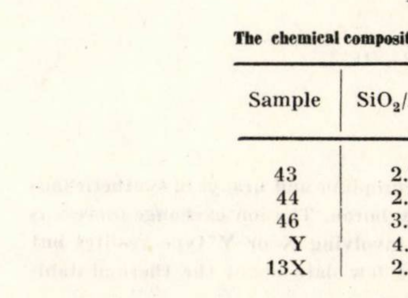

Fig. 1. — The exchange capacity variation for europium vs. time and for 25° temperature: 1 — Y; 2 — 46; 3 — 44; 4 — 13X; 4 — 43.

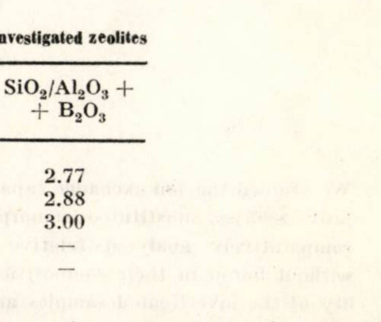

Fig. 2. — The exchange capacity variation for uranyl ion vs. time and contact time sample 46.

The contact time was varied from 10 minutes to 28 hours and the temperature between 25 and 85°. On the basis of the practical data it was found that the ion exchange process can be conducted in such a manner as to substitute either only the sodium ions from S_{III} positions, or also those from S_{II} positions.

RESULTS AND DISCUSSION

Kinetics of the ion exchange process shows that the ion exchange capacity for a certain contact time is greater for samples number 43,44 and 46, compared to that of Y sample. It is explicable because the $SiO_2/Al_2O_3 + B_2O_3$ ratio in our synthesis samples is lower than that of the Y sample. At the same contact time these data prompt us to consider that the windows of the cavities of the samples obtained by us are large enough and they allow a rapid diffusion of the ions from the inside to the outside and vice versa. As a result of the fact that the openings of the pores which link the cavities to each other have a sufficiently large diameter, both in our samples and in the reference samples, the rate of the ion exchange process at the first contact with europium solutions is high enough and after 10 minutes about 14% of the total sodium ions are exchanged. This value is about similar to the percentage of the sodium ions which are placed inside of the faujasite cavities, in the S_{III} positions. After an almost total substitution of sodium ions by those of europium, the rate of the exchange process slowly decreases, so that for 10 hours contact time, only 47% of the total number of sodium ions of sample 46 are exchanged by europium. As regards the rate of the europium exchange process for a given temperature and a certain contact time, the investigated samples are situated in the following order : $43 > 13X > 44 > 46 > Y$.

The temperature influence on the ion exchange process with europium is insignificant. This may be illustrated by the fact that at a temperature of 25° and 24 hours contact time, the degree of exchange on the Y sample is 56.68% and at 85°, for the same contact time, it is only 64.98%. It also results from these data that for a 24 hours contact time and at 85° the ion exchange process involved only 91% of the total sodium ions, placed in the S_{II} positions. This demonstrates that not all S_{II} positions are identical and as accessible for ion exchange process, the influence of diffusion being more marked. The same observations may be reported for samples number 43, 44, 46 and 13X.

The sodium ions exchange from the S_I positions, placed inside the hexagonal prisms, is difficult to obtain with europium or uranyl ions and we consider that in our experiments, this did not take place. It is estimated that this drawback is due to the hydrated europium or uranyl radius, which has a higher value than that of the opening window of the hexagonal prism [2]. On the basis of the experiments the ion exchange of sodium ions by europium was found to have positive influence on the thermal stability of all the investigated samples.

Using the derivatographic method is was found that there is a great difference between the thermal stability of the Y sample in sodium form and that of the Y sample with 63.27% exchanged by europium. In this way it was found that the temperature at which the destruction of the crystalline structure takes place at maximum rate is 898° for the sample in the sodium form and 967° for the sample in the sodium-europium form. The same effect was also found for samples with boron in the network. It results from the analysis of the experimental data that the crystalline

---

[5] H. S. Sherry, *J. Colloid Inter. Science*, **28**, 288 (1968).

structure of the sample number 46, with 60.25% sodium exchanged, resists up to 858° temperature. This temperature is by 78° higher than the destruction temperature of the sample 46, but only in the sodium form. As regards the ion exchange with uranyl ion compared to europium, this takes place at a lower rate and is more dependent on the temperature. Thus, it was found that for an exchange only of the sodium ions placed in the S_{III} positions it is necessary to have a contact time of four hours at 25° or one hour for a temperature of 40°. This may be explained by the fact that the uranyl ion has a bigger radius than that of the europium and as a result, the diffusion to the exchange positions is lower.

Analysing the ion exchange capacity value we can find that in the case of the uranyl ion exchange, the sodium ions placed in the S I positions did not participate in the exchange process.

From the point of view of the thermal stability the samples in the uranyl form are inferior to those with europium. This is due to the uranium tendency to form high oxides more stable in the presence of oxygen and high temperatures.

CONCLUSIONS

The investigations of the ion exchange with rare earth by zeolites faujasite type substituted isomorphously or unsubstituted by boron led to the following conclusions :

— By the ion exchange method we have obtained zeolites of faujasite type substituted isomorphously by boron, in which sodium was replaced in different proportions by europium and uranyl.

— To exchange about the same quantity of sodium ions only from the S_{III} positions of a faujasite zeolite structure it is necessary to have a contact time of 10 minutes for europium and 4 hours for uranyl ions, at a temperature of 25°.

— According to the rate of the exchange process with europium for a given temperature and for a certain contact time, the investigated samples range in the order $43 > 13X > 44 > 46 > Y$.

— Replacement of sodium ions by those of europium for a faujasite structure substituted isomorphously or unsubstituted by boron, induces the increase of the network thermal stability, yet this remins lower than in the case of the same type of structure without boron. The thermal stability of zeolites with europium is higher than that of zeolites with uranyl.

COMPTES RENDUS

R. DAUDEL, ,,*Quantum theory of chemical reactivity*'', D. Reidel Publishing Company, Dodrecht. Holland, 1973, 158 p.

The aim of Professor Daudel's book is to point out how the application of quantum mechanics to the chemical phenomena may contribute to make clear a vital aspect of today chemistry, namely the chemical reactivity. As the author writes in the preface, it is intended for students as well as for physical-chemists and chemists, research workers and engineers taking an interest in quantum chemistry for its own sake or for its application in industry, pharmacology and the life sciences.

Divided into four chapters, the book is based on the transition state method used in order to expose the main factors which determine chemical equilibrium and rate constants.

The introduction of the first part presents the importance of the walls, the part played by the impurities and the intervention of the solvent, as factors determining the course of a reaction. After this brief introduction, the theory of Eyring and Polanyi is examined and equations are established for equilibrium constants in the gaseous phase as well as for rate constants of bimolecular, monomolecular and termolecular processes in the gaseous phase.

The second chapter contains an analysis of both intermolecular forces and methods of calculation of intermolecular interactions, being mainly devoted to the interactions between unbonded atoms.

As a conclusion of this part it is discussed the possibility to make conformational analysis based on these types of calculations and the limits of such theoretical calculations of molecular conformation energy. The possibility to predict conformational equilibrium constants is also discussed.

In the third chapter, equilibrium constants of reversible reactions are treated, presenting the actual state of the quantum theory of balanced reactions in solution. There is a survey of the role played by different factors which determine oxido-reduction potentials, particularly the polarographic half-wave potentials, strength of acids and bases as well as the tautomeric equilibria. The solvent effect is underlined and some applications in biochemistry and in the analysis of the mechanism of mutations are presented.

The last part contains the examination of the methods which make it possible to estimate theoretically the rate constants of a few reactions of organic chemistry. This capter is an application of quantum chemistry methods to the study of nucleophilic, electrophilic and radical substitutions, addition and polymerization reactions and of some reactions in radiation chemistry and photochemistry.

The book contains, in a particularly clear and condensed style, the most significant information in this field. A large and meaningful list of papers is quoted and critical surveys of various aspects of the topics are presented.

In conclusion this book represents an excellent tool for chemists which are interested in the application of the most modern methods in the interpretation and prediction of the chemical reactivity of molecules.

Marina Olteneanu

NOTE POUR LES AUTEURS

La *Revue Roumaine de Chimie* publie des articles en anglais, français, russe, allemand ou espagnol. Les auteurs sont priés d'envoyer des articles, notes, communications et comptes rendus inédits.

Les manuscrits seront dactylographiés à deux intervalles. Les tableaux seront dactylographiés sur feuilles séparées, de même que la légende des figures. Les diagrammes seront tracés à l'encre de Chine sur papier calque. Les tableaux et les figures seront numérotés par des chiffres arabes, en nombre strictement nécessaire. Prière de ne pas inscrire les mêmes données dans les tableaux et les figures. Les formules chimiques seront incluses dans le texte ; en outre, elles seront transcrites sur des feuilles séparées. Les auteurs sont priés d'indiquer les caractères italiques (en soulignant les lettres au crayon), ainsi que tout autre caractère spécial. L'ordre des références bibliographiques sera celui de leur mention dans le texte ; le nom de l'auteur sera précédé de l'initiale du prénom ; les publications périodiques seront présentées suivant les prescriptions internationales. Les références seront ajoutées à la fin de l'article ; elles paraîtront comme des notes, au bas de la page. Le texte sera précédé d'un résumé, comprenant 15 lignes au maximum.

L'entière responsabilité du contenu des articles appartient aux auteurs. On publie des articles dus aux collaborateurs roumains ou étrangers. Les auteurs recevront 50 tirés à part.

INTERDIFFUSION COEFFICIENTS OF SILVER (I) IN MOLTEN SODIUM NITRATE – ALKALINE EARTH NITRATES MIXTURES

NAROTTAM P. BANSAL

Department of Chemistry, Ramjas College, University of Delhi,
Delhi – 110007, India

Received November 13, 1973

The interdiffusion coefficients D, of silver (I) in molten binary eutectic $NaNO_3-M(NO_3)_2$ (M = Ba, Sr, Ca) mixtures have been determined in the temperature range 572–692 K using a chronopotentiometric method. The temperature variation of D in the three melts in the range studied could be expressed, respectively, by the equations

$$D = 0.633 \times 10^{-3} \exp\left(-\frac{4070}{RT}\right),$$

$$D = 1.159 \times 10^{-3} \exp\left(-\frac{4704}{RT}\right),$$

$$D = 0.648 \times 10^{-3} \exp\left(-\frac{4175}{RT}\right).$$

Values of D in these solvents have been compared with those available in other nitrate melts and the effect of the presence of divalent alkaline earth metal cations in the solvent on the diffusion process has been discussed. Applicability of Stokes-Einstein equation to $NaNO_3-Ca(NO_3)_2$ system has also been described.

INTRODUCTION

The diffusion coefficients in molten melts are important for relating thermodynamic and transport properties,[1] evaluation of structural models for transport processes [2] and the theoretical equations of electroanalytical chemistry.[3,4] Of the several techniques employed for the determination of diffusion coefficients in molten salts, mention may be made of the constant mass diffusion cell (Laity and Miller[5]), the gravimetric method using a porous frit (Sjoblom[6,7]), polarography[8,9] and oscillographic polarography.[10,11] More recently chronopotentiometry has also been applied for the determination of diffusion coefficients of various metal ions in different molten salts[12–15] and their mixtures.[15–18] Laity and McIntyre[19] have shown, via irreversible thermodynamics, that at low solute concentrations the chronopotentiometric diffusion coefficient of an ion may be equated to both its interdiffusion and self-diffusion coefficients.

In chronopotentiometry, the solution of a depolarizer in the presence of a large excess of an indifferent electrolyte is electrolysed at constant current and variations of the potential of the microelectrode with time are recorded *versus* a suitable reference. The diffusion coefficient (D) of the electroactive species is computed from the equation

$$D^{\star} = \frac{4 i_0^2 \, \tau}{\pi F^2 \, n^2 \, c^{02}} \tag{1}$$

where i_0 is the current density (amp cm^{-2}), τ the transition time (sec), F the Faraday constant, n the number of electrons required in the reduction process and C° the bulk concentration (mole cm^{-3}) of the depolarizer. In the derivation of eq. (1) it has been assumed that the whole electrolysis current is used in the Faradaic process, but actually a part of it is always consumed in charging the electrode double layer capacitance. However, it has been shown that eq. (1) may still be employed provided that τ is much larger than the time used in charging the double layer.

* The thermodynamic diffusion coefficient, D', is related to the ordinary diffusion coefficient D as

$$D' = D / \left[1 + \frac{d \ln \gamma}{d \ln X} \right]$$

where γ and X are the activity coefficient and mole fraction of the solute. In the present investigation, the concentration of Ag(I) is very low so that $d \ln\gamma / d \ln X$ may be taken as zero.

The present communication reports the interdiffusion coefficients of Ag(I) in molten binary eutectic $NaNO_3-M(NO_3)_2$ (M = Ba, Sr, Ca) mixtures in the temperature range 572–692 K using the chronopotentiometric method with a view to examine the influence of the presence of doubly charged alkaline earth cations on the diffusion process of Ag(I) in the mixed solvents. The Arrhenius activation energies for the diffusion process have also been computed.

MATERIALS AND EXPERIMENTAL METHOD

Sodium nitrate, barium nitrate and silver nitrate were AnalaR(BDH) chemicals and were used without further purification except for drying. Strontium nitrate, laboratory reagent (BDH), was twice recrystallized from demineralized water and dried at 523–573 K for several days. Anhydrous calcium nitrate was prepared from the tetrahydrate by melting under reduced pressure when most of the water was expelled, finely powdering the solid mass and vacuum drying at 573 K for 6–8 hrs.

The method of solvent preparation was essentially the same in all cases and has been described elsewhere.[20,21] About 2 moles of the eutectic mixture was used for each run. A slow stream of dry and oxygen free nitrogen was always kept flowing over the melt surface during the period of measurements. The temperature was measured with a calibrated chromel-alumel thermocouple and controlled within $\pm 1°$ of the set value.

The micro-electrode was a small platinum foil, welded to a small length of platinum wire emerging from a platinum-soda lead glass seal in a piece of glass tubing. The surface area of the microelectrode, as determined from optical micrometry, was 0.398 cm^2. The counter electrode was a large platinum foil of area *circ.* 2 cm^2. The reference electrode was Ag^2/Ag in the melt as solvent. Both the reference and the counter electrodes were separated from the main solution by glass tubes having fritted discs of porosity G-4 at the bottoms.

An oscilloscope method of recording the chronopotentiograms was employed and details of the set up have already been described earlier.[20,22] The potential-time traces were displayed on the long persistence screen of a Hewlett-Packard (model 122-A) oscilloscope, the time base being provided by Z-modulation of the electron beam with a square wave from a Hewlett-Packard function generator (model 3300-A). The traces were photographed with a Fairchild-Dumont (type 450A) camera attachment on 35 mm Indu IP-200 panchromatic film. The analysis was made from enlargements made with a Nikon Profile Projector.

At the same temperature 4–5 chronopotentiograms were recorded using different current densities. After recording a chronopotentiogram, the metal deposited on the microelectrode surface was anodically stripped off, the electrode wiggled for a few seconds and the solution allowed to attain equilibrium for a few minutes before taking the next observation.

RESULTS AND DISCUSSION

The method described by Thalmayer *et al.*[15] was used for determining the transition time from the chronopotentiograms. The uncertainty in τ was less than 2%. τ was kept in the range 0.4–1.5 sec; for smaller τ, the time used in charging the electrical double layer becomes significant and for larger τ the diffusion layer extends sufficiently farther from the electrode surface into the solution such that convection interferes.

The concentration of the depolarizer and the quantity of the melt were such that 40–50 chronopotentiograms could be run on a sample without affecting the initial depolarizer concentration. Densities of the solvent at different temperatures were taken from the work of McAuley *et al.*[23]

Verification of Sand's Equation

Typical data of τ measurements for the reduction of Ag(I) in molten $NaNO_3-Sr(NO_3)_2$ at 611 K using different current densities for various $C^\circ_{Ag}+$'s are presented in Table 1. Figures 1 and 2 represent the plots

[23] W. J. McAuley, E. Rhodes and A. R. Ubbelohde. *Proc. Roy. Soc.*, **289A**, 151 (1966).

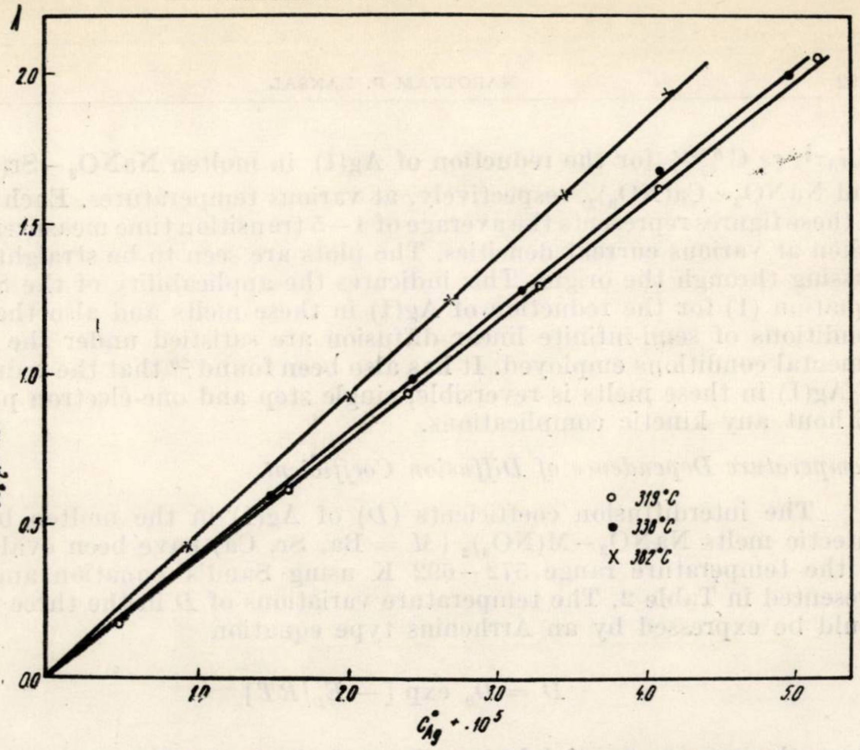

Fig. 1. — Plots of $i_0\tau^{\frac{1}{2}}$ vs. $C^0_{Ag}+$ in molten $NaNO_3 - Sr(NO_3)_2$ at various temperatures.

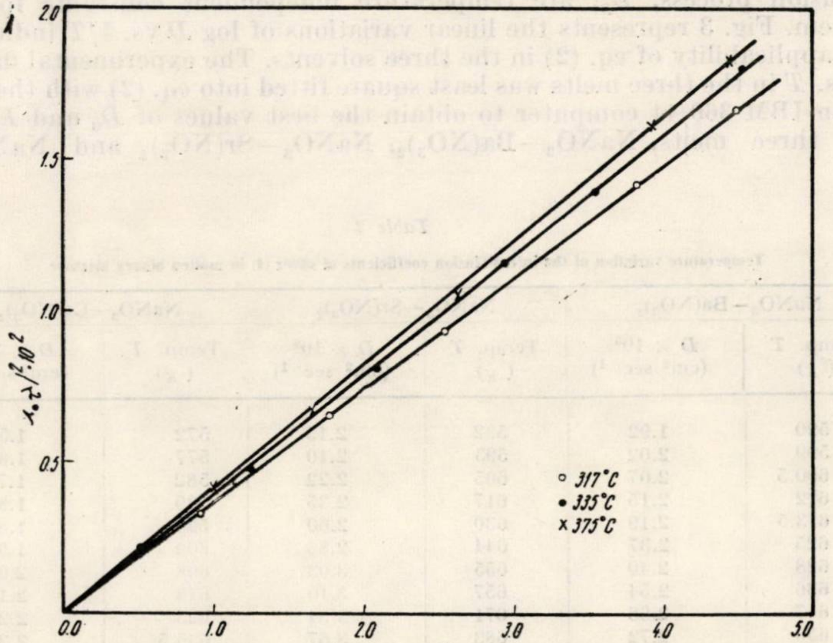

Fig. 2. — Variations of $i_0\tau^{\frac{1}{2}}$ with $C^0_{Ag}+$ in molten $NaNO_3 - Ca(NO_3)_2$ at various temperatures.

of $i_0\tau^{\frac{1}{2}}$ *vs* $C^{0}_{Ag^+}$ for the reduction of Ag(I) in molten $NaNO_3-Sr(NO_3)_2$ and $NaNO_3-Ca(NO_3)_2$, respectively, at various temperatures. Each point in these figures represents the average of 4—5 transition time measurements taken at various current densities. The plots are seen to be straight lines passing through the origin. This indicates the applicability of the Sand's equation (1) for the reduction of Ag(I) in these melts and also that the conditions of semi-infinite linear diffusion are satisfied under the experimental conditions employed. It has also been found [20] that the reduction of Ag(I) in these melts is reversible, single step and one-electron process without any kinetic complications.

Temperature Dependence of Diffusion Coefficient

The interdiffusion coefficients (D) of Ag(I) in the molten binary eutectic melts $NaNO_3-M(NO_3)_2$ (M = Ba, Sr, Ca) have been evaluated in the temperature range 572—692 K using Sand's equation and are presented in Table 2. The temperature variations of D in the three melts could be expressed by an Arrhenius type equation

$$D = D_0 \exp\left[-E_D/RT\right] \qquad (2)$$

where the pre-exponential factor, D_0, and the activation energy for the diffusion process, E_D, are temperature independent constants for the system. Fig. 3 represents the linear variations of log D vs. $1/T$ indicating the applicability of eq. (2) in the three solvents. The experimental data of D vs. T in the three melts was least square fitted into eq. (2) with the help of an IBM 360/44 computer to obtain the best values of D_0 and E_D. In the three melts, $NaNO_3-Ba(NO_3)_2$, $NaNO_3-Sr(NO_3)_2$ and $NaNO_3-$

Effect of the Presence of Divalent Cations on the Diffusion of Silver (I)

The data have also been analysed to study the influence of the introduction of divalent alkaline earth metal cations (Ba^{2+}, Sr^{2+}, Ca^{2+}) into the solvent on the diffusion of Ag(I) in the mixed melt. The values of the diffusion coefficients of Ag(I) along with the activation energies for diffusion process in various nitrate melts have been summarized in Table 3. The value of D is seen to be less in the three mixed melts studied as compared to that in pure $NaNO_3$. The specific conductance of these binary mixtures have also been reported [24-26] to be lower than of molten $NaNO_3$. On the other hand, incorporation of the divalent cations into crystals of uni-univalent halides and nitrates increases the extent of ionic migration (Wagner effect [27]). It has been pointed out that the extent of ion migration depends on the number of vacancies in a system. Incorporation of small concentrations of divalent cations in the solid solutions in uni-univalent crystals of halides and nitrates is considered merely to create an equivalent number of cation vacancies in the lattice to keep the whole assembly electrically neutral (one divalent cation will replace two monovalent cations in the lattice). The increased number of vacancies enhances the ion-migration in the mixed crystal. The molten salts being much more compressible than the corresponding crystals, the introduction of doubly charged cations causes electrostriction, resulting in a shrinkage of the free volume.[28] This would hinder ionic migration and consequently a decrease in ionic conductance and in the diffusion coefficient also, is observed. Since the sizes of Na^+ (0.95Å) and Ca^{2+} (0.99 Å) ions are virtually the same, a smaller value of D in $NaNO_3-Ca(NO_3)_2$ as compared to that in pure $NaNO_3$ can be considered to arise due to

charge differences on two ions. However, the trend in the values of D in other mixed melts is not explicable from the consideration of the differences in the charge densities alone.

Applicability of Stokes-Einstein Equation

The viscosity and the diffusion coefficient are correlated by the Stokes-Einstein equation

$$D_i = \frac{k\,T}{a\pi\eta r_i}\,, \tag{6}$$

where r_i is the radius of the diffusing ion (cm), η the viscosity of the solvent (g cm^{-1} sec^{-1}) and k the Boltzmann constant. In the classical formulation, the value of the constant a is 6 for the diffusion of a big particle. Li and Chang [29] have modified the S—E equation for the diffusion of a small particle and obtained a value of 4 for the constant a. Forcheri [30] has reported a value 4.6 for the self-diffusion coefficient of Tl in $TlNO_3$ and other diffusion coefficients in alkali nitrates. Sternberg and Herdlicka[13,14,31] have also found a value of 4.6 for the constant a for the chronopotentiometric diffusion coefficients of Ag(I) in molten alkali nitrates and chlorides. The radius of silver ion found in literature is $r_{Ag^+} = 1.13$ Å. The study of thermodynamic properties of silver halide-alkali halide systems [32] indicates that the radius of silver ion is smaller than 1.13 Å. The average kinetic radius of silver ion in molten alkali nitrates has been calculated [14] to be 1.00 Å. Using $r_{Ag^+} = 1.00$ Å, $a = 4.6$ and $\eta = 26.5 \times 10^{-3}$ poise for the viscosity [33] of molten $NaNO_3-Ca(NO_3)_2$ (94.0 : 6.0 mole %) at 623 K, the value of D as computed from equation (6) comes to be 2.24×10^{-5} cm^2 sec^{-1}. The experimental value of D in this melt at 623 K is 2.2×10^{-5} cm^2 sec^{-1}. This shows the applicability of the Stokes-Einstein equation indicating that the diffusion of Ag(I) ions is controlled by the viscous forces according to the Stokes mechanism. Similar comparison in the other melts could not be made due to the non-availability of the viscosity data.

The author is grateful to the Council of Scientific and Industrial Research, New Delhi, India, for the award of a research fellowship. Thanks are also due to Professor H. C. Gaur, Department of Chemistry, University of Delhi, for providing necessary facilities to carry out these investigations.

THERMAL DECOMPOSITION OF POTASSIUM FERRATE. VI

D. FĂTU * and ALEXANDRA SCHIOPESCU**

* Department of Physical Chemistry, Faculty of Chemistry, University of Bucharest, Romania — Bd. Republicii nr. 64

** Department of Chemistry and Physics, Institute of Petroleum, Gas and Geology, Str. Traian Vuia nr. 6 — Bucharest, Romania

Received June 23, 1973

The thermal decomposition of potassium ferrate (VI) has been studied by means of the thermo-gravimetric analysis (T.G.A.), derivative thermogravimetric analysis (D.T.G.A.) and differential thermal analysis (D.T.A.). The thermal stability of this compound is discussed based on experimental results and some conclusions are presented regarding the kinetics of the decomposition process.

1. INTRODUCTION

The potassium ferrate (VI) has formed the subject of a number of studies which resulted in the development of some methods for its preparation in pure state.

Scholder *et al.*[1] studied the thermal decomposition of potassium ferrate (VI) in an oxygen atmosphere. It was shown that the process may be described by means of the following equations :

$$\text{I. } 2K_2FeO_4 \rightarrow K_3FeO_4 + KFeO_2 + 0_2 \qquad (T < 700)$$

$$\text{II. } K_3FeO_4 \rightarrow KFeO_2 + K_2O + 1/20_2 \qquad (T > 700)$$

The recent investigations carried out by Ichida [2] on the decomposition products of K_2FeO_4 failed to reveal through the Mössbauer effect the valence (V) state of iron. Since the X rays analysis indicates the presence of the compound $KFeO_2$ and the Mössbauer spectrum leads to the conclusion that the valence state is Fe (III) in the decomposition products, the author[2] proposes for the thermal decomposition the following equation:

---

[1] V. R. Scholder and K. Kraus, *Z. anorg. Chem.*, **268**, 279 (1952).

[2] Toshio Ichida, *Bull. Chem. Soc. Japan*, **46**, 71 (1973).

$$\text{III. } K_2FeO_4 \rightarrow KFeO_2 + KO_x + (2 - x/2)\, O_2$$

The present paper is an attempt to obtain additional information on the decomposition process of potassium ferrate (VI) by means of thermoanalytical approaches.

2. EXPERIMENTAL

The potassium ferrate (VI) was prepared according to the method postulated by Schreyer *et al.*[3] The T.G., D.T.G., D.T.A., and T. analysis curves were simultaneously plotted by means of a Paulik, Paulik, Erdey type M.O.M. Budapest – derivatograph. The samples were heated in the air at a 10°/min. rate. The reference substance used for obtaining D.T.A. curve was Al_2O_3 calcined at 1200°.

The reactant grains were studied during the decomposition by means of a Karl Zeiss Jena optical microscope.

3. RESULTS AND DISCUSSION

The inspection of the thermoanalytical curves (Fig. 1) shows that the air thermal decomposition of the freshly prepared potassium ferrate (VI) will begin at a temperature of 50° if the heating rate is 10°/min.

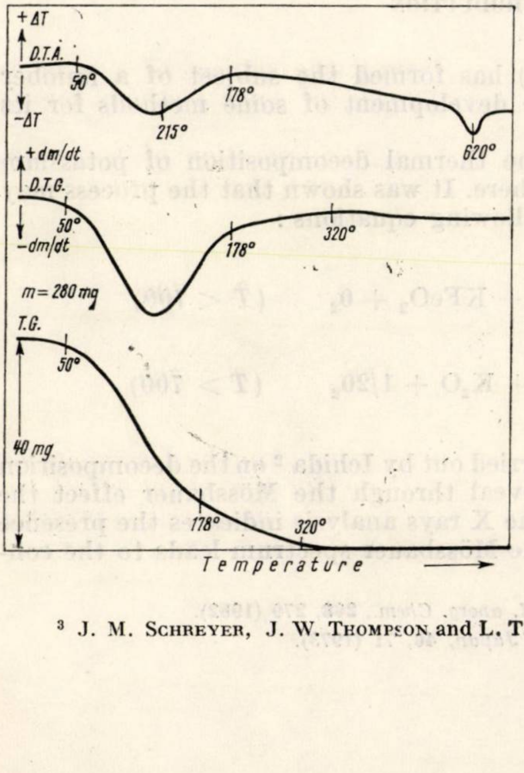

Fig. 1. – Aspect of thermoanalytical curves corresponding to the thermal decomposition of K_2FeO_4.

---

[3] J. M. Schreyer, J. W. Thompson and L. T. Ockerman, *Analyt. Chem.*, 22, 691 (1950).

The mass variation — determined from the data of the T.G. curve — corresponds to the release of 3/4 moles O_2 for each mole of decomposed K_2FeO_4. Since the solid decomposition products are ($K_2O.Fe_2O_3$) and the potassium oxide (K_2O), the overall stoichiometric equation of the process can be formulated as follows :

$$\text{IV. } 2\ K_2FeO_4 \rightarrow K_2O.Fe_2O_3 + K_2O + 3/2\ O_2$$

The reactant decomposition is total at a temperature of 320°. At temperatures ranging within 178°—380° the decomposition rate has a reduced value and as the thermal effect corresponding to this step is equally reduced, it cannot be observed on the D.T.A. curve.

At a temperature of 620° (see the D.T.A. curve) a second endothermic effects is recorded which is not accompanied by a mass variation this time. This endothermic effect may be assigned to the phase transition presented by ferric oxide (III).

The observations made on the microscope reveal some green — yellowish nuclei constitued of $K_2O.Fe_2O_3$ mixed with K_2O which arise and grow in the reactant mass in the course of the thermal decomposition.

Consequently the thermal decomposition process of potassium ferrate (VI) may be considered to be the result of the occurrence and growth of the nuclei.

The kinetics of such a process may be expressed by means of equation [4] :

$$\alpha = Kt^{(\lambda+\beta)}, \tag{1}$$

where α represents the decomposition degree

K — global rate constant

t — time

λ — number of dimensions according to which the growth of nuclei takes place

β — number of nucleation steps.

The formation of some bulky tridimensional nuclei is observed during the decomposition of potassium ferrate (VI). Therefore $\lambda = 3$. Considering that the nucleation takes place during one single step ($\beta = 1$) and that the temperature dependence of parameter K may be expressed by the Arrhenius' relation,

$$K = Z\,e^{-E/RT}, \tag{2}$$

in which

Z — represents the preexponential factor

E — the overall activation energy

R — the gas constant

T — the absolute temperature.

---

[4] P. W. M. Jacobs and F. C. Tompkins, "Chemistry of the Solid State", W. E. Garner, Butterworth Scientific Publications, London, 1955, p. 191.

Equation (1) may be thus transcribed :

$$\alpha = Z\, e^{-E/RT}\, t^{(\lambda+\beta)}\,. \tag{3}$$

Hence, in a log form, it results :

$$-\lg\frac{\alpha}{t^4} = -\lg Z + \frac{E(\text{cal/mol})}{4.575}\cdot\frac{1}{T}. \tag{4}$$

The above equation can be graphically verified by plotting the diagram $-\lg(\alpha/t^4) \div 1/T$.

The value $E = 9.2$ kcal/mole was determined for the activation energy from the angular coefficient of the straight line obtained in this manner (Fig. 2). From the ordinate at the origin it results that $Z = 0.76\ \text{mn}^{-4}$.

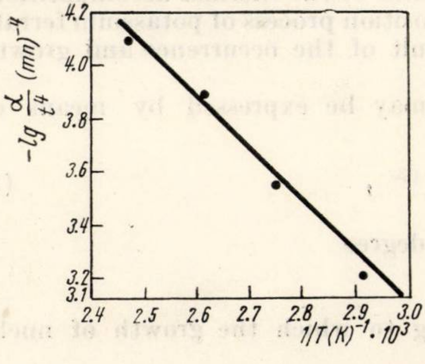

Fig. 2. — Graphical verification of equation (4).

The equation (4) describes satisfactorily the kinetics of the decomposition of potassium ferrate (IV) in the $0.05 \leqslant \alpha \leqslant 0.7$ range. The elimination of the volatile component and the formation of the new solid phase results in the division of crystals, so that by the end of the process the non-decomposed reactant grains are disseminated in the mass of the reaction product.

Assuming that the decomposition probability in the time unit is similar for any reactant grain, it results that the rate of the process $(d\alpha/dt)$ is proportional to the reactant fraction $(1-\alpha)$ existing at the moment t. Based on these hypotheses, [5] the rate of the final decomposition is formulated as follows :

$$\frac{d\alpha}{dt} = K(1-\alpha). \tag{5}$$

---

[5] A. K. Galwey, "Chemistry of Solids", Chapman and Hall, London, 1967, 139.

The temperature dependence of the K constant is described by Arrhenius' law, so that the preceding equation may be transcribed again under the form:

$$\frac{d\alpha}{dt} = Z'e^{-E/RT} \cdot (1 - \alpha), \tag{6}$$

where Z' and E' represent the preexponential factor and the activation energy of the final decomposition stage, respectively.

Finally in a log form, one obtains the equivalent expression

$$\lg \frac{d\alpha/dt}{1 - \alpha} = \lg Z' - \frac{E'}{4.575} \cdot \frac{1}{T} \cdot \tag{7}$$

The reaction rate (expressed in arbitrary units), the non-decomposed reactant fraction and the temperature are determined from the data of the D.T.G., T.G. and temperature (t) curves and this enables us to plot the diagram $\lg [(d\alpha/dt)/(1 - \alpha)] \div 1/T$ — (Fig. 3) and to calculate the values of the parameters Z and E. The equation (7) describes satisfactorily the kinetics of the process in the $0.6 \leqslant \alpha \leqslant 0.95$ range.

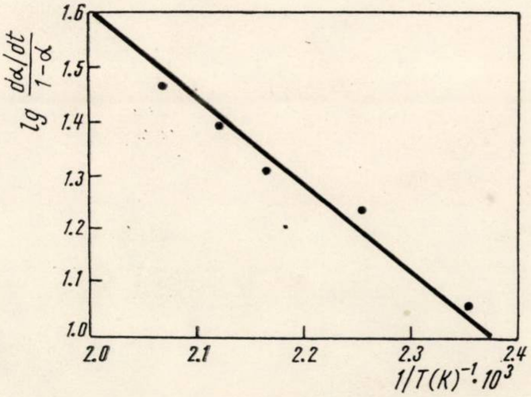

Fig. 3. — Graphical verification of equation (7).

The calculation leads to the results $E = 8.1$ kcal/mole, $Z = 3.1\ 10^3\ (\text{mn})^{-1}$.

The reaction heat is about 10.4 kcal/mole. This value has been determined from the area of D.T.A. peak.

To accomplish this, potassium ferrate (VI) was mixed in ≈ a 2/1 mass proportion with cadmium carbonate which was used as a standard substance. A thermal effect[6] $Q = 26.02$ kcal/mole was considered for the decomposition process of cadmium carbonate.

---

[6] A. G. Berg, "Vvedenie v Termografiyu" Izd. Akad. Nauk S.S.S.R. Moscow, 1961, 231.

4. CONCLUSIONS

When using a 10°/mn heating rate, the decomposition of the freshly prepared potassium ferrate (VI) begins at a temperature of 50°.

Taking into account the nature of the reaction products and the reaction of the sample mass, the decomposition process may be expressed by the stoichiometric equation:

$$2K_2FeO_4 \rightarrow K_2O.Fe_2O_3 + K_2O + 3/2\, O_2.$$

Within the $0.05 \leqslant \alpha \leqslant 0.7$ range the kinetics of the process is described by the equation $\alpha = kt^4$.

The final period of the process corresponds to a first order kinetics.

From the data provided by the D.T.A. curve the reaction heat was estimated at 10.4 kcal/mole value.

Received January 17, 1971

The crystalline systems were determined and the parameters of the elementary cells were calculated for $(NH_4)_2[OsX_6]$ and $[Os(NH_3)_5N_2]X_2$ (X = Cl, Br). Compounds $(NH_4)_2[OsCl_6]$ and $(NH_4)_2[OsBr_6]$ crystallize in the cubic system and the parameters of the elementary cells are : a = 8.94 Å and a = 9.86 Å, respectively. Compounds $[Os(NH_6)_5N_2]Cl_2$ and $[Os(NH_3)_5N_2]Br_2$ belong to the tetragonal system having the parameters of the elementary cells : a = 17.50 Å, c = 16.73 Å and a = 20.74 Å, c = 18.63 Å, respectively.

Structural determinations based on the X-ray studies were made for compounds $K_2[OsCl_6]$ and $K_2[OsBr_6]$.[1] These compounds are isomorphic with those prepared by us. Early attempts at determining the structure of coordinative compounds with molecular nitrogen were made by Bottomely and Nyburg [2] for compound $[Ru(NH_3)_5N_2]Cl_2$ and were carried on with similar types of compounds of metals Cu, Ni, Re.[3–9]

The present paper aims at determining the parameters of the elementary cells and at establishing the spatial groups for compounds $(NH_4)_2[OsX_6]$ and $[Os(NH_3)_5N_2]X_2$ (X = Cl, Br).

EXPERIMENTAL

The compounds were synthesized according to methods mentioned in the literature.[10,11] Diffraction diagrams on powders of the studied compounds $(NH_4)_2[OsCl_6]$, $(NH_4)_2[OsBr_6]$, $[Os(NH_3)_5N_2]Cl_2$ and $[Os(NH_3)_5N_2]Br_2$ were recorded on a HZG 1 type diffractometer (German DR) using radiation CuK_α (λ = 1.5405 Å) filtered through Ni.

RESULTS AND DISCUSSION

The results of the studies carried out are listed in the tables below. These exhibit, besides the experimental and calculated $1/d^2 Å^{-2}$, the indices (hkl) and I/I_0.

It results from table 1 that the crystalline system for compounds $(NH_4)_2[OsBr_6]$ is cubic, having the parameter of the elementary cell a = 8.94 Å. From the extinction conditions of the indices (khl) it results that :

hko ; h + k = 2n
hoo ; h = 2n
hkl ; no conditions.

---

[10] F. P. Dwyer and J. W. Hogarth, "Inorganic Synthesis", V, McGraw-Hill, New York, 204, 1957.

[11] A. D. Allen and J. R. Stevens, *Chem. Comm.*, 1147 (1967).

Based on these conditions, Pn3 and Pn3m are suggested as probable spatial groups.

The compound $(NH_4)_2[OsCl_6]$ also crystallizes in the cubic system having the parameter of the elementary cell a = 9.86 Å.

By following the extinction conditions of indices (hkl) :

hkl; h + k = 2n
h + l = 2n
k + l = 2n
hko; h + k = 2n
h, k = 2n
hkl; h + l = 2n

the following spatial groups were proposed for this compound : Fm3m, Fn32, $F\bar{4}3m$ and F23.

In the series of compounds of a $M_2^I[OsX_6]$ type, where $M_2^I = NH_4^+$, Na^+ and K^+ (X=Cl or Br), all compounds crystallize in the cubic system. However, the value of the parameter of the elementary cell decreases as the ionic radius of the alkaline metal decreases.

Table 3

The variation of the parameter of the elementary cell of the compounds $M_2[OsX_6]$ as a function of the ionic radius

Compound	M_I^+	Ionic radius [Å]	a [Å]
$K_2[OsCl_6]$	K^+	1.33	9.73
$(NH_4)_2[OsCl_6]$	NH_4^+	0.99 – 1.113	8.94
$Na_2[OsCl_6]$	Na^+	0.95	8.86
$K_2[OsBr_6]$	K^+	1.33	10.30
$(NH_4)_2[OsBr_6]$	NH_4^+	0.99 – 1.113	9.86
$Na_2[OsBr_6]$	Na^+	0.95	—

The results obtained in the case of the compounds with molecular nitrogen $[Os(NH_3)_5N_2]Cl_2$ and $[Os(NH_3)_5N_2]Br_2$ are further discussed. Both compounds crystallize in the tetragonal system.

The coordinative compound $[Os(NH_3)_5N_2]Br_2$ has the parameters of the elementary cell : a = 17.45 Å and c = 16.73 Å. The following extinction conditions of indices (hkl) result from table 4 :

hkl; no condition
hko; h + k = 2n
okl; no condition
hhl; l = 2n
ool; no condition

Based on the above, the spatial group $P4_2/nmc$ was proposed for this compound.

The results obtained for the similar substance $[Os(NH_3)_5N_2]Cl_2$ are listed in table 5, the parameters of the elementary cell being : $a = 20.74$ Å and $c = 18.63$ Å. The extinction conditions of indices (hkl) are :

hkl ; no condition
hko ; $h + k = 2n$
hhl ; no condition
okl ; $k + 1 = 2n$
ool ; no condition

and this leads to the following probable spatial group : $P4_2/nnm$.

These coordination compounds have been observed to present a slight deviation from the cubic system, as the ratio $a/c = 1.04$, respectively 1.11. This fact compares well with the results obtained by Bottomely and Nyburg [2] who determined the crystalline systems for similar compounds with molecular nitrogen of Ru(II), compounds which crystallize in the cubic system.

Revue Roumaine de Chimie, 19, 8, 1307–1315 (1974)

Ni(II) CHELATES SYNTHETIZED WITH 1-METHYL-2-CARBETHOXY-GLYOXALANIL-(1)-METHOXY-PHENYLHYDRAZONES-(2)

A. C. BANCIU and P. SPACU

Center of Chemical Physics, Dumbrava Roşie, 23
Bucharest, Romania

Received December 21, 1973

Using the three 1-methyl-2-carbethoxy-glyoxalanil-(1)-methoxy-phenylhydrazones-(2) as ligands, depending on the preparation conditions, two different types of Ni(II) complexes were obtained, some of them containing the mentioned ligands and others having the anil group from the ligand molecule substituted by an imino group. The elemental analysis data, IR and electronic spectra as well as the magnetic measurements show that all prepared complexes are tetracoordinate chelates with a low spin square-planar arrangement of the Ni(II)-nitrogen bonds. The intense colour of the chelates is due to the charge transfer metal → ligand bands occurring in the visible range.

In the previous papers [1,2] Ni(II) complexes with different 1-methyl-2-carbethoxy-glyoxalanil-(1)-arylhydrazones-(2) have been already reported. In a very recent paper [3] the ligands and the complexes formed by the Co(II) ion with the three 1-methyl-2-carbethoxy-glyoxalanil-(1)-methoxy-phenylhydrazones-(2), (Ia—c) have also been studied.

The aim of the present note is to study the five Ni(II) complexes prepared with the compounds Ia—c. The preparation of these organic compounds has been described elsewhere.[3]

EXPERIMENTAL

Reagents. Acetoacetic ester (Merck, reagent for synthesis, min. content 98%), aniline (tridistilled), *p*-anisidine (VEB Berlin – Chemie, *p.a.*), *m*-anisidine (B.D.H., laboratory reagent, boiling interval 243–248°), *o*-anisidine (B.D.H., laboratory reagent, boiling interval 222–226°), anhydrous $NaCH_3COO$ (Austranal, p.a.), $NaNO_2$ (Reactivul, Bucharest, p.a.), $NiCl_2.6H_2O$ (Reactivul, Bucharest, *p.a.*), 25% solution NH_3 (Reactivul, Bucharest, p.a.).

Preparation of the Ni(II) chelates. The Ni(II) chelates were synthetized using a known method,[4] under the refluxing conditions of alcoholic solutions of the reagents, working with 1/100 m amounts of ligand and 1/200 m $NiCl_2.6H_2O$ plus a slight excess of 15% from the theoretical quantity of the last mentioned reagent, in order to complete the reaction.

In the presence of a small quantity of triethylamine (circ. 1 ml), using the ligands Ia and Ib, the chelates IIa–1 and IIb–1 were obtained. The attempts to prepare the corresponding Ni(II) chelate using the compound Ic have invariably failed, as well as the earlier attempts [2] to obtain the Ni(II) chelate with the *o*-tolylhydrazone-(2) corresponding to the compound Ic.

Using the same reagent quantities and the same reaction conditions as indicated above, but in the presence of about 20 ccm of 25% NH_3 solution, using the three compounds Ia–c the chelates IIa–2, IIb–2 and IIc, were obtained. Under the cathalytical action of the Ni(II) salt, the NH_3 induces the splitting of the anil group and its substitution by the imino group, NH, in the ligand molecule.[5] For this reason, the complexes IIa –2, IIb–2 and IIc are formed with each from the three ligands which could not be isolated during the reaction and arised from the degradation of each from the compound Ia–c. The obtained compounds were washed with 3% acetic acid, warmed at 40°, till the washing solutions did not contain Ni(II) ions. The hardly soluble chelates IIa–2, IIb–2 and IIc were repeatedly washed with warmed abs. ethanol, and the more soluble chelates IIa–1 and IIb–1 have been recrystallized from abs. ethanol in the presence of active charcoal. After washings and recrystallizations respectively, the compounds have been dried under vacuum on ai$-P_2O_5$.

[5] B. Hirsch and A. Bassl, *Z. Chem.*, 2, 340 (1962).

The elemental analyses of C, H and N have been carried out through microcombustion. For the Ni(II) dosing, the chelates were disintegrated with H_2SO_4 and H_2O_2 and the Ni(II) ion then dosed with dimethylglyoxime.

The absorption spectra of the chelates were recorded by means of a VSU−2 Carl Zeiss (Jena) spectrophotometer, on acetonic solutions of $0.25 \times 10^{-4} - 2.5 \times 10^{-4}$ mol/l concentration (complexes IIa−2, IIb−2 and IIc) and $0.5 \times 10^{-4} - 5 \times 10^{-4}$ mol/l (complexes IIa−1 and IIb−1).

The reflectance spectra of the chelates were recorded with a VSU−1 Carl Zeiss (Jena) spectrophotometer, using MgO as standard.

The IR spectra of the compounds were recorded within 400−4000 cm^{-1}, with a UR−10 Carl Zeiss (Jena) spectrophotometer, using pellets of KBr.

The magnetic susceptibility were determined at room temperature according to Faraday method, using $Hg[Co(NCS)_4]$ as reference.

RESULTS AND DISCUSSION

The analytical data for all Ni(II) complexes are given in table 1. These data together with the IR spectral results have allowed to establish the chelatic structural formulas IIa-c for all complexes.

Table 1

Analytical data of the Ni(II) chelates

Chelate	Ni %		C %		H %		N %		m.p. °C
	Calc.	Found	Calc.	Found	Calc.	Found	Calc.	Found	
IIa−1	7.98	7.39	62.06	61.89	5.48	5.93	11.43	11.80	168 −170.5
IIb−1	7.98	7.48	62.06	62.62	5.48	5.88	11.43	11.72	133 −136
IIa−2	10.06	9.82	53.54	52.89	5.53	5.99	14.41	14.52	218 −220.5
IIb−2	10.06	9.58	53.54	53.97	5.53	5.92	14.41	14.83	190.5−193
IIc	10.06	9.66	53.54	52.94	5.53	5.70	14.41	14.79	215 −218.

The IR spectra of one from the used ligands, and namely the 1-methyl-2-carbethoxy-glyoxalanil-(1)-*p*-methoxy-phenylhydrazone-(2), (Ia), and of the chelates IIa−1 and IIa−2, obtained with this ligand, are systematized in table 2.

The most striking differences in the IR spectra between the free ligand and the chelates are observed within the 1290−1370 cm^{-1} range. An absorption band of mean intensity occurs in this range for the free ligand, with maxima at 1300 and 1330 cm^{-1}. In the case of the corresponding chelates, the appearance of a very intense band has been, on the contrary, observed, for the chelate IIa−1 as a shoulder at 1300 and with maxima at 1325 and 1360 cm^{-1}, and for the chelate IIa−2 with maxima placed at 1295 and 1320 cm^{-1}, which are the most intense bands from the whole IR domain of the chelates. One knows[6] that in the range 1280−1360 cm^{-1} must appear a band characteristic to the secondary aromatic amines (C_6H_5-NH-) and almost in the same region (1310−1370 cm^{-1}) must occur an intense band characteristic to the tertiary aromatic amines ($C_6H_5-\bar{N}=$), both representing the C−N stretching

vs = very strong; s = strong; m = medium; w = weak; sh = shoulder.

vibration inside these groups. The expected structural modifications due to the coordination of the nitrogen atom of the hydrazone group to which the aryl radical is directly bound must be naturally reflected in the IR spectra, as has been shown above. The strong enhancement of the absorption bands in the chelate spectra in this domain, compared with the band of the free ligand, shows that the coordination took place to the nitrogen atom of the hydrazone group. The intense band occurring at 1700 cm^{-1} could be undoubtedly assigned[6] to the esteric group ($COOC_2H_5$) and it remains unshifted in the spectra of both chelates, showing that this group does not participate into coordination, a possibility which could not be a priori ignored. It should be expected, in the contrary case, that this absorption band to be strongly shifted, at approximately 1635–1665 cm^{-1}, which obviously is not the case.

The most striking difference between the IR spectra of the two chelates consists in the fact that in the spectrum of the chelate IIa–2 occurs a very intense band at 3320 cm^{-1}. This band is ascribed [6] as being proper to the imino group, NH, frequency. Its appearance agrees with the chemical analysis data, indicating the fact that in the chelate IIa–2 the coordinated ligand does no more contain the anil group, but the imino one, in agreement with the structural formula suggested by the chemical analysis.

The appearance of absorption bands with maxima at 1075 and 1110 cm^{-1} in the free ligand, at 1040 and 1080 cm^{-1} in the chelate IIa$-$1 and at 1085 cm^{-1} in the chelate IIa$-$2 is also important. The above absorption bands are ascribed to the etheric aliphatic group (CH_3-O-). In the case of the chelate IIa$-$2 there is a very intense band at 1250 cm^{-1} (while for the free ligand and the chelate IIa$-$1 the domain 1230$-$1270 cm^{-1} is overlapped by maxima of more broad bands, comprised between 1170 and 1260 cm^{-1}), which could be assigned to the alkyl-aryl-etheric group ($CH_3-O-C_6H_4-$). The appearance of these bands (1085 and 1250 cm^{-1}) in the IR spectrum of the chelate IIa$-$2 shows that the *p*-anisidyl group ($p-CH_3O-C_6H_4-$) has been maintained in the molecule, i.e. under the reaction conditions for the synthesis of the chelate from the original ligand molecule, Ia, the anil group ($C_6H_5-N=$) and not the hydrazonic group ($p-CH_3O-C_6H_4-NH-N=$) is splitted, in agreement with the formulation IIa$-$2 of the chelate.

ELECTRONIC SPECTRA AND MAGNETIC PROPERTIES

The only small differences between the absorption bands in the electronic spectra of the chelates and those in the reflectance spectra recorded for the compounds in the solid state, show that the chelate dissolution was not accompanied by important structural modifications (dissociations, etc.), the same molecular species being existent both in solution and solid state.

The magnetic susceptibility measurements performed on the chelates IIa$-$1, IIa$-$2 and IIc have shown that all compounds are diamagnetic.

The spectra of the chelates IIa$-$2, IIb$-$2 and IIc

The absorption spectra in the visible range for the complexes IIa$-$2, IIb$-$2 and IIc are plotted in figure 1.

One strikely observes that the spectra of IIa$-$2 and IIb$-$2 are very similar both in their shape and position of the maxima which practically coincide on the whole visible domain. The above observation allows us to ascribe likely the diamagnetic properties to the chelate IIb$-$2 for which the magnetic behaviour was not studied. The intense absorption maxima of $\varepsilon \approx 6500$ coincide for both mentioned chelates, appearing exactly at 475 nm. The shoulders occurring at higher wavelengths represent bands with maxima placed approximately at 560 nm, but with low intensity, of $\varepsilon \approx 700$, i.e. of a order size lower than that of the first mentioned bands.

The spectrum of the chelate IIc differs very much when compared with those of the chelates IIa$-$2 and IIb$-$2. Much more, this spectrum is different from those of the corresponding chelate IIc, already described,[2] where instead of $Y = o-CH_3O-C_6H_4-$ as in the present case, the substituent attached to the two of the four nitrogen donor atoms, was

$Y = o-CH_3-C_6H_4-$. In the case of the last mentioned complex, its electronic spectrum shows a hypsochromic shift only, of 40 nm, in the whole visible range against the spectra which practically coincide between them, of the corresponding chelates IIa—2 ($Y = p-CH_3-C_6H_4-$) and IIb—2 ($Y = m-CH_3-C_6H_4-$). The maximum of the intense band

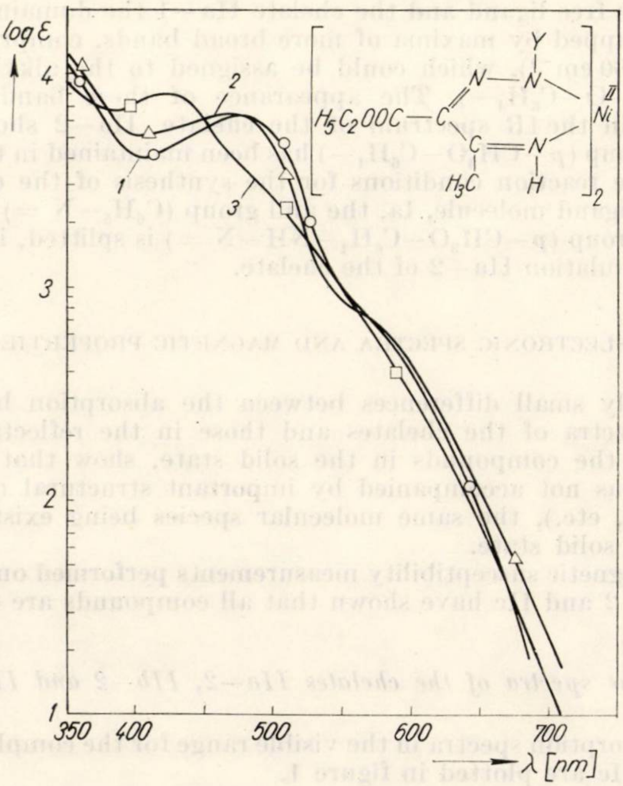

Fig. 1. — Electronic spectra of the Ni(II) chelates. *1.* Chelate IIb—2; $X = H$, $Y = m-CH_3O-C_6H_4$; *2.* Chelate IIa—2 $X = -H$, $Y = p-CH_3O-C_6H_4$; *3.* Chelate IIc; $X = -H$, $Y = o-CH_3O-C_6H_4$;

occurring at 430 nm, takes $\varepsilon = 4800$, that is a lower value than in the corresponding complexes of type IIa—2 and IIb—2 ($\varepsilon \approx 6000$), and the shoulder observed at 530 nm is less intense, with $\varepsilon \approx 400$. In the present case the single analogy between the electronic spectrum of the chelate IIc ($Y = o-CH_3OC_6H_4-$) and that of the type IIc already mentioned ($Y = p-CH_3-C_6H_4$) consists in the obvious hypsochromic shift of the first intense band from the visible range. This band has a maximum placed at 420 nm, compared with 475 nm in the case of the chelates IIa—2 and IIb—2. This maximum shows however, in this case $\varepsilon \approx 8000$, higher than that for the chelates IIa—2 and IIb—2 ($\varepsilon = 6500$). Near to 460 nm ($\varepsilon = 4500$) there is a very broad shoulder extented at the end of the visible range (at about 700 nm). The gaussian analysis of the spectrum shows that this shoulder must include an intense band with $\varepsilon \approx 2500$, with the maximun placed approximately at 480 nm. The high intensity of this band ($\varepsilon > 2000$) makes it comparable with the first bands only from the visible domain of the chelates ($\varepsilon = 6500...8000$) and not with the bands occurring as shoulders for the complexes IIa—2 and IIb—2 at approximately 560 nm ($\varepsilon \approx 700$). This situation is strikingly similar with the case of the square-planar Ni(II) mixed ligand complexes, containing alkyl-aryl-phosphines, studied by Coussmaker et al,[7] where a band occurring approximately at 460 nm with $\varepsilon \approx 2700$ was included into the disscusion of the "high intensity and freqency bands".

The diamagnetism of the complexes shows that Ni(II) ($3d^8$) has a square-planar arrangement of the metal-ligand bonds with low spin electron distribution.

The high intensity of the bands appearing at 475 nm in the case of the chelates IIa—2 and IIb—2 ($\varepsilon = 6500$) and that of the two bands (at 420 nm with $\varepsilon = 8000$ and the shoulder at 480 nm with $\varepsilon \sim 2500$) of the chelate IIc shows these bands as being of a charge transfer (CT) nature. Taking into account the Jørgensen's formula [8,9]:

$$\nu_{CT} = 30{,}000\,(x_N - x_{Ni})\ \mathrm{cm}^{-1}$$

where[8] $x_{Ni(\text{square-planar})} = 2.2$ and [9]$x_N = 3.2$ are the corresponding optical electronegativities, one may conclude that a ligand → metal CT transition must occur at approximately 330 nm (30,000 cm^{-1}) which, obviously, is not the case. The only remained alternative is to ascribe these bands to a CT metal → ligand mechanism, i.e. from the filled MO's practically localized on the central metal ion, to the free antibonding MO's mainly placed on the organic ligand.

The absorption bands of almost an order of lower intensity ($\varepsilon \approx 700$) occurring for the chelates IIa—2 and IIb—2 as shoulders to the intense CT bands, could be undoubtedly ascribed to spin-allowed d—d transitions.

If one uses the most probable MO energy pattern for the studied chelates, i.e. an orbital scheme for weak D_{4h}-distortion, corresponding to the orbital sequence $e_g\,(d_{xz}, d_{yz}) < b_{2g}(d_{xy}) < a_{1g}\,(d_{z^2}) < b_{1g}\,(d_{x^2-y^2})$, the most like assignement of the d—d bands may correspond to a transition up to the double degenerate excited spectral term ${}^1E_g$, i.e.

$${}^1A_{1g}\,(e_g^4\, b_{2g}^2\, a_{1g}^2) \rightarrow {}^2E_g\,(e_g^3\, b_{2g}^2\, a_{1g}^2\, b_{1g}^1).$$

This assignement implies a transition from the most stable "π" antibonding orbital (e_g) : to the highest "σ" antibonding orbital (b_{1g}) arisen from the d orbitals of the Ni(II) ion. Having in view the relative high intensity of these bands ($\varepsilon \approx 700$) for a centrosymmetric environment, this assignement constitutes, of course, only an attempt.

[9] C. K. JØRGENSEN, "Electron Transfer Spectra", in "Progress in Inorganic Chemistry", vol. 12, Interscience, New York, 1970, p. 101—158.

The very broad shoulder at 460–700 nm of the chelate IIc includes, certainly a very weak d–d band, overlapped by the more intense CT band. The appearance of an intense CT band at approximately 480 nm in the spectrum of the chelate IIc cannot be explained through different electronic effects but through more strong steric hindrances caused by the methoxy group, CH_3O, attached to the ortho position of the phenyl radical of the hydrazonic group. In the case of a less bulky substituent, as an example the methyl group, CH_3, (the case of the chelate IIc already described by us,[2] where $Y = o-CH_3-C_6H_4-$) only a shoulder at 500 nm representing a weak d–d band is observed in the spectrum of the chelate ($\varepsilon \approx 400$). The steric repulsions caused by the *p*-anisidyl group ($Y = o-CH_3O-C_6H_4-$) bound to the nitrogen donor atoms, even though much stronger than those produced by other substituents, are not able to impose a tetrahedral configuration for the complex, which remains square-planar, diamagnetic. The same important conclusion, that is the maintaining of a preponderant square-planar symmetry for the metal-nitrogen bonds, is valid for the chelates IIa–1 and IIb–1. In these complexes to each coordination point (the nitrogen donor atoms of the ligands) bulky groups are attached : to two of the four nitrogen donor atoms there are *p*- or *m*-anisidyl groups ($Y = CH_3O-C_6H_4-$) and phenyl radicals ($X = -C_6H_5$) to the other two nitrogen atoms.

The spectra of the chelates IIa–1 and IIb–1 are plotted in figure 2.

The spectra are very similar between them in the whole visible range, except an insignificative shift of 10–15 nm. This similitude allows also to ascribe diamagnetic properties to the chelate IIb–1, for which the magnetic susceptibility measurements were not carried out.

Even though the electronic spectra of these complexes are similar with those of the chelates IIa–2 and IIb–2, there are nevertheless some differences. Thus, the intense bands ($\varepsilon \approx 4600$), which can be regarded as charge-transfer metal → ligand, occur as shoulders of the more intense bands placed in the UV range. The positions of these shoulders, approximately at 500 nm, shows a slight bathochromic shift only, of about 20 nm, of these CT bands, compared with those of the chelates IIa–2 and IIb–2. The very broad shoulders at 600 nm shows, on the contrary, a marked bathochromic shift, of about 60 nm, against the corresponding shoulders, ascribed as d–d transitions, in the chelates IIa–2 and IIb–2. The intensity of these shoulders is unusually high, $\varepsilon > 1100$, for the majority of tetrahedral complexes. For this reason more likely is the assignement of these bands as charge transfer metal → ligand transitions, taking also into consideration that for centrosymmetric environments as that square-planar, the d–d transitions are weak, even for the d^8 electronic configuration for which the intensity of this kind of transitions takes unusual high values, $\varepsilon \approx 10^2$. Thus, for the square-planar Ni(II) complexes these kinds of bands were reported in different papers as being d–d transitions having invariably $\varepsilon < 700$.

The high width of these shoulders occurring approximately at 600 nm in the spectra of these complexes, comparable with that of the broad shoulder appearing in the spectra of the already discussed chelate IIc, shows more probably the fact that they include more than a single band, which could not be resolved. If the intense band ($\varepsilon > 1100$) is a CT metal → ligand transition, it overlaps the more weak bands corresponding to d—d transitions.

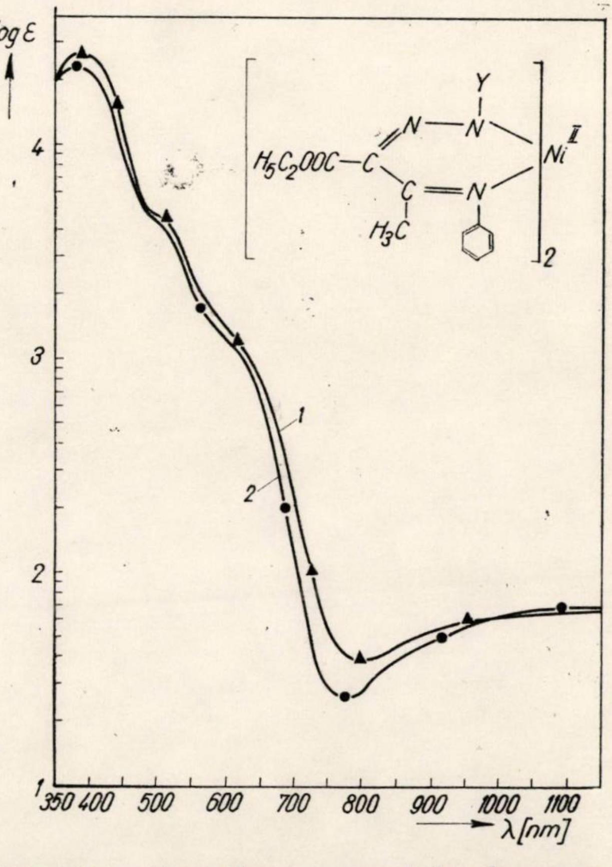

Fig. 2. — Electronic spectra of the Ni(II) chelates. *1.* Chelate IIa—1 : $X = C_6H_5$, $Y = p-CH_3O-C_6H_4$; *2.* Chelate IIb—1 : $X = C_6H_5$, $Y = m-CH_3O-C_6H_4$.

It should be expected that these bands to occur even in this range, in view of the bathochromic shift of the whole visible range of the chelate IIa—1 and IIb—1, compared with that of the already discussed chelates IIa—2 and IIb—2, where the d—d bands appeared as shoulders at approximately 540 nm. On the other hand, it should be not excluded the possibility that the absorption bands with $\varepsilon > 1100$, occurring as shoulders at about 600 nm, to be of d—d nature, their intensity being enhanced by the proximity of the more intense bands, at 500 nm, undoubtedly due to a charge transfer mechanism.

The authors thank lecturer V. Mincu of the University of Bucharest for the magnetic susceptibility measurements.

ON THE REACTIVITY OF SOME METAL-SULPHUR COMBINATIONS IN LIQUID AMMONIA

P. MARKOV, S. CHORBADJIEV and V. TARPANOV

Department of Organic Chemistry, University of Sofia, Bulgaria

Received November 6, 1973

It was established that magnesium and sulphur react in liquid ammonia while calcium practically does not interact with sulphur under the same conditions. Considerable differences were found in the character of the interaction of benzyl chloride and benzhydryl chloride with the combinations magnesium-sulphur and sodium-sulphur in liquid ammonia.

The reactivity of alkali metals with sulphur in liquid ammonia was well studied.[1–3] Depending on the ratio metal-sulphur different alkali sulphides were obtained. In one of our previous papers [4] we reported the interaction between different halogen organic compounds and the sodium-sulphur combination in liquid ammonia using the ratio RX : Na : S 2 : 2 : 1 and 1 : 1 : 1. In all the cases the corresponding organic mono- and disulphides were isolated. Only in the case of benzyl chloride the corresponding disulphide was not obtained. In some cases besides these reaction products higher sulphides were found.

The present work continues the investigation in this field aiming to elucidate the influence of the nature of the metal used and the ratio metal-sulphur on the course of the interaction with halogen organic compounds. The interaction of benzyl chloride and benzhydryl chloride with the combinations sodium-sulphur, magnesium-sulphur and calcium-sulphur in liquid ammonia was studied.

The reaction of magnesium with sulphur had been studied in detail.[5] It is established that the elements combine to form magnesium sulphide, MgS. There are several different methods of preparing magnesium sulphide, in all the cases the reaction being carried out at high temperatures. There are no data regarding the existence of other magnesium sulphides.[6] The

[6] "Inorganic Sulphur Chemistry", edited by G. Nickless, Elsevier Publishing Company, Amsterdam, 1968, p. 689–690.

interaction of sulphur with magnesium suspended in liquid ammonia has not been studied so far.

Our study showed that magnesium and sulphur react in liquid ammonia forming a yellow-orange precipitate which when exposed to air changed quickly and, on adding water, it evolved hydrogen sulphide forming magnesium hydroxide. The product of the interaction between magnesium and sulphur in 1 : 1 ratio was isolated under inert solvent (ether-benzene). On decomposing it with dilute hydrochloric acid it was found that 45% of the sulphur had been combined.

An analogous experiment showed that calcium and sulphur did not interact in liquid ammonia, the sulphur being recovered almost completely. This result is to a certain extent in contradiction with the fact that calcium possesses a higher affinity for sulphur than magnesium itself.[7] On the other hand it is well known that calcium dissolves in liquid ammonia forming calcium-ammonium [8] while magnesium is practically insoluble in this medium. The observed difference in the reactivity of the two alkali-earth metals towards sulphur in liquid ammonia could be explained with the formation of a ligand sphere of ammonia molecules round the calcium atoms.

The interaction of benzyl chloride and benzhydryl chloride with the combinations magnesium-sulphur and calcium-sulphur was studied in detail. Only the reaction between benzyl chloride and magnesium-sulphur combination gave organic sulphide. The interaction of calcium-sulphur combination with benzyl chloride and benzhydryl chloride led to the formation of *trans*-stilbene (8%) and tetraphenyl ethane (27%), respectively. These hydrocarbons were due to a Wurtz type reaction.

The results of the reaction between benzyl chloride and magnesium-sulphur combination are presented in table 1. They show that regardless of the chosen magnesium + sulphur ratio high yields of dibenzyl disulphide were obtained. Other organic sulphides were not isolated from the reaction mixture. This fact could be of preparative significance. The obtained results mean that magnesium and sulphur in liquid ammonia form a product containing a chain of two sulphur atoms.

Table 1

Interaction of benzyl chloride with magnesium-sulphur combination

Halogencontaining compound	Ratio RX : Mg : S	Reaction product	Yield of purified product, %	M.p. °C
Benzyl chloride	1 : 1 : 1	Dibenzyl disulphide	66.7	70
Benzyl chloride	2 : 2 : 3	Dibenzyl disulphide	71.6	69
Benzyl chloride	1 : 1 : 2	Dibenzyl disulphide	82.3	69
Benzyl chloride	1 : 1 : 4	Dibenzyl disulphide	77.7	69

As it was mentioned benzhydryl chloride does not react with magnesium-sulphur combination. A series of experiments was carried out using the same reaction ratios as in the case of benzyl chloride. In all the cases the benzhydryl chloride was recovered completely. It should be remarked that when the ratio benzhydryl chloride : magnesium : sulphur was 1 : 1 : 2 and 1 : 1 : 4 a small amount (less than 1%) of tetraphenyl ethylene was isolated from the reaction mixture.

[7] J. W. MELLOR, "A Comprehensive Treatise on Inorganic and Theoretical Chemistry", vol. **10**, Longmans, Green and Co., London, 1957, p. 87.

[8] J. W. MELLOR, *ibid.*, vol. **3**, p. 639.

The question about the lack of reactivity of benzhydryl chloride with magnesium-sulphur combination cannot be solved entirely as the detailed mechanism of the reaction is not known. Whereas it is sure that this is a nucleophilic substitution it must be assumed that in this case the nucleophilic attack is hindered in comparison with the case of benzyl chloride. On the other hand it is well known that the reactivity of the chlorine atom in benzhydryl chloride is much greater which is due to additional delocalization possibility of the positive charge in the intermediate carbonium ion. That is why it is reasonable to accept that the steric factors are of primary importance for the examined interaction.

On the other hand it could be expected that, because of the coordinating ability of magnesium in liquid ammonia, the reactive particles are very bulky. This decreases the possibility of the access to the reaction centre of benzhydryl chloride. Aiming to verify this assumption, the reactivity of benzhydryl chloride with sodium-sulphur combination was studied.

It is well known that sodium possesses insignificant coordinating ability towards electron-donor molecules. Also, it should not be ignored the difference in the polarities of sodium-sulphur and magnesium-sulphur bonds. Moreover, up to now there are no data on obtaining different benzhydryl sulphides by means of the interaction between benzhydryl chloride and alkali sulphides.

The results of the experiments carried out with benzhydryl chloride and sodium-sulphur combination are given in table 2. The ratio of reaction components 1 : 1 : 1 gave the highest yield of dibenzhydryl disulphide. An increase in the amount of sulphur led to a certain decreasing in the yields of organic disulphide. Other sulphides were not obtained. No reaction was observed when 2 : 1 ratio of sodium : sulphur was used. Only small amount (less than 4%) of tetraphenyl ethylene was isolated from the reaction mixture. Whereas in this case sodium monosulphide, Na_2S, is formed [2] it could be concluded that benzhydryl chloride is not reactive towards this sulphide. On the other hand, as it was shown earlier,[4]

Table 2

Interaction of benzhydryl chloride with sodium-sulphur combination

Halogencontaining compound	Ratio RX :Na :S	Reaction product	Yield of purified product, %	M.p. °C
Benzhydryl chloride	2 : 2 : 1	Tetraphenyl ethylene	3.8	222 – 223
Benzhydryl chloride	1 : 1 : 1	Dibenzhydryl disulphide	77.2	153
Benzhydryl chloride	2 : 2 : 3	Dibenzhydryl disulphide	52.9	153
Benzhydryl chloride	1 :1 : 2	Dibenzhydryl disulphide	52.3	153

benzyl chloride reacts with sodium sulphide in liquid ammonia with the formation of the corresponding monosulphide. In this sense the observed difference is very unexpected.

The obtained results show that the course of the reaction depends on the nature of the metal used as well as on the structural characteristics of the halogen-organic compounds. More detailed investigation is necessary for elucidation of the nature of the products that are formed during the interaction between alkali and alkali-earth metals with sulphur in liquid ammonia. The character of the interaction of these products with halogen organic compounds is a matter of additional study.

EXPERIMENTAL

The melting points of the obtained products were determined on a Koffler apparatus and were not corrected. The experiments were carried out with commercially dry liquid ammonia in a threeneck flask fitted with a dropping funnel and a tube for releasing the evaporating ammonia.

Interaction between magnesium and sulphur. A 1 : 1 ratio was used. Powdered sulphur (0.8 g, 0.025 gA) and magnesium (0.6 g, 0.025 gA) were added to about 750 ml liquid ammonia. The mixture was left to stay for 48 hours during which the solution became orange-brown and an orange-brown precipitate was formed. After adding 100 ml of dry ether the liquid ammonia was evaporated by means of an alcohol bath and then 100 ml of dry benzene was added. The mixture was heated and a hydrochloric acid (1 : 1) was dropped into it. The evolved hydrogen sulphide was passed through a washing bottle containing a solution of zinc sulphate, ammonium chloride and ammonia. The precipitate of zinc sulphide was filtered off and decomposed with hot hydrochloric acid (1 : 1). The zinc containing solution was titrated with complexon II. The determined amount of zinc corresponded to 45.0% of the sulphur used in the reaction.

Interaction of calcium with sulphur. This interaction in liquid ammonia was carried out analogously to that of magnesium and sulphur. When the reaction mixture was decomposed with hydrochloric acid no hydrogen sulphide evolved and 91.5% of the sulphur was recovered.

Interaction of magnesium-sulphur combination with benzyl chloride and benzhydryl chloride. To about 800 ml of liquid ammonia 0.025 gA (0.6g) of magnesium and the corresponding amount of sulphur according to the ratio used was added (See table 1). Three hours later 0.05 gM of the halogen derivative dissolved in 50 ml of dry ether was added. After staying for 48 hours 150 ml of dry ether was added and the liquid ammonia was removed by means of an alcohol bath. 150 ml of water was added and the mixture was extracted with ether. The extracts were washed with water, dried with sodium sulphate and the ether was distilled. The remaining dibenzyl disulphide was recrystallized from ethyl alcohol and identified by its m.p. and quantitative analysis (found : % C 68.43, H 5.85 ; calculated : % C 68.29, H 5.64). The yields of crude dibenzyl disulphide were very high and for the different ratios benzyl chloride : magnesium : sulphur they were : ratio 1 : 1 : 1 — 85.9% ; ratio 2 : 2 : 3 — 89.1% ; ratio 1 : 1 : 2—97.2% and ratio 1 : 1 : 4—97.2%.

In the experiments with benzhydryl chloride after removing of the ether from the extract the residue was distilled in vacuum (161—162°/16 mm Hg; refractive index n_D^{20} 1.5952). In all the cases the initially added benzhydryl chloride was recovered almost completely. When the ratio magnesium : sulphur was 1 : 2 and 1 : 4 after distilling of the unreacted benzhydryl chloride a small residue (less than 1%) was obtained which after recrystallization from petroleum ether was identified as tetraphenyl ethylene (m.p. 223—224°).

Interaction of benzyl chloride and benzhydryl chloride with calcium-sulphur combination. The reaction was carried out analogously to the case of magnesium-sulphur combination. The ratio RX : Ca : S was 1 : 1 : 1. The halogen derivatives were recovered from the reaction mixtures. In the case of benzyl chloride some amount of trans-stilbene was isolated (yield 8%, m.p. 123—124°, quantitative analysis : found % C 92.80, H 7.08, calculated % C 93.20, H 6.78). In the experiment with benzhydryl chloride tetraphenyl ethane was found in the distillation residue (yield 27%, m.p. 210—211°, quantitative analysis : found % C 93.18, H 6.49, calculated % C 93.40, H 6.58).

Interaction of sodium-sulphur combination with benzhydryl chloride. This interaction was carried out in the same way as described in our previous paper.[4] The amounts of sodium and benzhydryl chloride were 0.05 gA and 0.05 gM respectively, and the quantity of sulphur depended on the chosen ratio metal : sulphur (See table 2). The obtained dibenzhydryl disulphide was recrystallized from ethyl alcohol (m.p. 153°, quantitative analysis : found % C 78. 28, H 5.51, calculated % C 78.64, H 5.52). The yields of crude product for the different ratios benzhydryl chloride : sodium : sulphur were as follows : ratio 1 : 1 : 1 — 97.2%; ratio 2 : 2 : 3 — 72.2%; ratio 1 : 1 : 2 — 63.5%.

When the sodium : sulphur ratio was 2 : 1 after distilling of the unreacted benzhydryl chloride 3.8% of tetraphenyl ethylene was isolated and recrystallized from petroleum ether (m.p. 222—223°; quantitative analysis: found % C 94.29, H 6.06, calculated % C 93.97, H 6.03; TLC upon silicagel G and silicagel G impregnated with 10% of silver nitrate, mobile phase petroleum etherbenzene 9 : 1, Rf values 0.49 and 0.29, resp.).

CHEMICAL GRAPHS. XXII [1]

VALENCE ISOMERS OF HETEROANNULENES OR OF SUBSTITUTED ANNULENES. COISOMERIC CUBIC MULTIGRAPHS

ALEXANDRU T. BALABAN

Institute of Atomic Physics, P.O. Box 35, Bucharest

Received 27 March, 1974

By applying Pólya's counting theorem to the cycle indices of valence isomers of [n]annulenes (cubic multigraphs with n points), the numbers of constitutional isomers for heteroannulenes or substituted annulenes are presented (all multigraphs with $n = 4$ and 6, and a few with $n = 8$ and 10). Cases of coisomeric graphs (i.e. those like benzene and benzprismane yielding the same numbers of constitutional isomers because they possess the same cycle indices) are reviewed. Examples of known heteroannulene valence isomers are presented. Reaction graphs $L(2^n, M)$ for some of the above molecules M are discussed.

1. INTRODUCTION

Valence isomers were defined as molecules whose reduced structural graphs have the same partition of their vertex degrees.[2,3a] By *reduced* structural graphs, we mean graphs whose points (vertices) represent atoms with valence *higher than one*, and whose lines (edges) represent covalent bonds. It is necessary to specify that these are *structural graphs*, because reduced *reaction graphs* [3b] also exist (in the latter graphs, points represent chemical species, and lines represent elementary reactions).

Valence isomers of annulenes yield reduced structural graphs which are cubic (trivalent) multigraphs, i.e. regular multigraphs [4] of degree three. By an algorithm based on general cubic graphs, a systematic approach was devised for the construction of all possible cubic multigraphs with n points, i.e. of order n. This enabled us to enumerate these graphs for $n = 4$, 6, 8, and 10,[5] and more recently for $n = 12$.[6] A mathematical approach for the corresponding numerical problem was discovered by R. W. Robinson,[7–8] but it is not yet amenable for numerical computation, and still less for constructing the various graphs.

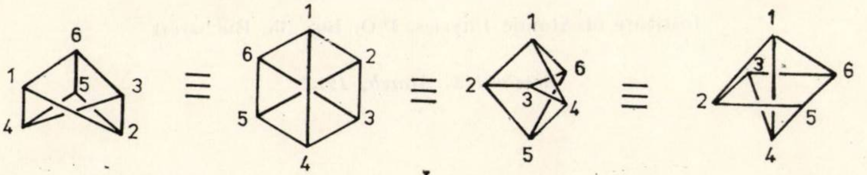
[6] A. T. Balaban, *Rev. Roumaine Chim.*, **17**, 865 (1972).

Taking account of the chemical counterparts of cubic multigraphs, it was natural to discuss in more detail *planar* cubic multigraphs,* since no molecule is yet known whose reduced structural graph is non-planar. The smallest cubic graph which is non-planar is I, which corresponds to the reduced structural graph of the diagonal benzene formula proposed by Claus [10] before it was modified into the centric formula.[11]



I

Formula I results from that of benzprismane by inverting two bonds so as to convert the closed strip of three condensed four-membered rings into a Möbius strip. We will call accordingly graph I "benz-möbius-stripane". This should not be misinterpreted as involving a Möbius strip of six atomic orbitals in a simple ring of six carbon atoms, as discussed in the literature.[12]

The five other valence isomers of benzene [5] are all planar graphs, since they can be written in a plane without crossing lines, and are all known as chemical species.

VALENCE ISOMERS OF HETEROANNULENES OR OF SUBSTITUTED ANNULENES

To find out the numbers of valence isomers of heteroannulenes such as pyridine, or of substituted annulenes such as chlorobenzene, we start from the valence isomers of annulenes and examine how many isomers result from each by introducing heteroatoms or substituents. The most powerful and elegant procedure consists in applying Pólya's counting theorem.[3c, 13–16]

---

* It should be emphasized that "planarity" is here meant as a topological,[4] not a geometrical, concept. Planar multigraphs can exist in various geometries, including tridimensional ones. Chemical texts [9] occasionally mention "non-planar valence isomers" meaning tridimensional molecules whose reduced structural graphs are planar multigraphs.

[12] E. Heilbronner, *Tetrahedron Letters*, **1964**, 1923.

Pólya showed that the number of such isomers results by substituting a figure counting series y_k into the cycle index $Z(A)$ of the reduced structural graph of the respective molecule. The cycle index is the expression of symmetry operations around proper or improper axes of rotation (disregarding symmetry operations involving centres or planes of symmetry). Expressed as operations on permutation groups A, the cycle index $Z(A)$ is a sum of terms Πy_k^j, where $j + k = n$, n being the order of the graph.

$$Z(A) = \frac{1}{|A|} \sum_{\alpha \in A} \prod_{k=1} y_k^{j_k(\alpha)}$$

where $|A|$ is the order of the group A, and $j_k(\alpha)$ is the number of cycles of length k in the disjoint-cycle representation of the permutation α.

The figure counting series to be substituted for y_k is

$$y_k = \sum_{i=1}^{m} x_i^k$$

where m is the number of different kinds of substituents ($m \leqslant n$).

The result of this substitution is a configuration counting series, or a counting polynomial. In it, the coefficient of any term $\prod_i x_i^{k_i}$ gives the number of isomers with k_i substituents (heteroatoms) of type i.

Table 1 presents in detail the derivation of cycle indices for valence isomers of [4]- and [6]annulene. Unless otherwise stated, the cycle indices are topological rather than geometrical, expressing constitutional isomerism rather than stereoisomerism. The symmetry operations are represented as cyclic permutations of vertices, according to their numbering given in the formulas. Each symmetry operation corresponds to a term y_k^j in the cycle index. For completeness, with the graphs of order 6 we included the non-planar graph I representing the chemically impossible benz-möbius-stripane; it has the highest symmetry from all cubic multigraphs of order 6, being the "6-cage".[4,17] It is the graph of the

"three houses – three utilities problem", therefore it also has a trigonal axis.

For the two valence isomers of [4]annulene (cyclobutadiene and tetrahedrane), four cycle indices are presented in table 3, since cyclobutadiene could exist in a triplet D_{4h} square geometry, or in a singlet D_{2h} rectangular geometry with localized double bonds; for tetrahedrane one may consider topological (constitutional) isomerism when all 4! permutations between the vertices of the complete graph K_4 are possible (cf. next paragraph), or geometrical isomerism when only half of these permutations, corresponding to the symmetry axes of a tetrahedron, are allowed. In other words, when the symmetry operations are performed on a geometrical object we obtain numbers of isomers including stereoisomerism, and when they are performed on a topological object (graph which may assume all possible geometries), we obtain numbers of isomers excluding stereoisomerism, i.e. constitutional isomers.

In the case of the complete graph K_n with n points, let

$$n = 1.k_1 + 2.k_2 + 3.k_3 + \ldots$$

be one of the partitions of n. Then, according to the Cauchy identity[18] extended over all partitions of n, denoted by $p(n)$

$$n! = \sum \frac{n!}{1^{k_1}\cdot k_1!2^{k_2}\cdot k_2!3^{k_3}\cdot k_3!\ldots}$$

the n! permutations can be grouped, according to their cyclic representations, as a sum of $p(n)$ terms. Thus for the complete graph K_4 (tetrahedrane excluding stereoisomerism), the $4! = 24$ permutations are grouped into $p(4) = 5$ terms (according to the respective cycle index formula in table 3). Accordingly the Cauchy identity becomes

$$\begin{array}{ccccccccccc} \text{Partition:} & & 1+1+1+1 & & 2+1+1 & & 2+2 & & 3+1 & & 4 \\ 24 & = & \dfrac{4!}{1^4\cdot 4!} & + & \dfrac{4!}{1^2\cdot 2!2^1\cdot 1!} & + & \dfrac{4!}{2^2\cdot 2!} & + & \dfrac{4!}{3^1\cdot 1!1^1\cdot 1!} & + & \dfrac{4!}{4!\cdot 1!} = 1+6+3+8+6. \end{array}$$

These are the coefficients of the cycle index for tetrahedrane excluding stereoisomerism presented in table 3. Since all permutations are allowed, this case was not included in table 1.

On the other hand, for benzene, only the delocalized D_{6h} structure was considered; thus [6]annulene is represented by the cyclic graph C_6 which is regular of degree 2, rather than 3.

Table 2 presents the coefficients of the terms $\prod_{i=1}^{n} x_i^j$ resulted from the figure counting series $y_k = \sum_{i=1}^{n} x_i^k$, grouped according to the partition of exponents j. Only those partitions are considered which will be encountered in the next tables. By operating with the coefficients presented in table 2 according to the cycle indices from tables 3 and 4, the numbers of isomers shown in the right-hand side of tables 3 and 4 were found: to convert the figure counting series into numbers of isomers, we have

Benz-möbius-stripane	$\frac{1}{36}(y_1^6 + 6y_2^3 + 9y_1^2y_2^2 + 4y_3^2 + 12y_6 + 4y_1^3y_3)$

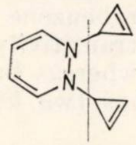
[a] Cycle indices were calculated to express only constitutional isomerism, unless otherwise stated.

to apply Pólya's theorem. These numbers are grouped according to the partition of substituents.*

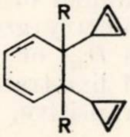
Thus, valence isomers of [4]annulene can have one of the four CH groups substituted (partition 3, 1), or two of them substituted by one type (partition 2,2) or by two types of substituents (partition 2, 1, 1). There exist [18,19] five partitions of 4 as indicated above by $p(4) = 5$, and eleven partitions of 6, as seen in the headings of tables 3 and 4, respectively.

---

* Since heteroatoms give the same numbers of constitutional isomers as do substituents, one may replace "substituent" by "heteroatom" in this and subsequent phrases. However, when stereoisomerism is not ignored the numbers of valence isomers for aza-annulenes and substituted annulenes may be different because of the easy nitrogen inversion e.g. in the case of



and



[19] A. T. Balaban, *Rev. Roumaine Chim.*, **16**, 9 (1972).

4

substituted [6] annulene

1	1	3	3	3	6	11	10	16	30	60
1	1	2	2	3	3	4	4	6	10	20

It is apparent from table 4 that benzene and benzprismane (triprismane) have the same cycle index and hence afford the same numbers of substituted isomers, if stereoisomerism is ignored. This is a general property of [n]annulenes and their $\left(\frac{n}{2}\right)$-prismane valence isomers with $n = 6$ and $n \geqslant 10$, as will be shown further below in the case of delocalized cyclodecapentaene and pentaprismane. The presence of an improper axis of rotation S_6 in triprismane explains the occurrence of the cyclic permutations involving all six vertices, which in benzene are derived from the proper axis C_6.

It shoul be emphasized that the number of isomers depends only on the cycle index, and not on the symmetry group (for benzene the point group is D_{6h}, for benzprismane it is D_{3h}) or on the transitivity of lines in the graph (benzene is point- and line-transitive, whereas benzprismane is point-transitive but line- intransitive, i.e. it has two kinds of lines or C—C bonds).

We will call such molecules (or graphs, respectively) having identical cycle indices, "coisomeric". Coisomeric graphs must have the same symmetry operations and the same vertex transitivity, i. e. the same partition of different types of vertices.

Historically, the coincidence of cycle indices for benzene and benzprismane formulas caused much confusion and debate during the years when the benzene formula was under discussion. Ladenburg [20] had advocated the triprismane formula for benzene against Kekulé's, since the former formula explained the numbers of isomers without having recourse to Kekulé's additional hypothesis of "oscillating valencies" (refined into today's delocalized bonds). The correspondence between *ortho*, *meta*, and *para*-disubstituted isomers in both cases is seen from table 5 on the basis of numbers of isomers on going from partition 4, 2 to parition 3, 2, 1.* In agreement with tables 4 and 5, there are 3 and 4 isomers, respectively, for triprismane with two identical substituents (partition 2, 4) when ignoring, respectively including, stereoisomerism, but 6 and 10 isomers, respectively, for partition 3, 2, 1. The *para*-substituted derivatives have two orthogonal axes C_2, and afford therefore the smallest number of isomers. The *ortho*- and *meta*-substituted derivatives have only one C_2 axis : in the *ortho*-derivatives (point group C_{2h} for the triprismane derivative), this axis does not pass through two points, therefore an intermediate number of isomers is obtained. In *meta*-derivatives, this axis passes through two atoms (point group C_{2v} for the triprismane derivative) and leads to the highest number of isomers. This may be generalized to all [n]annulenes and $\left(\frac{n}{2}\right)$-prismanes (which are coisomeric, with the exception of $n = 8$ since the cube has a higher symmetry than the octogon).

---

* The presence or absence of a bond between *ortho*, *meta* or *para* positions is opposite in benzene and benzprismane.

[20] A. Ladenburg, *Ber. dtsch. chem. Ges.*, **12**, 141, 272 (1879).

Table 5

***ortho*-Disubstituted derivatives $C_6H_4A_2$ afford two constitutional isomers $C_6H_3A_2B$, *meta*-substituted ones afford three, and *para*-substituted ones afford one isomer in benzene and triprismane (benzprismane), ignoring the possible stereoisomerism of the latter (indicated by asterisks)**

Partition	Benzene			Benzprismane		
4+2	 ortho	 meta	 para	 "ortho"	 "meta"	 "para"
3+2+1	 	  		 	  	
The polemic around the benzene formula gradually favoured the Kekulé formula when *ortho*-fused systems like naphthalene were discovered, since their prismane formulas were extremely awkward, and was ended when Baeyer [21] showed that *o*-disubstituted benzenes afford on hydrogenation only one isomer of a cyclohexane derivative, a fact which could not be rationalized by Ladenburg's formula. Also, no optical activity could be demonstrated in substituted benzenes, as required by the triprismane formula (in table 5, enantiomeric structures are indicated by asterisks).

A complete search was made for cycle indices of all possible planar valence isomers of [8]annulene, and three pairs of coisomeric graphs were found, which are presented in table 6. It should be mentioned that two other pairs of cubic planar multigraphs of order 8 afford the same numbers of mono- and disubstituted isomers, but since they have different cycle indices, this is only a coincidence: indeed, the numbers of tri- and tetrasubstituted isomers are different, as seen from table 7. Similar cases exist for $n = 10$.

Table 6 also presents examples of coisomeric valence isomers of [10]annulene, namely pairs, triplets, quadruplets, and quintets. For $n = 10$, table 6 may not be exhaustive, but it is so for $n = 6$ and 8.

Table 7

Pairs of cubic graphs of order 8 which are not coisomeric

Formula	Cycle index	Number of isomers			
		7, 1	6, 2	5, 3	4, 4
	$\frac{1}{8}(y_1^8 + 2y_1^4y_2^2 + 2y_4^2 + 3y_2^4)$	2	7	10	15
	$\frac{1}{16}(y_1^8 + 2y_1^6y_2 + 3y_1^4y_2^2 + 4y_2^4 + 6y_2^2y_4)$	2	7	9	13
	$\frac{1}{4}(y_1^8 + 2y_1^2y_2^3 + y_2^4)$	3	10	17	22
	$\frac{1}{8}(y_1^8 + 2y_1^6y_2 + y_1^4y_2^2 + 2y_2^4 + 2y_2^2y_4)$	3	10	15	20

As noted above, pentaprismane is coisomeric with delocalized [10]annulene. Pentaprismane is not yet known, and [10]annulene is much less stable than benzene. It is interesting to note that bullvalene is coisomeric with a saturated valence isomer of [10]annulene. Another observation concerning table 6 is provided by the five coisomeric valence isomers of [10]annulene with cycle index $(y_1^{10} + y_2^5)/2$: two of these have point group C_{2h} (including a symmetry centre and one plane of symmetry), the remaining three have point group C_{2v} (including two symmetry planes). The number of isomers does not depend on reflections, but only on symmetry axes.

EXAMPLES

1. *Valence isomers of substituted annulenes.* The first valence isomers of [4]- and [6]annulene to be prepared were substituted ones (tetramethylcyclobutadiene,[22] t-butyl-substituted Dewar-benzene [23] and benzprismane,[24] phenyl-substituted bicyclopropenyl [25]). Since the literature

was summerized in recently published reviews for valence isomers of $[n]$annulenes with or without substituents, we will only quote these reviews: $n = 4$,[26] $n = 4 - 10$,[5,6,27] $n = 6, 10$,[28a] $n = 10$,[28b] $n = 12$,[6] and $n > 12$.[29]

2. *Valence isomers of heteroannulenes.* Two reviews have so far been published on this topic.[27] In the following, a few non-exhaustive examples will show the huge non-explored area offered by these interesting possibilities, especially for larger n values where steric strain is less severe. According to table 4, there should exist 9 constitutional planar valence isomers of pyridine, 24 of diazine and 25 of triazine.

Valence isomers of pyridine were claimed,[30] then retracted,[31] and finally first prepared by a photochemical reaction: one of the two possible Dewar-pyridines, namely that with the heteroatom at a bridgehead position.[32] Pentakis-pentafluoropyridine valence isomers, namely a similar Dewar-pyridine and an azabenzprismane, were recently obtained.[9] The photochemical conversions of pyrylium salts are believed to involve oxonia-analogues of benzvalene, or, less probably, of benzprismane or Dewar-benzene.[33]

The photochemical rearrangement of perfluoro-(4,5-bisisopropylpyridazine) into the corresponding pyrazine derivative [34a] proceeds *via* diaza-Dewar-benzene intermediates, one of which could be isolated.[34b]

Valence isomers of mono- and diazacyclooctatetraene are known. The heteroatom exerts a strong influence on the valence tautomerism between [8]annulene and bicyclo[4.2.0]octa-2,4,7-triene. Monoazacyclooctatetraene or azocine (with a 2-alkoxy substituent) evidences by spectroscopic methods only the existence of the monocyclic tautomer, II, but the mobile equilibrium with the bicyclic tautomer III in minute amounts allows diene reactions leading to products IV derived from the latter, namely with the heteroatom in position 7 (the other three possible bicyclic isomers are absent).[35] By contrast, hydrolysis of the alkoxy

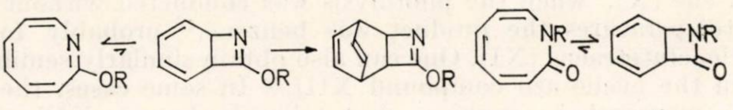
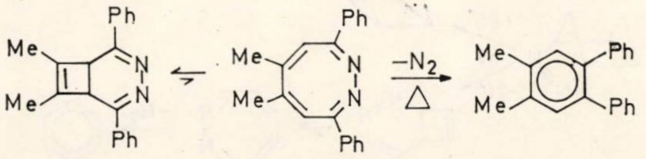
group affords the amide which exists entirely as the bicyclic valence isomer V [36]



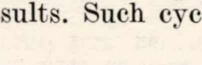
II III IV V

1,2-Diazacyclooctatetraene with phenyl and methyl substituents also exists as the bicyclic tautomer VI. On heating, it splits off nitrogen, affording a benzene derivative, presumably *via* the monocyclic valence isomer, VII [37]

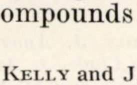


VI VII

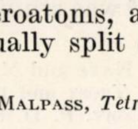
It was predicted by M. J. S. Dewar [38a] and by R. Hoffmann [38b] that the low-barrier degenerate rearrangement of semibullvalene could become even easier with appropriate donor (Do) or acceptor (Acc) substituents (VIIIa) or with heteroatoms (VIIIb), so that such structures would be good candidates for mesovalent molecules.[38a] By contrast, hexamethyl-2-methoxy-azasemibullvalene (IX) presents no degenerate rearrangement in the temperature range −40° to 150°.[39]



VIIIa



VIIIb



IX

If two carbon atoms joined by a double bond in a valence isomer of an [*n*]annulene are replaced by nitrogen heteroatoms, a cyclic azo compound results. Such cyclic azo compounds usually split off nitrogen thermally or photolytically affording valence isomers of [n-2]annulenes: thus was synthesized benzprismane[40] from 7,8-diazatetracyclo[3.3.0.0^{2,4}.0^{3,6}]oct-7-ene (X), when the photolysis was conducted without cooling; at low temperatures the product was benzene,[41] probably formed *via* diazacyclooctatetraene (XI). One can also obtain similarly semibullvalene XII from the cyclic azo compound XIII.[42] In some cases, the reaction takes an unexpected course, e. g. 1,2-diazabasketene XIV (7,8-diazapentacyclo[4.2.2.0^{2,5}.0^{3,9}.0^{4,10}]dec-7-ene) yields the unsubstituted azocine XVI by loss of hydrogen cyanide from a diazaderivative XV of the Nenitzescu hydrocarbon, formed intermediately.[43] Cyclic bis-azo derivatives are also known[44]

In the valence isomers of hetero-[10]annulenes, 1,6-dimethyl-2,5-diphenyl-3,4-azabicyclo[4.4.0]deca-2,4,7,9-tetraene, XVII, undergoes a facile 1,5-carbon migration.[45] The degenerate rearrangement of azabullvalene[46] was studied by Paquette[47] using NMR techniques at variable temperatures. 2-Methoxyazabullvalene (3-methoxy-4-azatricyclo[3.3.2.$0^{2,8}$]deca-3,6,9-triene, XVIII) can be obtained photochemically from 8-methoxy-7-azabicyclo[4.2.2]deca-2,4,7,9-tetraene, XIX.[48] Pyrolysis of either of these two valence isomers affords the same mixture of substituted quinoline and isoquinoline isomers, XXIV, and this was interpreted as involving the transient formation of four common valence isomeric intermediates XX – XXIII[48]

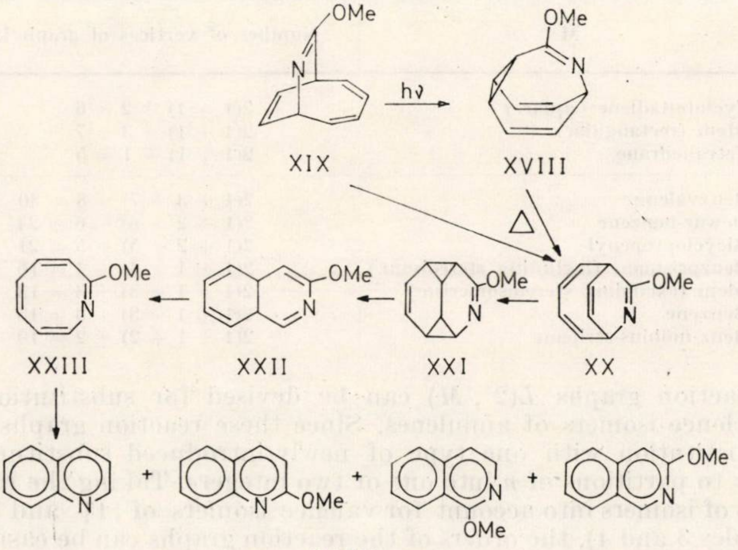
XVII



REACTION GRAPHS FOR SUBSTITUTING VALENCE ISOMERS OF [n]ANNULENES

In a previous paper,[49] reaction graphs corresponding to substitution reactions were defined and discussed. When the *s* substitution sites are non-equivalent, or when they become so at a certain step of the substitution, the reaction graphs are denoted by $L(r^s, M)$, where M is the reduced structural graph of the molecule undergoing substitution, and r is the number of types of substituents (thus, in the case of one type of substituent, e. g. in progressive halogenations, deuterations, or alkylations, $r = 2$, i. e. the preexisting hydrogens, and the newly introduced Hal, D or Alk groups).

---

[48] L. A. Paquette, G. R. Krow and J. R. Malpass, *J. Amer. Chem. Soc.*, **91**, 5522 (1969); L. A. Paquette, C. R. Krow, J. R. Malpass and T. J. Barton, *ibid.*, **90**, 3600 (1968).

[49] A. T. Balaban, and F. Kerek, *Rev. Roumaine Chim.*, **19**, 631 (1974).

Thus the progressive substitution (with one type of substituent) of a valence isomer of an [n]annulene gives rise to a reaction graph $L(2^n, M)$ which provides a graphical illustration of Pólya's configuration counting series for terms corresponding to partitions of n into two integers. In the previous paper,[49] the graph $L(2^6$, benzene) was presented. The same reaction graph applies to substitution of benzprismane if stereoisomerism is disregarded.

Table 8

Order of reaction graphs $L(2^n, M)$ for substitution of valence isomers of [4]- and [6]annulene

n	M	Number of vertices of graph $L(2^n, M)$
4	Cyclobutadiene (square)	$2(1 + 1) + 2 = 6$
	Idem (rectangular)	$2(1 + 1) + 3 = 7$
	Tetrahedrane	$2(1 + 1) + 1 = 5$
6	Benzvalene	$2(1 + 3 + 7) + 8 = 30$
	Dewar-benzene	$2(1 + 2 + 6) + 6 = 24$
	Bicyclopropenyl	$2(1 + 2 + 5) + 5 = 21$
	Benzprismane (including stereoisom.)	$2(1 + 1 + 4) + 4 = 16$
	Idem (excluding stereoisomerism)	$2(1 + 1 + 3) + 3 = 13$
	Benzene	$2(1 + 1 + 3) + 3 = 13$
	Benz-möbius-stripane	$2(1 + 1 + 2) + 2 = 10$

Reaction graphs $L(2^n, M)$ can be devised for substitution of all other valence isomers of annulenes. Since these reaction graphs concern only substitution with one type of newly-introduced substituent, they all apply to partitions of n into one or two integers. Taking the respective numbers of isomers into account for valence isomers of [4]- and [6]annulene (tables 3 and 4), the orders of the reaction graphs can be easily calculated as follows : since the numbers of isomers for partitions $n, 0$; $n - 1, 1$; $n - 2, 2$; ... ; $n/2 + 1, n/2 - 1$ are equal to those for partitions $0, n$; $1, n - 1$; $2, n - 2$; ... ; $n/2 - 1, n/2 + 1$, respectively, one has to add twice these numbers to the number of isomers for partition $n/2, n/2$. The results are presented in table 8 which gives the orders (numbers of vertices) of these graphs.

CARBONIUM ION REACTIONS. X*

NITROUS ACID DEAMINATION OF 5-AMINOMETHYL-5H-6,7-DIHYDRO-DIBENZO[*a,c*]CYCLOHEPTENE

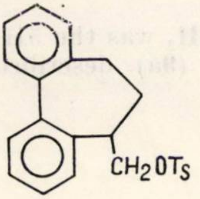
M. BANCIU, ECATERINA DRAGU, DOINA GEORGESCU and
ECATERINA CIORĂNESCU
Laboratory of Organic Chemistry, Polytechnic Institute, str. Polizu nr. 1, Bucharest,
Romania

Received February 4, 1974

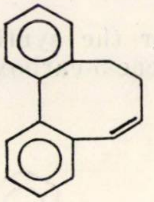
The title compound, **1-NH$_2$**, was synthesized and subjected to nitrous acid deamination. The major reaction products were: the ring enlarged alcohol **5**, the tertiary alcohol **10** and the unrearranged alcohol **1-OH**. Two olefins, **2** and **3**, are also formed in small quantities. The reaction mechanism and a comparison with the known solvolysis of the tosylate with the same skeleton are presented.

INTRODUCTION

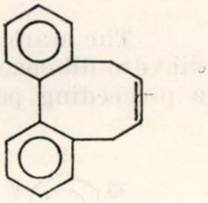
As previously described,[1] the acetolysis of 5-tosyloxymethyl-5H-6,7-dihydro-dibenzo[*a,c*]cycloheptene **(1-OTs)** proceeds with extensive ring enlargement, giving rise (after LiAlH$_4$-reduction) to compounds **1-OH** – **5** (see Table 1).



1-OTs



2

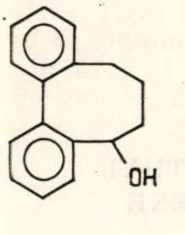


3

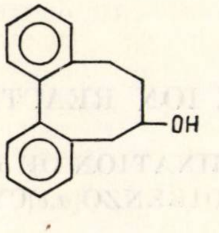
---

* Part IX. A. Banciu, M. Elian, A. Bucur, D. Georgescu, E. Ciorănescu and C. D. Nenitzescu, *Rev. Roumaine Chim.*, **19**, 213 (1974).

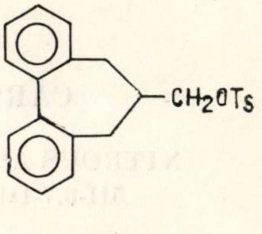
[1] E. Ciorănescu, M. Banciu, M. Elian, A. Bucur and C. D. Nenitzescu, *Liebigs Ann. Chem.*, **739**, 121 (1970).



4

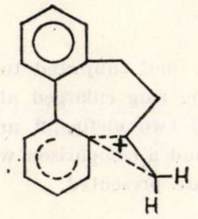


5

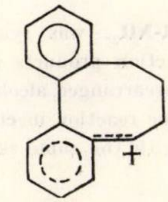


6-OTs

The reaction rate of **1-OTs**, 20 times greater than that of the isomeric tosylate **6-OTs** (at 110°), indicated [1] the assistance of a neighbouring phenyl group and the intermediate appearance of a phenonium ion **7**. The product distribution suggested the intervention of a benzylic ion **8** (generating **2** and **4**) beside the phenonium ion (giving rise to **3**, **5** and **1-OH**).



7

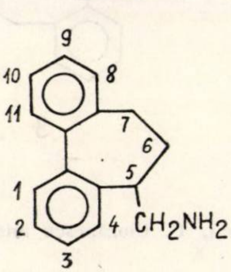


8

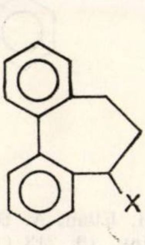
In the present paper the results obtained on nitrous acid deamination of the amine **1-NH$_2$**, possessing the same skeleton as the above tosylate, are described.

RESULTS AND DISCUSSION

The starting material for the synthesis of **1-NH$_2$** was the 5H-6,7-dihydro-dibenzo[*a,c*]cycloheptene-5-carboxylic acid (**9a**) described in a preceeding paper [1]:



1-NH$_2$



a: X = COOH
b: X = COCl
c: X = CONH$_2$
d: X = CN

9

The acid chloride **9b** afforded, on treatment with NH_3 solution, the crystalline amide **9c** (m.p. 204°). Due to the poor solubility of **9c** in ether, the $LiAlH_4$-reduction of the amide was performed in THF, giving rise to amine **1-NH$_2$** in 38% yield. This yield could be augmented up to 75% by conversion of **9c** to the corresponding nitrile **9d** (m.p. 81−3°) and subsequent $LiAlH_4$-reduction carried out in ether.

The amine **1-NH$_2$**, a viscous oil, was characterised through its crystalline hydrochloride (m.p. 219−220°) and acetoxy-derivative (m.p. 162°) (for IR- and NMR-spectra see Experimental part).

The nitrous acid deaminations were performed with the free amine **1-NH$_2$** as well as with hydrochloride **1-NH$_2$·HCl** in the presence of sodium nitrite in anhydrous acetic acid. The temperature was maintained at 2−5° during the nitrite addition, then the reaction mixture was kept at room temperature for 24 hrs.

In Table 1 the product composition in the deamination of **1-NH$_2$** is presented (v.p.c. analyses after $LiAlH_4$-reduction) and for comparative purposes the results obtained [1] in the solvolysis of **1-OTs** are also registered.

Table 1

Product distribution in the nitrous acid deamination of 1-NH$_2$ and acetolysis of 1-OTs (after LiAlH$_4$-reduction)

Products % (v.p.c. analysis) / Starting compound (reaction conditions) (Solvent : AcOH)	2, 3	Unidentified olefins (2 components)	10	5	4	1-OH	Unidentified components
1-NH$_2$ + $NaNO_2$ (1 mole : 1 mole ; 5°)	5.0 + 3.0	0.8	20.0	52.0	—	15.5	3.7 (1 comp.)
1-NH$_2$·HCl + $NaNO_2$ (1 mole : 1−2.5 moles ; 5°)	1.5 + 0.5	10.0	17.5	53.5	—	10.0	7.0 (5 comp.)
1-OTs + NaOAc[a] (1 mole ; 3 moles ; 110°)	6.0 + 2.0	14	—	25.0	38.0	15.0	—

(a) data from ref.[1]

The v.p.c. analysis indicated the presence of 4 olefinic components in the deamination reaction mixture of the amine **1-NH$_2$** (as well as in the acetolysis products of **1-OTs**). It was proved that two of these olefins were identical (retention times and mixed samples in the v.p.c.) with olefins **2** and **3** obtained (as a mixture) after the method of Cope and Smith.[2] The remaining two alkenes have not been investigated.

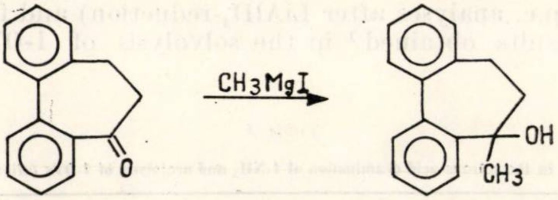
The major component of the reaction mixture ($> 50\%$) was identical with the authentic alcohol **5** prepared also after Cope and Smith.[2] The minor alcoholic component was found to be the unrearranged alcohol **1-OH**, described in our previous paper[1].

---

[2] A. C. Cope and R. D. Smith, *J. Amer. Chem. Soc.*, **78**, 1012 (1956).

A third alcohol, **10**, which does not appear in the solvolyses of **1-OTs**, was separated by preparative v.p.c. (of an enriched fraction containing **5** and **10**, obtained by column chromatography). The structure of 5-methyl-5H-6,7-dihydro-dibenzo[*a,c*]cycloheptene-5-ol was attributed to **10** on the basis of its IR- and NMR-spectra (see Experimental part).

By comparison (v.p.c. and spectral characteristics) with an authentic material obtained from the reaction of 5H-6,7-dihydro-dibenzo[*a,c*]cycloheptene-5-one (**11**)[3] with methyl magnesium iodide, the structure of **10** was confirmed.



11 **10**

The data from Table 1 show that the results obtained in the deamination of **1-NH$_2$** differ in two respects from those of the solvolysis of **1-OTs**. In the deamination of **1-NH$_2$** the tertiary alcohol **10** was formed, while the benzylic alcohol **4** was found to be absent. In the solvolysis of **1-OTs** this situation was reversed.

Differences in product distribution indicates specific intermediates for each case.

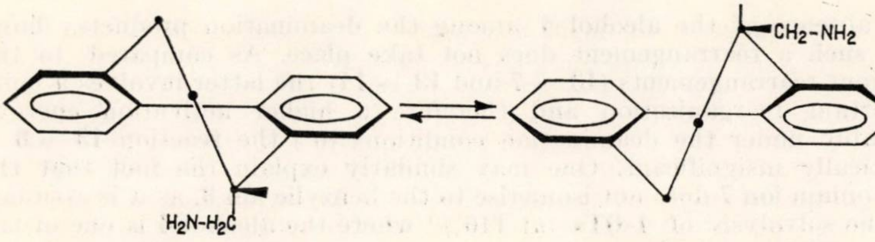
Comparisons between deamination and solvolyses of the same systems have frequently been made.[4] A general mechanism which could explain all the characteristic features of nitrous acid deaminations has not yet been advanced. It is generally assumed that the first intermediate formed from the diazonium ion, by N_2 elimination, is an open "hot" ion, highly reactive toward nucleophiles.

Inspection of Dreiding stereomodels reveals the existence, in the case of **1-NH$_2$**, of two conformations interconvertible by rotation of the aromatic rings around the C_2—C_3 bond, the —CH_2—NH_2 group being either in the pseudo-axial or in the pseudo-equatorial position.

---

[3] J. W. Cook, G. T. Dickson and J. D. London, *J. Chem. Soc.*, **1947**, 746.

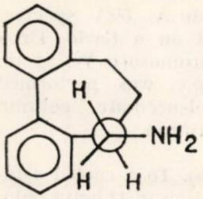
[4] J. H. Ridd, *Quart. Rev.*, **15**, 418 (1961); H. Zollinger, "Azo and Diazo Chemistry", Interscience, New-York, 1961, p. 123; R. Huisgen and C. Rückhardt, *Liebigs Ann. Chem.*, **601**, 1, 21 (1961); E. H. White in "The Chemistry of Amino Group", S. Patai (Editor), Interscience, London, 1968, p. 407.



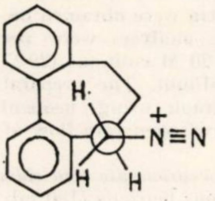
1-NH$_2$ (axial) **1-NH$_2$** (equatorial)

It seems that the axial conformation is favoured over the more hindered equatorial one in which the repulsions between the $-CH_2NH_2$ group and neighbouring atoms are more important.

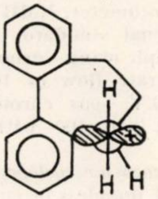
If it is assumed [5] that the "hot" carbonium ion produced by decomposition of the diazonium ion retains the conformation of the initial amine, then the intermediates **12** and **13** would be formed successively from **1-NH$_2$**.



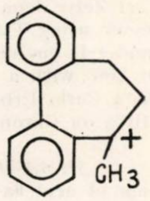
1-NH$_2$



12



13



14

The highly reactive open carbonium ion **13** rearranges rapidly into other more stable intermediates. There are several ways by which this stabilization could occur.

The assistance of the phenyl group from the β-position may lead to the phenonium ion **7**. This can further give rise to the acetates of the ring-enlarged alcohol **5** and of the unrearranged alcohol **1-OH** as well as to the olefin **3** (may be also to the olefin **2**). The predominant population of the axial conformation of the starting material, the only one which can lead to a phenonium ion, is in agreement with the formation of the alcohol **5** as the major product ($>50\%$).

A hydride shift in the "hot" carbonium ion **13** (irrespective of the axial or equatorial precursor) leads to the stable tertiary benzylic ion **14** from which the alcohol **10** (20%) is formed (the latter alcohol does not appear in the solvolysis of **1-OTs**).

A third possibility for the stabilization of ion **13** is an alkyl migration which would lead to the benzylic ion **8** (Demyanov ring expansion).

---

[5] F. A. Abd Elhafez and J. D. Cram, *J. Amer. Chem. Soc.*, **74**, 5846 (1952); J. D. Cram and J. E. McCarthy, *ibid.*, **79**, 2866 (1957).

The absence of the alcohol **4** among the deamination products shows that such a rearrangement does not take place. As compared to the previous rearrangements (**13** → **7** and **13** → **14**) the latter involves a more important reorganization and therefore a higher activation energy; probably under the deamination conditions (0°) the reaction **13** → **8** is kinetically insignificant. One may similarly explain the fact that the phenonium ion **7** does not isomerise to the benzylic ion **8**, as it is assumed for the solvolysis of **1-OTs** (at 110°)[1] where the alcohol **4** is one of the major products.

Finally, one may suppose that at least part of the alcohol **1-OH** (of its acetate respectively) arises from the reaction of ion **13** with the solvent or even from a direct displacement on the diazonium ion as was suggested in other cases.[6]

EXPERIMENTAL

Melting points are uncorrected. IR spectra were recorded with a double-beam UR−20 Carl Zeiss Jena spectrophotometer. NMR spectra were obtained on a Varian A−60A spectrometer using TMS as internal standard. V.p.c. analyses were performed on a Carlo Erba model D gas chromatograph using Carbowax 20 M columns (20% on Chromosorb W), 1 m, at 200° with a hydrogen rate flow of 100 ml/min. The preparative v.p.c. was performed on a Carlo Erba model G.V. gas chromatograph using neopentylglycolsuccinate column (10% on Chromosorb W), 2 m, 190° with a hydrogen rate flow of 120 ml/min.

5H-6,7-Dihydro-dibenzo[a,c]cycloheptene-5-carboxylic acid chloride (**9b**). To a cooled solution of acid **9a**[1] (20 g; 84 mmoles) in anhydrous benzene (180 ml) a solution of thionyl chloride (14 g; 12.2 ml; 118 mmoles) in 75 ml anhydrous benzene was added dropwise with stirring for 1 hr. The solution was then refluxed for 4 hrs. The solvent and excess $SOCl_2$ were evaporated *in vacuo*. The residue was then treated with ether (2 × 50 ml) which was subsequently evaporated, affording the *acid chloride* **9b** 20.3 g (95%) as a pale-yellow oil. *IR spectrum* (CCl_4, cm^{-1}): 1073 m, 1460 m, 1494 m, 1780 s (shoulder), 1815 vs, 2865 m, 2934 vs, 2960 s, 3036 m and 3073 m. The acid chloride was utilized in the next step without further purification.

5H-6,7-Dihydro-dibenzo[a,c]cycloheptene-5-carboxamide (**9c**). A solution of acid chloride **9b** (20.3 g; 79 mmoles) in 200 ml anhydrous benzene was added dropwise with vigorous stirring to an ice-cooled solution of 28% ammonia (300 ml). Instantaneously a white precipitate of amide **9c** was formed. The reaction mixture was stirred for 1 hr., then diluted with 500 ml water and filtered. The precipitate was washed on the funnel with a little ether, leading to 17 g (90% yield) of the crude amide **9c**, m.p. 202−3°. After two recrystallizations from methanol the *amide* **9c** melts at 204°. (*Found*: C, 80.95; H, 6.56; N, 5.95. $C_{16}H_{15}NO$ requires C, 80.97; H, 6.38; N, 5.91%). *IR spectrum* (CH_2Cl_2, cm^{-1}): 1036 w, 1481 m, 1589 m, 1691 s, 2862 vw, 2953 w, 3045−3085 m, 3401 m, 3516 m.

The nitrile of 5H-6,7-dihydro-dibenzo[a,c]cycloheptene-5-carboxylic acid (**9d**). $POCl_3$ (12.5 g; 7.5 ml; 84 mmoles) was poured over solid amide **9c** (2.5 g; 10.5 mmoles) and the reaction mixture was maintained at 85° for 1 hr. After cooling, the reaction mixture was poured in ice-cooled water and ether-extracted. The organic layer was washed with $NaHCO_3$, with water and then evaporated *in vacuo* affording a viscous oil (2.2 g; 95%) which crystallizes rapidly. The *nitrile* **9d** has a m.p. 81−3° (ethanol). (*Found*: C, 87.54; H, 6.25; N, 6.32. $C_{16}H_{13}N$ requires: C, 87.63; H, 5.98; N, 6.39%. *IR spectrum* (CS_2, CCl_4, cm^{-1}): 760 vs, 1465 m, 1490 m, 2250 w, 2882 w, 2931 w, 2952 m, 3028 w, 3082 w.

5-Aminomethyl-5H-6,7-dihydro-dibenzo[a,c]cycloheptene (**1-NH$_2$**). (a) *By $LiAlH_4$-reduction of the amide* **9c**. To a suspension of $LiAlH_4$ (1 g; 26.3 mmoles) in anhydrous tetrahydrofuran (30 ml) a solution of amide **9c** (4.8 g; 20.3 mmoles) in tetrahydrofuran (150 ml) was added dropwise during 2 hrs. The reaction mixture was refluxed for 8 hrs and left overnight. After decomposition with cold water (50 ml) the organic layer was separated and the aqueous one was ether-extracted. The combined organic layers were washed with water, dried and evaporated under inert atmosphere, affording 4.0 g (88%) crude **1-NH$_2$**, a viscous oil which could not be crystallized.

[6] E. F. Cox, M. C. Caserio, M. S. Silver and J. D. Roberts, *J. Amer. Chem. Soc.*, **83**, 2719 (1961).

The hydrochloride of the amine **1-NH$_2$** was precipitated from the crude oily amine by treating with HCl-saturated ether. After dissolving in 5 ml anhydrous ethanol, filtration and reprecipitation with anhydrous ether the *hydrochloride of the amine* (**1-NH$_2$·HCl**) was obtained (2 g; 38%) m.p. 219–220° (*Found* : C, 73.79 ; H, 7.22 ; Cl, 14.43 ; N, 5.62. $C_{16}H_{18}NCl$ requires : C, 73.96 ; H, 6.99 ; Cl, 13.65 ; N, 5.39%). *IR spectrum* (KBr, cm^{-1}) : 733 w (shoulder), 751 s, 757 s, 771 m (shoulder), 1443 m, 1481 m, 1517 m, 1590 m, 1611 m, 2500–3200 m, 2900 s.

1-NH$_2$-Acetate, from the oily amine **1-NH$_2$** (liberated on neutralization of **1-NH$_2$·HCl**) with Ac_2O, 0.5 hr at 100° ; m.p. 162° (methanol) (*Found* : C, 81.73 ; H, 7.42. $C_{18}H_{19}NO$ requires : C, 81.46 ; H, 7.22%). *IR spectrum* (KBr, cm^{-1}) : 751 vs, 1372 m, 1449 s, 1487 s, 1575 vs, 1650 vs, 1655 s (shoulder), 2848 m, 2875 m, 2920 m, 2930 m, 3021 m, 3070 m, 3276 vs. *NMR spectrum* ($CDCl_3$, δ ppm) : 1.79 s (3H) ; 1.8–3.0 m (5H) ; 3.53 t (2H ; $J_{CH} \approx J_{NH} \approx 7.8$ cps) ; 5.52 m (1H) ; 7.2–7.5 m (8H, arom).

(b) *By LiAlH$_4$-reduction of the nitrile* **9d**. The reduction was carried out in anhydrous ether after the procedure described for (a). From 4.4 g nitrile **9d**, 4.1 g (79%) *1-NH$_2$-hydrochloride* with m.p. 219° were obtained (75% yield calculated from the amide **9c**).

Deamination reactions of 5-aminomethyl-5H-6,7-dihydro-dibenzo[a,c] cycloheptene (**1-NH$_2$**). To an ice-cooled solution of **1-NH$_2$** hydrochloride (2.0 g; 7.7 mmoles) in anhydrous acetic acid (110 ml), $NaNO_2$ (0.55 g, 8 mmoles) was added in small portions, then the reaction mixture was left overnight. After pouring in cold water (100 ml) and neutralization with solid Na_2CO_3 the mixture was ether-extracted. The ethereal layer was washed with water, dried and evaporated *in vacuo*, affording an oily mixture (2 g ; 97%) of acetates which was subsequently reduced with $LiAlH_4$ (0.3 g ; 7.9 mmoles) in 100 ml anhydrous ether. After the usual work-up a partially crystallized reaction mixture was obtained (1.35 g ; 80%) whose composition was determined by v.p.c. analysis (Table 1). For the components **2** + **3** and **5**, authentic samples were synthesized (in view of a v.p.c. comparison) after Cope and Smith.[1] The alcohol **1–OH** was obtained as in reference[1].

The structure of *5-methyl-5H-6,7-dihydro-dibenzo[a,c]cycloheptene-5-ol* for the component **10** was proved in two ways :

(a) The reaction mixture from the deamination of the amine **1-NH$_2$** was chromatographied on a neutral Al_2O_3 column, eluting with a mixture of petroleum ether and dietyl ether (70 : 30), yielding a mixture of **10** and **5**. (V.p.c. analysis indicates 36% **10** and 64% **5**.) Preparative v.p.c. of this mixture affords the alcohol **10** (uncrystallizable oil).

IR spectrum (CCl_4 ; cm^{-1}) : 950 m, 1064 m, 1447 s, 1481 m, 2855 m, 2938 s, 3023 m, 3065 s, 3100 w, 3200–3550 w, 3608 m.

NMR spectrum ($CDCl_3$; δ ppm) : 1.28 s (3H) ; 1.94 s (OH) ; 2.1–3.8 m (4H) ; 7.1–7.85 m (8H, arom.).

(b) *The treatment of 5H-6,7-dihydro-dibenzo[a,c]cycloheptene-5-one* (**11**)[3] with a slight excess of methyl magnesium iodide in anhydrous ether affords, after usual work-up, the alcohol **10** whose IR and NMR spectra were identical with those of the preparatively v.p.c.-separated *5-methyl-5H-6,7-dihydro-dibenzo[a,c]cycloheptene-5-ol*.

Other deaminations, using different molar ratios of reactants as well as the free amine **1-NH$_2$** (obtained on neutralization of **1-NH$_2$·HCl**) were performed using the same procedure ; the results are also given in Table 1.

Received November 13, 1973

The action of water-activated aluminium chloride on 2,2-, 1,1-, 1,2- and 1,3-diphenylbutane at 100° was investigated using different reaction periods. Both gaseous and nongaseous products were separated, identified and estimated by modern analytical techniques. In all cases, the gaseous products were shown to be mixtures consisting chiefly of isobutane in addition to smaller amounts of lower and higher components. On the other hand, the nongaseous products were shown to consist of varying proportions of methyl-, ethyl-, propyl- and butylbenzenes in fractions boiling below 184° and of starting and rearranged diphenylbutanes in higher fractions.

In a preceding part of this series [1] we reported the results of treatment of 1,1- and 1,2-diphenylbutane with $AlCl_3$ in benzene both at room temperature and at 68–70°. Under such conditions we observed two main types of reactions : First, dephenylation of both isomers to *n*-butylbenzene and, second : isomerisation in accordance with the sequence : 1,1-diphenylbutane → 1,2-diphenylbutane → 1,3-diphenylbutane. Fragmentation reactions were inappreciable, however.

In the present article we wish to report the results of further experiments in which 2,2-, 1,1-, 1,2- and 1,3-diphenylbutane were subjected to the action of water-activated $AlCl_3$ at 100° for various periods. Using such conditions, we hoped, to induce some dealkylation and fragmentation reactions and to obtain some information regarding the patterns of these reactions with such straight-chained diphenylbutanes.

RESULTS AND DISCUSSION

The conditions and results of treatment of 2,2-, 1,1-, 1,2- and 1,3-diphenylbutane with water-activated $AlCl_3$ are summarized in Tables 1–6 in this section and Tables 7–9 in the experimental section.

---

[1] R. M. Roberts and A. A. Khalaf, Part IV of this series, *Rev. Roumaine Chim.*, **18**, 1937 (1973).

It can be seen from the results of Tables 1, 3 and 5 that, similar to branched diphenylbutanes, the fragmentation products from non-branched diphenylbutanes contained varying amounts of methyl-, ethyl-, dimethyl- and propylbenzenes. Again butylbenzenes resulting mainly from direct dephenylation of the starting diphenylbutanes constituted the major part of the liquid mixtures boiling in the range extending from 85 to 184°. Significantly, however, the relative yields of the produced alkylbenzenes revealed an obvious dependence upon both the positions

Table 1

Liquid dealkylation and fragmentation products from 2,2-diphenylbutane[a]

d Percentage of each alkane in the gaseous mixture as found by v.p.c.

of the two phenyl groups in the chain and the reaction conditions. These facts will become apparent as we proceed with our discussion.

Regarding the fragmentation of 2,2-diphenylbutane, the data given in Table 1, show that ethylbenzene remained to be the major fragmentation product given by this isomer under all conditions employed. This is supposed to arise from isomerisation of 2,2-diphenylbutane to 2,3-diphenylbutane,[2] followed by the cleavage of the latter to ethylbenzene as suggested before.[2,3] Besides ethylbenzene, smaller amounts of the fragments toluene, *o*-xylene and *n*- and isopropylbenzene were also formed. These can result from the fragmentation of other isomeric diphenylbutanes produced by the rearrangement of the starting 2,2-diphenylbutane isomer. In fact, it has been previously shown that aluminum chloride, catalyzes the rearrangement of 2,2-diphenylbutane to 2,3-diphenylbutane and of the latter to 1,1-diphenyl-2-methylpropane, 1,2-diphenyl-2-methylpropane and 1,3-diphenylbutane.[2]

From the results of Table 3, it is noted that *n*-propylbenzene was the chief fragmentation product obtained from 1,1-diphenylbutane during the early stages of reaction (up to 15 min.). After longer reaction times, however, ethylbenzene and isopropylbenzene became more abundant. This observation is explicable in terms of the expected stepwise isomerisation of 1,1-diphenylbutane to 1,2- and 1,3-diphenylbutane[1]; the former can be considered as a precursor for *n*-propylbenzene formation and the latter as a precursor for ethylbenzene formation. The fragmentation results from 1,2- and 1,3-diphenylbutane given in Table 5 provide the experimental support for this suggestion. Thus if we compare the percentage yields of ethylbenzene and propylbenzene from 1,1-, 1,2- and 1,3-diphenylbutane after 10 min. of reaction, we find that the 1,2-isomer gave the highest percent of *n*-propylbenzene (2.4%) compared to 1.2% from the 1,1-isomer and 0% from the 1,3-isomer) and that the 1,3-isomer gave the highest percent of ethylbenzene (3.2% compared to 0,2% from the 1,1-isomer and 2.6% from the 1,2-isomer). The carbonium ion processes outlined in paths (a) to (e) of Scheme 1, illustrate diagramatically how toluene, ethylbenzene, isopropylbenzene and *n*-propylbenzene can be produced from 1,1-, 1,2- and 1,3-diphenylbutane through a series of various rearrangement and fragmentation reactions.

On the basis of path (b) of Scheme 1, one would expect 1,2-diphenylbutane to yield equal amounts of toluene and *n*-propylbenzene if not more of the former. The fact that toluene was obtained in much smaller amounts from the fragmentation of 1,1- and 1,2-diphenylbutane leads one to believe that path (a) could be the operable one. The detection of small amounts of diphenylmethane can be attributed to either path (e) or path (a) since in the latter the benzyl carbonium ion produced can alkylate benzene giving rise to diphenylmethane.[4]

In the fragmentation of 1,3-diphenylbutane according to paths (c) and (d), one would predict the rate of production of ethylbenzene to be roughly twice that of isopropylbenzene because the two primary carbonium ions involved are expected to be equally stable. This is in accordance with the experimental results obtained since the results of Table 5 show that the ratio of ethylbenzene to isopropylbenzene roughly amounts to 2 : 1.

Considering the significant differences in the fragmentation products obtained from the various diphenylbutanes, one can offer three generalizations that are helpful in explaining the distribution of fragmentation products in all of the compounds studied. First, cleavages which produce the most stable carbonium ions are always favoured. Secondly, under the conditions used, cleavages of the alkyl moieties may occur

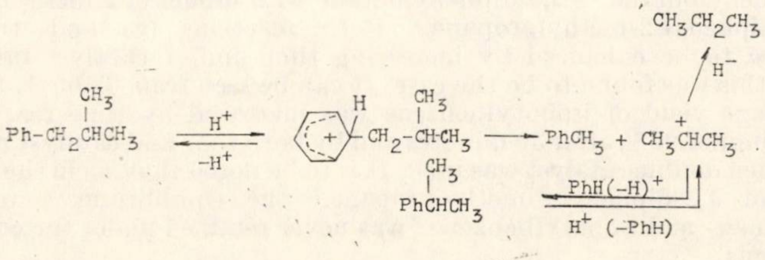
Scheme

Scheme 1

before isomerisations of diphenylbutanes, but rates of cleavages and isomerisations are of the same order. Thirdly, whereas diphenylbutanes are the major source of the fragmentation products, two other minor sources are worthy of note: (i) Cleavage of the butylbenzenes resulting from dephenylation of the starting diphenylbutanes as is exemplified by fragmentation of isobutylbenzene to toluene and isopropyl carbonium ion, the latter giving propane or isopropylbenzene as shown in Scheme 2



Scheme 2

(ii) Some of the fragmentation products could arise from the cleavage of the bimolecular reaction products. For example, the mechanism previously proposed [3] to account for the occurrence of isopentane in the gaseous products can also account for the presence of the fragmentation product, isopropylbenzene. Again, the bimolecular products, 1,2,3-trimethyl-1-ethylindan which is known [5,6] to result from the dimerisation of $Ph\overset{+}{C}(CH_3)C_2H_5$ and whose presence in the reaction mixture is highly likely can also contribute to the fragmentation process. In fact, as can be seen from Table 5, when a mixture consisting chiefly of the latter indan [5,6] was subjected to the fragmentation procedure it gave results quite similar to those obtained from 2,2-diphenylbutane under identical conditions.

So far in our discussion we have been primarily concerned with the fragmentation behaviour of the diphenylbutanes under consideration. As to the dealkylation behaviour, it can be seen from the results that, similar to other diphenylalkanes [2,3] both liquid and gaseous dealkylation products were produced. While 1,1-, 1,2- and 1,3-diphenylbutane, which contain one benzene ring in the 1-position, yielded almost exclusively *n*-butilbenzene mixed with negligible amounts of *sec*- and/or isobutylbenzene, 2,2-diphenylbutane with the two phenyl groups attached to the 2-position gave *sec*-butylbenzene mixed with varying amounts of *i*-butylbenzene depending upon the conditions employed. The formation of *n*-butylbenzene can be attributed to dephenylations at the 1-, 2- and 3-positions in the cases of 1,1-, 1,2- and 1,3-diphenylbutane, respectively.

---

[5] A. A. Khalaf and R. M. Roberts, *J. Org. Chem.*, **31**, 926 (1966).

[6] This was obtained by treating 2-chloro-2-phenylbutane with $AlCl_3$ in benzene. Also obtained by the reaction of 2-phenyl-2-butene with concentrated sulphuric acid in benzene.[5]

Similarly, the formation of *sec*-butylbenzene from 2,2-diphenylbutane can be attributed to direct dephenylation at the 2-position of the starting 2,2-isomer as well as to dephenylation of the 2,3-diphenylbutane produced by rearrangement therefrom.[2] The formation of considerable amounts of isobutylbenzene in the case of the 2,2-isomer can be attributed to two types of reactions : (a) rearrangement of the primarily formed *sec*-butylbenzene [7] and (b) dephenylation of 1,1- and 1,2-diphenyl-2-methylpropane produced by rearrangement through the previously established sequence : 2,2-diphenylbutane → 2,3-diphenylbutane→1,2-diphenyl-2-methylpropane → 1,1-diphenyl-2-methylpropane.[2] Both reactions (a) and (b) were expected to be enhanced by increasing time and/or catalyst ratio, and indeed this was found to be the case. It can be seen from Table 1, that the percentage yield of isobutylbenzene was increased by time reaching an upper limit of 20 % after 30 minutes and by both time and catalyst reaching 25 % when double catalyst was used. It is to be noted that, as in the cases of 1,1- and 1,2-diphenyl-2-methylpropane,[3] the equilibrium composition between *sec*- and isobutylbenzene [7] was never retained under the employed conditions.

In regard to the gaseous products, it is evident from Tables 2, 4 and 6 that :

(a) Except for one experiment (i.e. 8 D), the major alkane from all of the diphenylbutane isomers was isobutane. Its formation can be attributed to rapid rearrangement of *n*- and *sec*-butylbenzene to *t*-butylbenzene followed by immediate dealkylation as suggested before to give isobutane and benzene.[1-3]

(b) Small amounts of the lower alkanes, ethane, propane and *n*-butane were produced in most cases. The only exception to this was the formation of *n*-butane as the major alkane when 1,1-diphenylbutane was treated with double catalyst (exp. 8 D, Table 4). The reason for this abnormal behaviour is not clear.

(c) Isopentane was produced in all cases and its amount was usually larger than that of *n*-butane.

As suggested before,[8] the formation of isopentane can be explained in terms of unsymmetrical cleavage of an octane isomer formed from addition of *t*-butylcarbonium ion to isobutylene followed by hydride exchange.

EXPERIMENTAL

Analytical Procedures : These were similar to those described before.[3]

Starting Diphenylbutanes : These were prepared by the methods outlined in our previous publications.[1, 5]

Treatments of Diphenylbutanes with Water-activated $AlCl_3$ at 100° : These were carried out using the apparatus and the general procedure described before.[3]

2,2-Diphenylbutane :

Experiments 1C — 7C : 2,2-Diphenylbutane, 10.5 g (0.05 mole), was treated with 2.2 g (0.017 mole) of aluminium chloride and 0.15 ml (0.008 mole) of water at 100° for 5, 10, 15, 30, 60, 120 and 180 min in experiments 1C — 7C, respectively.

[8] R. M. Roberts and A. A. Khalaf, Part III of this series, *Rev. Roumaine Chim.*, **18**, 1929 (1973).

Experiment 8C : 2,2-Diphenylbutane, 10.5 g. (0.050 mole), was treated with 4.4 g (0.033 mole) of aluminum chloride and 0.3 ml (0.017 mole) of water at 100° for three hours.

The results for experiments 1C–8C are given in Tables 1 and 2 in the discussion section and Table 7 in this section.

Table 7

Distillation of the liquid products obtained from 2,2-diphenylbutane by treatment with $AlCl_3$ at 100°

Experiment N°	Distillation data, Weight, g.			
	Benzene	b.p. 81–168°	b.p. 168–176°	Residue[a]
1C	2.60	0.20	1.35	4.80
2C	2.83	0.30	1.36	4.95
3C	2.41	0.33	1.34	5.00
4C	2.40	0.40	1.47	5.00
5C	1.99	0.46	1.74	5.30
6C	1.89	0.76	1.80	5.00
7C	1.90	1.00	1.30	4.90
8C	2.82	0.72	1.00	5.30

[a] Contained *dl*- and *meso*-2,3-diphenylbutane and 1,2-diphenyl-2-methylpropane.

1,1-Diphenylbutane :

Experiments 1D–7D : 1,1-Diphenylbutane, 15.75 g (0.075 mole), was treated with 3.3 g (0.025 mole) of aluminum chloride and 0.225 ml (0.0125 mole) of water at 100° for 5, 10, 15, 30, 60, 120 and 180 min in experiments 1D–7D, respectively.

Experiment 8D : 1,1-Diphenylbutane, 5.25 g (0.025 mole), was treated with 1.1 g (0.008 mole) of aluminum chloride and 0.075 ml (0.004 mole) of water for two hours at 100°. In this experiment the speed of the magnetic stirring apparatus was double that used in experiments 1D–7D. At this point, the gaseous products were collected and analysed. The reaction flask was cooled and contents were treated with 1.1 g (0.008 mole) of aluminum chloride and 0.075 ml (0.004 mole) of water at 100° for three hours.

The results obtained for experiments 1D–8D are given in Tables 3 and 4 in the discussion section and Table 8 in this section.

6D	3.82	2.79	7.51
7D	3.95	2.92	8.50
8D	Crude mixture weighed 3.9 g.		

[a] Contained some 1,2- and 1,3-diphenylbutane as well as trace amounts of diphenylmethane.

1,2-Diphenylbutane :

1,2-Diphenylbutane, 10.5 g (0.05 mole) ,was treated with 2.2 g (0.017 mole) of aluminum chloride and 0.15 ml (0.008 mole) of water at 100° for 10 and 120 min. The results of these two experiments are given in Tables 5 and 6 in the discussion section and Table 9 in this section.

Table 9

Distillation of liquid products obtained from 1,2-diphenylbutane, 1,3-diphenylbutane and 1,2,3-trimethyl-1-ethyl-3-phenylindan by treatment with $AlCl_3$ at 100°

Compound	Distillation data, Weight, g				
	Benzene	b.p., 85−176°		b.p., 176−184°	Residue
1,2-Diphenylbutane	0.50		0.60		6.90
1,2-Diphenylbutane	0.70	0.20		1.00	5.60
1,3-Diphenylbutane	0.15		0.30		3.50
1,3-Diphenylbutane	1.30		2.40		3.30
Indan mixture	0.40	1.27			8.76

1,3-Diphenylbutane :

This was treated with aluminum chloride at 100° for 10 and 120 min. In the ten-minute experiment, the amounts of reactants were 5.2 g (0.025 mole) of the hydrocarbon, 1.1 g (0.008 mole) of aluminum chloride and 0.075 ml (0.004 mole) of water. In the two-hour experiment the amounts were 10.5 g (0.05 mole) of 1,3-diphenylbutane, 2.2 g (0.017 mole) of aluminum chloride and 0.15 ml (0.008 mole) of water. The results are given in Tables 5, 6 and 9.

1,2,3-Trimethyl-1-ethyl-3-phenylindan [6] :

The mixture containing this indan, 13.2 g (0.05 mole), was treated with 2.2 g (0.017 mole) of aluminum chloride and 0.15 ml and 0.15 ml (0.008 mole) of water at 100° for two hours. The results of this treatment are given in Tables 5, 6 and 9.

MODERN FRIEDEL-CRAFTS CHEMISTRY. VII [1]

ON THE QUESTION OF GROUP PARTICIPATION IN THE RATE-DETERMINING IONIZATION STEP DURING INTER- AND INTRAMOLECULAR FRIEDEL-CRAFTS ALKYLATIONS AND THE MECHANISM OF FORMATION OF 1-METHYLTETRALIN DURING THE $AlCl_3$-CATALYZED REACTION OF 1-CHLORO-2-METHYL-4-PHENYLBUTANE*

ALI ALI KHALAF
Chemistry Department, Assiut University, Assiut, Arab Republic of Egypt

Received November 13, 1973

The following halo and dihalo-compounds were prepared by unequivocal methods: 1,2-dibromo-2-methylpropane (isobutylene dibromide, 8 : X = Br), 1-chloro-2-methyl-2-phenylpropane (neophyl chloride, 9, X = Cl), 1-chloro-4-phenylbutane (12), 1-chloro-2-methyl-4-phenylbutane (13) and 1-chloro-2-methyl-4-p-tolybutane (14). The intramolecular alkylations of the last three chlorides (12, 13, and 14) and the intermolecular alkylations of benzene with the first two halides (8 and 9) as well as with *n*-propyl and *n*-butyl chlorides were investigated in the presence of the mild $AlCl_3/CH_3NO_2$ catalyst. The relative rates of these inter- and intramolecular reactions clearly demonstrated the occurrence of varying degrees of group participation during the rate determining ionization step in which the halide ion is removed. As regards variation in the extent of participation with the location of the aryl group relative to the halogen atom, the relative rates observed indicate that the sequence in β-aryl > δ-aryl > γ-aryl. This sequence correlates nicely with that observed previously for similar solvolytic reactions. Apart from the forthgoing findings, the results of this work also led to a new mechanism for the formation of 1-methyltetralin during the $AlCl_3$-catalyzed reaction of 1-chloro-2-methyl-4-phenyl-butane.

INTRODUCTION

It is very well established that many carbonium ion reactions are acclerated by neighbouring group participation. Such reactions are sometimes said to be anchimerically[2] assisted [3,4] as they proceed through an "internally attached form" of the involved substrate.[2,3,4] The results of many studies have shown that anchimeric assistance may involve participation by different groups such as aryl, alkyl, alkoxyl, aryloxyl, carboxyl, carbo-alkyoxyl, amino, alkylamino, dialkylamino, mercapto, thioalkyl, thioaryl and carboxylate anion or by single atoms such as hydrogen and the halogens.[5]

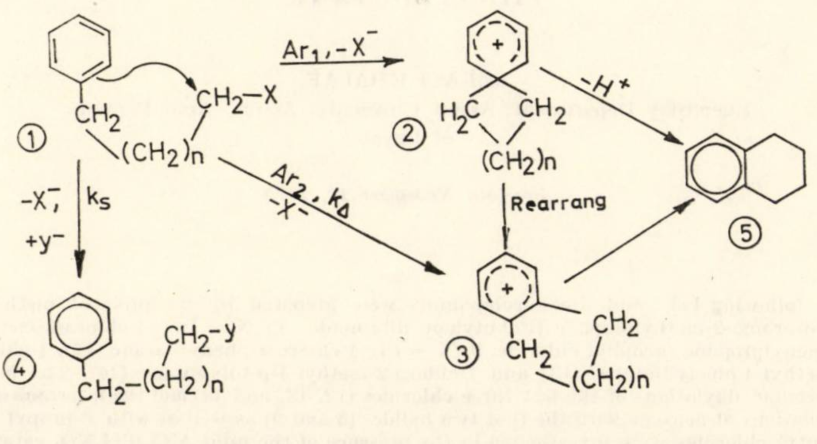
[4] S. Winstein and K. C. Schreiber, *J. Amer. Chem. Soc.*, **74**, 2171 (1952).

For many years it has been proposed that aryl participation plays a determining role during the solvolysis of β-arylalkyl systems.[6] Moreover, participation by aryl groups located at positions more distant than *beta* has also been shown to occur.[7] Examples of such participation are Ar_1-5 and Ar_2-6, illustrated schematically in Scheme 1, by the conversion of 1 to 2 and 3 ($n = 2$), respectively.[8]

Scheme 1



In systems of the type shown in Scheme 1, analysis of solvolytic reactions led to two important conclusions: First,[6a] there are two competing paths for displacement of the leaving group, which are designated as k_Δ and k_s. These paths are simultaneous reactions, each with its own characteristics, and there is no cross-over between them. The k_Δ path involves aryl participation as the leaving group leaves giving a nonclassical ion and this accounts for scrambling of the two carbons of the ethyl side chain in β-arylethyl systems [9] and for the formation of tetralin derivatives in δ-arylbutyl systems.[7] The k_s path involves direct S_N2 displacement of the leaving group by nucleophiles. Secondly, as regards variation of K_Δ in Ar_1-n participation with the size of the ring being formed in the intermediate spiro-carbonium ion, 2, the observed rate sequence is 3 (i.e. $n = 0) \gg 4$ (i.e. $n = 1) \ll 5$ (i.e. $n = 3) \gg 6$ (i.e. $n = 2$).[7]

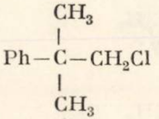
[5] For reviews of this subject, see (a) S. WINSTEIN, *Bull. Soc. chim. France*, **18**, C-55 (1951); (b) A. STREITWIESER, JR., *Chem. Revs.*, **56**, 675 (1956); (c) A. STREITWIESER, JR., "Solvolytic Displacement Reactions", McGraw-Hill Book Co., Inc., Nes York, N. Y., 1962.

[6] For example see the following recent references and the older references listed therein: a) M. G. JONES and J. L. COKE, *J. Amer. Chem. Soc.*, **91**, 4284 (1969); b) C. J. KIM and H. C. BROWN, *J. Amer. Chem. Soc.*, **91**, 4289 (1969); c) P. VON R. SCHLEYER, *J. Amer. Chem. Soc.*, **91**, 4297 (1969); d) A. F. DIAZ and S. WINSTEIN, *J. Amer. Chem. Soc.*, **91**, 4300 (1969), e) R. J. JABLONSKI and E. I. SNYDER, *J. Amer. Chem. Soc.*, **91**, 4445 (1969).

[7] a) R. HECK and S. WINSTEIN, *J. Amer. Chem. Soc.*, **79**, 3105 (1957); b) R. HECK and S. WINSTEIN, *J. Amer. Chem. Soc.*, **79**, 3114 (1957).

[8] S. WINSTEIN and his collaborators[7] has adopted a notation in which participation of a β-phenyl group is symbolized Ar_1-3. According to these authors, the general notation is Ar_a-n, where Ar denotes aryl and the subscript a refers to the position in the participating aryl group involved in the creation of the ring in the transition state for anchimerically assisted ionization. The size of the ring being made is indicated by the number n.

Gould [10] has pointed out that there are three principal types of evidence that point to neighbouring group participation. These are based on stereochemical changes, molecular rearrangements and relative rates. According to the latter evidence, if aryl participation occurs during the rate-determining step in a given reaction, the reaction is almost certain to be significantly more rapid than other reactions that are similar but do not involve such participation. It may then be asked whether the last criterion for neighbouring group participation, namely, the enhancement of reaction rate, is also applicable to cases involving inter- and intramolecular Friedel-Crafts alkylations. For this reason, the relative rates of intramolecular alkylations (cyclialkylations) of chlorides 12, 13 and 14, and of intermolecular alkylations of benzene with 1-chloro-2-methyl-2-phenylpropane (neophyl chloride, 9), n-propyl chloride and n-butyl chloride were investigated in the presence of the mild $AlCl_3/CH_3NO_2$ catalyst and the results obtained were correlated with anticipated participations

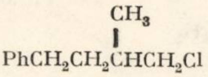


$$Ph-\underset{CH_3}{\overset{CH_3}{C}}-CH_2Cl$$

9

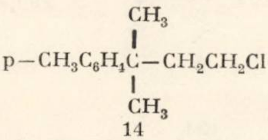
$Ph-CH_2CH_2CH_2CH_2Cl$

12



$$PhCH_2CH_2\overset{CH_3}{C}HCH_2Cl$$

13



$$p-CH_3C_6H_4\underset{CH_3}{\overset{CH_3}{C}}-CH_2CH_2Cl$$

14

Understandably, arylalkyl chlorides, 9, 12, 13 and 14 were specifically chosen because they offer good models wherein there exists the possibility for the following : a) a combination of β-phenyl and β-dimethyl participations in the reaction of chloride 9, (b) δ-phenyl participation in the reaction of chloride 12, (c) a combination of δ-phenyl and β-methyl participations in the reaction of chloride 13, (d) a combination of γ-p-tolyl and γ-dimethyl participations in the reaction of chloride 14.

RESULTS AND DISCUSSION

As Friedel-Crafts alkylations with the strong $AlCl_3$ catalyst are known to be rapid,[11] it seemed advisable to attempt the study of the relative rates of the concerned inter- and intramolecular alkylations in the presence of the moderated $AlCl_3/CH_3NO_2$ catalyst. This catalyst which is known to induce both inter-[12,13] and intramolecular[14] Friedel-Crafts alkylations with tertiary,[12] secondary[12c,13a] and benzylic[13b] type halides, can induce the reactions of ordinary primary halides only if they involve participation by aryl and/or alkyl groups.[12c,15,16] Illustration of these facts about the catalytic abilities of $AlCl_3/CH_3NO_2$ can be found in the finding that reaction of 1,3-dichloro-3-methylbutane (6) with benzene in the presence of $AlCl_3/CH_3NO_2$ gave 1-chloro-3-methyl-3-phenylbutane (7) and no diphenyl[15] while treatment of either 1,2-dibromo-2-methylpropane (8, $X = Br$) or 1-chloro-2-methyl-2-phenylpropane (neophyl chloride, 9, $X = Cl$) under the same conditions yielded a mixture of the two isomeric diphenyl propanes 10 and 11 (see Scheme 2).[15,16]

The failure of alkylation to occur at the primary carbon atom in 7, whereas it occurred readily in the reaction of 9 under the same experimental conditions, has strongly suggested phenyl participation as a deriving force in the case of halide 9.[15,16]

It appears from the previous discussion that the use of $AlCl_3/CH_3NO_2$ as catalyst is advantageous for the present purpose not only because it is milder and in general effects isomerizations to a lesser extent than does aluminum chloride alone,[17] but also because it offers a simple test for the occurrence and extent of group participation.

With the above essential background in mind, it is now suitable to look at the results of treatment of the chlorides : 1-chloro-2-methyl-2-phenylpropane (neophyl chloride, 9, X = Cl), 1-chloro-4-phenylbutane (12), 1-chloro-2-methyl-4-phenylbutane (13) and 1-chloro-3-methyl-3-p-tolybutane (14) with $AlCl_3/CH_3NO_2$ catalyst. In this work, chlorides 12, 13 and 14 were treated with the mild $AlCl_3/CH_3NO_2$ catalyst and the samples taken from the reaction mixtures after varying time intervals were decomposed and analysed by vapour-phase chromatography. The results obtained from 1-chloro-4-phenylbutane (12) and 1-chloro-2-methyl-4-phenyl-butane (13) are summarized in Tables 1 and 2, respectively. These are also shown graphically in Figure 1. Treatment of 1-chloro-3-methyl-3-p-tolylbutane (14) with $AlCl_3/CH_3NO_2$ under similar conditions resulted in inappreciable reaction, however.

[17] L. Schmerling, *Ind. Eng. Chem.*, **40**, 2072 (1948).

Examination of the results given in Tables 1 and 2 and the slopes of the curves drawn in Fig. 1 indicates clearly that the reaction of 1-chloro-2-methyl-4-phenylbutane (13) is much faster than that of 1-chloro-4-phenylbutane (14). The simplest and most ominous explanation for this result lies in the fact that the removal of the chloride ion from 1-chloro-2-methyl-4-phenylbutane (13) is assisted by both β-methyl and δ-phenyl participations while the removal of the chloride ion from 1-chloro-4-phenylbutane (12) is assisted solely by δ-phenyl participation. The failure of 1-chloro-3-methyl-3-p-tolylbutane (14) to undergo any significant reaction in the presence of the weak catalyst $AlCl_3/CH_3NO_2$ under conditions similar to those effecting intramolecular alkylations of chlorides 12 and 13 reveals that no appreciable incursion of γ-phenyl participation in the rate-determining ionization step is indicated for the γ-phenyl chloride examined. Apart from that, the behaviour of chloride 14 is in line with the known fact that primary closure to a five-membered ring is highly unfavourable.[11a,18–21]

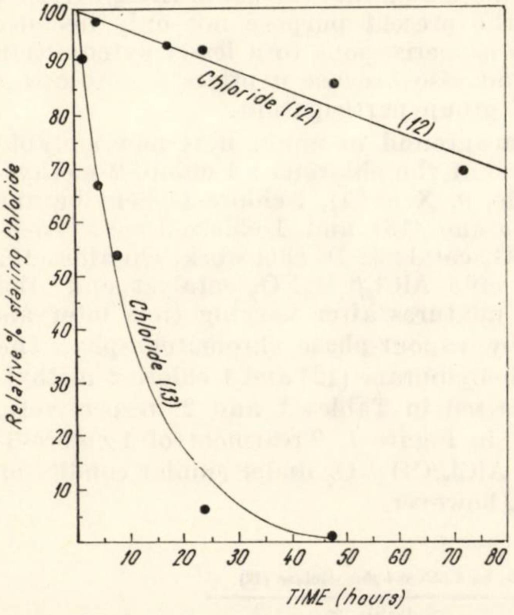

Fig. 1. — Rates of reaction of 1-chloro-4-phenylbutane (12) and 1-chloro-2-methyl-4-phenylbutane (13) with $AlCl_3/CH_3NO_2$ at room temperature; data are taken from Tables 1 and 2.

It may be of interest to indicate at this point that the difficulty of reaction of chloride 14 with the weak catalyst $AlCl_3/CH_3NO_2$ is parallel to that previously observed[17] in the reaction of *n*-propyl chloride with benzene and $AlCl_3/i{-}C_3H_7NO_2$. In the latter case a 4% yield of isopropylbenzene was only isolated after conducting the reaction for 18 hours at room temperature and for an additional hour at 60° to 70°C. This analogy in the behaviour of the primary arylalkyl chloride 14 and the primary *n*-propyl chloride again signifies that similar to the latter, the ionization of the former chloride is also unchimerically unassisted. Further support for this view was also obtained in this work when preliminary attempted alkylations of benzene with either *n*-propyl chloride or *n*-butyl

chloride in the presence of the weak $AlCl_3/CH_3NO_2$ catalyst at room temperature failed to yield any alkylation products. These results indicate that, similar to intramolecular γ-participations, intermolecular participations are also inappreciable in the course of Friedel-Crafts alkylations.

To compare the relative rates of reactions of primary halides involving γ-aryl or δ-aryl participation with those involving neighbouring β-aryl participation, it seemed desirable to investigate the relative rate of reaction of a compound such as 1-chloro-2-methyl-2-phenylpropane (neophyl chloride) under the influence of the moderated $AlCl_3/CH_3NO_2$ catalyst. Since this chloride cannot undergo intramolecular alkylation, its reaction with benzene was rather studied. To carry this intermolecular reaction under conditions resembling those used for the other chlorides, a solution of neophyl chloride in benzene was added at once to a stirred solution of the catalyst in carbon disulfide. In contrast to the cases of chlorides 12, 13 and 14 a relatively rapid evolution of hydrogen chloride was noted and the reaction was shown to be completed in about an hour. Analysis of the product mixture obtained from this reaction after one hour using various methods of identification showed it to be a mixture of 1,2-diphenyl-2-methyl-propane (10) and 1,1-diphenyl-2-methyl-propane (11) in a ratio of about 2 : 1 with none of the starting material remaining. A similar result was also obtained when 1,2-dibromo-2-methylpropane was allowed to react with benzene under comparable conditions. Notably, the products from benzene alkylation with both neophyl chloride and isobutylene dibromide in the presence of $AlCl_3/CH_3NO_2$ are similar to those reported before [16] and expressed structurally in Scheme 2.

The above observations of the enhanced alkylation of benzene with both neophyl chloride and isobutylene dibromide, coupled with the finding that Friedel-Crafts alkylation of aromatics with 2-phenylethyl-1-C^{14} chloride not only occurs rapidly but also results in products which show isotope position rearrangement corresponding to an essentially 50% rearrangement of the C^{14} labeled atom from the C−1 to the C−2 position in the original chloride [22] demonstrate clearly that the ionization of the halogen atom in β-arylalkyl halides is easier and comparatively faster than in γ- and in δ-arylalkyl halides.

In conclusion, it appears from the forthgoing results of this work that, similar to solvolytic reactions, the ionization of arylalkyl halides under Friedel-Crafts conditions is assisted, to a varying degree, by aryl participation depending upon the location of the aryl group relative to the halogen atom. As regards variation in the extent of participation with the distance of the aryl group from the reaction site, the observed relative rates for chlorides 9, 12, 13 and 14 shows that the sequence is β-aryl $>$ $>$ δ-aryl $>$ γ-aryl. It cannot be concluded on the basis of this work, however, whether the types of participation involved in the ionization of the δ-arylalkyl halides is of the Ar_1—5 (Structure 22) or the Ar_2—6 (Structure 23) type or a combination of both types. Nevertheless, it has been pointed out by Heck and Winstein [7b] that Ar_1-5- and Ar_2-6- assisted

ionizations have nearly equal rates for equivalent degrees of activation of the benzene ring. In this laboratory, further work is being conducted to cast some light on the type or types of participation that may be involved under Friedel-Crafts conditions.

Mechanism of Formation of 1-Methyltetralin During the $AlCl_3$-Catalyzed Reaction of 1-Chloro-2-methyl-4-phenylbutane (13)

Apart from its main objectives in this study, the $AlCl_3/CH_3NO_2$-catalyzed Friedel-Crafts intramolecular alkylation (cyclialkylation) of 1-chloro-2-methyl-4-phenylbutane (13) has also provided a very interesting piece of information which is worthy of mention. In this work, treatment of chloride 13 with the mild $AlCl_3/CH_3NO_2$ catalyst gave a mixture of 2-methyltetralin and 1,1-dimethylindan. Previously, however, the treatment of chloride 13 with the strong $AlCl_3$ catalyst was shown by Khalaf and Roberts [11a] to give a more complex mixture consisting of the cyclization product 1,1-dimethylindan (15), 1-methyltetralin (16) and 2-methyltetralin and of the hydride exchange product isopentylbenzene (17). While the cyclization product, 2-methyltetralin was the major component from reactions conducted in carbon disulfide solvent, the hydride exchange product, isopentylbenzene, was the major product in the hydrocarbon solvent, petroleum ether. The results from the $AlCl_3$-catalyzed reaction of chloride 13 was explained by the authors in terms of Scheme 3.

The fact that 1-methyltetralin (16) was produced in the reaction of 1-chloro-2-methyl-4-phenylbutane (13) in the presence of $AlCl_3$ but not in the presence of $AlCl_3/CH_3NO_2$ is significant as it has some bearing on the mode of formation of 16. The formation of 16 from 13 in the presence of $AlCl_3$ was suggested by Khalaf and Roberts [11a] to follow the route 19 → 20 → 21 → 16 as shown in Scheme 3. On the basis of the present results, this route can be disqualified as if it is the operable one, it should be possible to obtain 1-methyltetralin regardless of the type of catalyst initiating the reaction. This is because carbonium ion 19 (or its equivalent) would always be present whether the catalysts is $AlCl_3$ or $AlCl_3/CH_3NO_2$. An alternative plausible mechanism for the formation of 1-methyltetralin during the $AlCl_3$-catalyzed reaction of chloride 13 is offered in Scheme 4.

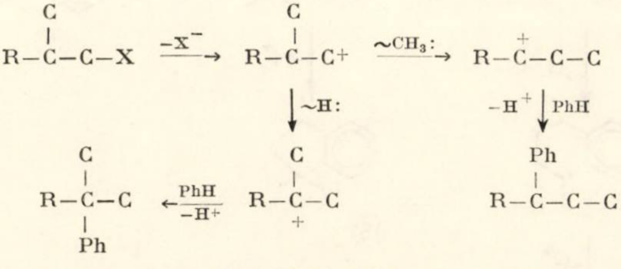
According to the above mechanism, the primarily formed 2-methyltetralin is subsequently isomerized to 1-methyltetralin via the route 18 → → 24 → 25 → 16. The abstraction of a hydride ion from 18 to produce 24 can only occur in the presence of the strong $AlCl_3$ catalyst.[12,14,16–19,21]

Experimental credence to the mechanism of Scheme 4 can be found in the recently reported transformation of 1,1-dimethyltetralin to 2,2-dimethyltetralin in the presence of $AlCl_3$.[21] Scheme 4 is also in agreement with the fact that alkylations of benzene with 1-halo-2-methylalkanes such as isobutyl halides [23] or 1-chloro-2-methylbutane [12c] do not yield products resulting from methyl migration as illustrated in Scheme 5.

Scheme 5



R = CH_3 or C_2H_5

As to the formation of 1,1-dimethylindan from chloride 13, it is evident from Table 2 that this product was usually produced in a percent ratio somewhat greater than that of 2-methyltetralin. It can be inferred from this finding that tertiary closure to a five-membered ring is somewhat favoured over primary closure to a six-membered ring.

EXPERIMENTAL

ANALYTICAL PROCEDURES

The infrared spectra (ir) were done using either a Pye Unicam Sp 200G Grating IR Spectrophotometer or a Beckman IR–5A Spectrophotometer. A varian A 60 spectrometer was used for nuclear magnetic resonance analysis (nmr). Vapour-phase chromatographic analysis (vpc) were carried out using either a Pye Series 104 Chromatograph or a Becman GC–2A instrument. The columns used were: a) 12-ft., 30% silicone gum rubber SE-30; b) 12 ft., 15% Bentone-34, c) 12-ft., 20% DEGA, d) 5-ft., 3% PEGA; e) 5-ft., 3% DNP.

SYNTHESIS OF STARTING MATERIALS AND FINAL PRODUCTS

Of the required materials, the following compounds were either available from previous work or were synthesized according to the procedures described in the references indicated: 1,2-dibromo-2-methylpropane (8; X = Br) [16]; 1-chloro-2-methyl-2-phenylpropane (9; X = = Cl)[16]; 1,2-diphenyl-2-methylpropane (10)[16]; 1,1-diphenyl-2-methylpropane (11)[16]; tetralin [11a]; 1,1-dimethylindan (15),[11a] 1-methyltetralin (16) [11a]; isopentylbenzene (17),[11a] 2-methyltetralin (18).[11a] The rest of the required materials were prepared as described below.

[23] R. M. Roberts and D. Shiengthong, *J. Amer. Chem. Soc.*, **82**, 732 (1960).

Synthesis of 1-chloro-4-phenylbutane (12):

Preparation of γ-chlorobutyrophenone: In a 250-ml roundbottomed flask equipped with a magnetic stirrer, a pressure-equalizing dropping funnel, and an efficient reflux condenser were placed 14.9 g (0.11 mole) of anhydrous $AlCl_3$, 18.3 g (0.3 mole) of nitromethane and 78 g (1 mole) of dry benzene, respectively.

A solution of 14.1 g (0.1 mole) of 4-chlorobutyryl chloride in 40 ml of dry benzene was placed in the dropping funnel and added over a period of one hour to the stirred solution in the flask. After addition was complete, the reaction mixture was stirred at room temperature for 2 hr and then decomposed by pouring over a 100 ml of cold 10% solution of hydrochloric acid. The organic layer was separated, washed with 10% sodium bicarbonate solution followed by water and finally dried for overnight over anhydrous sodium sulfate. Removal of the solvent under atmospheric pressure gave 14.5 g (75% yield) of γ-chlorobutyrophenone: b.p. 131–132° (4 mm); n_D^{25} 1.5528 lit.[24] b.p. 120–121° (3 mm); n_D^{20} 1.55433.

Reduction of γ-chlorobutyrophenone to 1-chloro-4-phenylbutane (12): This was accomplished catalytically using 9.1 g (0.05 mol) of γ-chlorobutyrophenone, 30 ml of glacial acetic acid, 0.5 ml of perchloric acid and 2 g of 5% palladium on carbon with an initial pressure of 65 psi.[25] When the required amount of hydrogen was consumed, the reaction mixture was removed from the apparatus. The catalyst was filtered off with a sintered glass crucible and discarded. The filtrate was diluted with water and extracted with petroleum ether (b.p. 60–80°) which was then washed with water followed by dilute sodium bicarbonate solution and finally dried over anhydrous sodium sulfate. Removal of the solvent and purification of the residue by distillation under vacuum gave 7.2 g (90% yield) of a colourless liquid whose physical and spectroscopic properties were identical with those published previously [11a] for 1-chloro-4-phenylbutane (12).

Synthesis of 1-chloro-2-methyl-4-phenylbutane (13):

Preparation of 2-Methyl-3-benzolylpropionic acid: 2-Methyl-3-benzoylpropionic acid was prepared by a modification of the procedure described previously.[11a] In a dry, one-liter, three-necked, round-bottomed flask fitted with a mechanical stirrer, a reflux condenser carrying a calcium chloride tube and a pressure-equalizing dropping funnel were placed 34.2 g (0.3 mol) of methylsuccinic anhydride (pyrotartaric anhydride) and 500 ml of dry thiophene--free benzene. A solution of 95 g (0.7 mol) of $AlCl_3$ in 183 g (3.0 mol) of nitromethane was added to the stirred contents of the flask. When addition was completed in 1.5 h, stirring was allowed to continue for two additional hours at room temperature and for half an hour at 60°. The reaction mixture was then decomposed with dilute hydrochloric acid and the organic layer was separated, washed with water and dried over anhydrous sodium sulfate. Evaporation of the organic solvent with gentle heating under suction left a solid residue which on crystallization from carbon tetrachloride gave 46 g (80% yield) of 2-methyl-3-benzoylpropionic acid: m.p. 141–142°. Reported m.p.: 140.5° by Oppenheim [26], 139–140° by Alexander and Mudrak [27] and 139 by Khalaf and Roberts.[11a]

Reduction of 2-Methyl-3-benzoylpropionic Acid to 2-Methyl-4-phenylbutyric Acid: This reduction was accomplished catalytically following essentially the procedure previously described [25] for the reduction of γ-chlorobutyrophenone to 1-chloro-4-phenylbutane with the exception that only water was used to wash the petroleum ether extract. Starting with 38.4 g (0.2 mol) of 2-methyl-3-benzoylpropionic acid, 100 ml of glacial acetic acid, 0.5 ml of 70% perchloric acid and 3 g of 5% palladium on charcoal gave 32 g (90% yield) of 2-methyl-4-phenylbutyric acid: b.p. 178–180° (18 mm) [lit. b.p. 176–178° (17 mm) [28] and 175–178° (16 mm) [11a]].

Conversion of 2-Methyl-4-phenylbutyric acid to 1-Chloro-2-methyl-4-phenylbutane (13): This conversion followed essentially the reported method.[11a] Accordingly, 2-methyl-4-phenylbutyric acid was reduced by lithium aluminum hydride [29] to 1-hydroxy-2-methyl-4-phenylbutane which upon treatment with thionyl chloride in pyridine [30] gave the desired 1-chloro-2-methyl-4-phenylbutane: b.p.: 136–138° (20 mm); n_D^{24} 1.5126 [lit.[11a] b.p. 134–135° (19 mm) and 100–101° (5 mm); n_D^{25} 1.5123]. The overall yield of the chloride was 68% based on the starting acid.

Synthesis of 1-Chloro-3-methyl-3-p-tolylbutane (14):

This was carried out as previously described by this author.[31]

ALKYLATION PROCEDURES

In all alkylations the apparatus used was a 50-ml, two-necked, round-bottomed flask fitted with a reflux condenser, a pressure-equalizing dropping funnel and a stirring magnet. A calcium chloride tube was also attached to the top of the condenser.

(a) *Intermolecular Alkylation of Benzene with 1,2-Dibromo-2-methylpropane (Isobutylene Dibromide) and 1-Chloro-2-methyl-2-phenylpropane (Neophyl Chloride), Using $AlCl_3/CH_3NO_2$ as Catalyst*: A solution of 0.66 g (0.05 mole) of $AlCl_3$ in 1.5 ml of CH_3NO_2 was introduced into the flask followed by 50 ml of CS_2. To the stirred contents of the flask was added rapidly through the dropping funnel a solution of 0.025 mole of the halide (1.2 g of neophyl chloride and 1.4 g of isobutylene dibromide) in 20.4 g (0.256 mole) of dry benzene. After one hour, the reaction mixture was decomposed by the addition of dilute hydrochloric acid and the organic layer was separated, washed, dried and analysed by vpc. The products from both chlorides were found to be mixtures of 63–67% 1,2-diphenyl-2-methylpropane and 37–33% 1,1,-diphenyl-2-methylpropane with none of the starting halides present.

(b) *Intramolecular Alkylation (Cyclialkylation) of 1-Chloro-4-phenylbutane (12), 1-Chloro-2-methyl-4-phenylbutane (13) and 1-Chloro-3-methyl-3-p-tolylbutane Using $AlCl_3/CH_3NO_2$ as Catalyst*: To a solution of 1.6 g of $AlCl_3$ in 3 ml of CH_3NO_2 was added at once a solution of 2.2 g of the chloride in 10 ml of CS_2 and the resulting reaction mixture was stirred while 0.1 ml samples were taken after varying time intervals and decomposed by rapid introduction into marked small vials containing dilute HCl. The organic layers resulting after decomposition were dried and analysed by vpc. The results obtained for chlorides 12 and 13 are embedded in Tables 1 and 2, respectively. Chloride 14 showed no appreciable reaction under the employed conditions, however.

MODERN FRIEDEL-CRAFTS CHEMISTRY. VIII*

CYCLIALKYLATIONS OF SOME ARYL- AND DIARYLALKANOLS IN THE PRESENCE OF THE MILD $AlCl_3/CH_3NO_2$ CATALYST**

ALI ALI KHALAF

Department of Chemistry, Assiut University, Assiut, Arab Republic of Egypt

Received November 13, 1973

Alcohols 1 through 18 were obtained and their cyclidehydrations were investigated in the presence of the mild $AlCl_3/CH_3NO_2$ catalyst at ambient temperature. Under these conditions, both secondary and tertiary alcohols underwent facile cyclialkylation to tetralins but only tertiary alcohols could be closed to indans. The products obtained from these reactions were exactly similar to those obtained before from cyclialkylations of the same alcohols with H_2SO_4 or of the corresponding chlorides with $AlCl_3/CH_3NO_2$. However, the yields of the cyclialkylation products obtained under present conditions were, in most cases, better than those reported from other cyclization procedures starting with either the alcohols or the corresponding chlorides. This, in addition to the fact that undesirable side reactions are often minimized under the employed conditions, make the $AlCl_3/CH_3NO_2$ catalyzed cyclidehydrations of secondary and tertiary alcohols a very convenient and efficient pathway for the synthesis of both indan and tetralin derivatives.

INTRODUCTION

For some time, this author has been engaged in a number of research studies relating to the mechanistic aspects and synthetic potentialities of Friedel-Crafts cyclialkylation reaction.[1-7] These studies together with the work of others[8] have shown that direct formation of indan and tetralin derivatives can be achieved through two main routes: First, intermolecular alkylation of aromatics with bifunctional alkylating agents including diols, dienes and dihaloalkanes as exemplified by the reactions of equations 1[9,10] and 2.[8d] Second, intramolecular alkylations of arylhaloalkanes as exemplified by the reactions of equations 3[1,2] and 4.[5] In most instants, the catalysts employed to bring about cyclization were

protonic-acids in reactions involving alcohols and alkenes but Lewis-acids in reactions involving halides. Very recently, the mild $FeCl_3$ and $AlCl_3$/ /CH_3NO_2 catalysts have been used extensively to effect cyclialkylations of secondary and tertiary arylhaloalkanes.[5,7] The application of such mild catalysts have been found to be superior to the strong $AlCl_3$ not only because they inhibit side carbonium ion processes but also because they give better yields of purer products.[7] A similar finding was also observed when some secondary and tertiary mono- and diphenylalkanols were cyclized in the presence of the mild $AlCl_3/CH_3NO_2$ catalyst.[5] Since the yields from these $AlCl_3/CH_3/NO_2$-catalyzed cyclialkylations of arylalkanols were as good as those obtained from similar reactions of the corresponding arylhaloalkanes, it seemed attractive to investigate more of these reactions in order to evaluate their usefulness and applicability in the synthesis of indan and tetralin derivatives. Understandably, the use of alcohols instead of the chlorides is preferable not only because it saves both the time and the effort needed to convert the alcohols to the chlorides, but also because it is more economical as it avoids the material loss which the conversion step necessitates. In the present work, a number of different mono- and diphenylalkanols were obtained and their cyclialkylations in the presence of $AlCl_3/CH_3NO_2$ were investigated.

RESULTS AND DISCUSSION

The primary : phenylalkanols 1 to 4 tolylalkanol 5 and diphenylalkanols 6 and 7, the secondary : phenylalkanols 8 to 11 and the tertiary : phenylalkanols 12 to 14, tolylalkanols 15 to 17 and diphenylalkanol 18 were subjected at room temperature to the action of $AlCl_3/$ $/CH_3NO_2$ catalyst in petroleum ether solvent. The results obtained are summarized in Table 1 and in equations 5 to 15.

From examining the results of this work (Table 1 and equations 5 through 15), one can reach the following conclusions regarding the cyclidehydration characteristics of mono- and diarylalkanols in the presence of the mild $AlCl_3/CH_3NO_2$ catalyst :

(1) The cyclidehydration of primary mono- and diarylalkanols cannot be effected with $AlCl_3/CH_3NO_2$ at ambient temperatures; the starting alcohols are recovered unchanged after hydrolysis.

(2) In contrast to primary mono- and diarylalkanols, secondary and tertiary mono- and diarylalkanols undergo facile cyclidehydration to tetralins either directly as in the cases of alcohols 9 and 13 (equations 6 and 10) or via rearrangement as in the cases of alcohols 10, 11 and 14 (equations 7, 8 and 11).

(3) With facilities comparable to those observed in cyclidehydrations of secondary and tertiary alcohols to tetralins, tertiary mono- and diarylalkanols undergo ring closures to indans (e.g. alcohols 12, 15, 16 and 17, equations 9, 12 ,13 and 14).

(4) In accordance with former findings,[1,2] secondary arylalkanols failed to cyclize to indans (e.g. alcohol 8; equation 5). As secondary arylalkanols have been shown to cyclize readily to tetralins, this noted failure cannot be attributed to a difficulty in ionizing the alcohol to the intermediate secondary carbonium ion (equation 5) but rather to a difficulty in closing this ion to an indan.[1,2,5,7]

(5) Similar to the previously reported cyclialkylations of secondary and tertiary alcohols with H_2SO_4[2,3] and of the corresponding secondary and tertiary chlorides with $AlCl_3/CH_3NO_2$ or $FeCl_3$[7] the cyclidehydration of secondary and tertiary alcohols with $AlCl_3/CH_3NO_2$ catalyst proceeds with none of the complicating side reactions which are known to accompany $AlCl_3$-catalyzed cyclialkylations.[1,5]

(6) The yields from the $AlCl_3/CH_3/NO_2$-catalyzed cyclidehydrations of alcohols 6 to 15 are, in most cases, better than those from the H_2SO_4-catalyzed cyclidehydration and, at least, as good as the yields from the $AlCl_3/CH_3NO_2$-catalyzed cyclialkylation of the corresponding chlorides.

Evaluation of the above findings, in terms of the motives that inspired this work, demonstrates clearly that the mild $AlCl_3/CH_3NO_2$ complex can be used to effect cyclidehydrations of both secondary and tertiary mono- and diarylalkanols. As this catalyst invariably produces good yields of clean cyclic products regardless of whether the starting material is the alcohol or the chloride, it is advantageous to start with the alcohol for reasons stated before in the introduction part.

Concerning the mechanism of interaction of the alcohols with the catalyst, it appears from the results that two distinct modes can be recognized. First, the interaction between primary alcohols and the catalyst which seems to involve the formation of aluminium trialkoxide as shown in equation 16. This proposed interaction

$$3\ RCH_2OH + AlCl_3 \rightarrow (RCH_2O)_3\,Al + 3\ HCl \qquad 16$$

is justified by two experimental observations: (a) the evolution of HCl gas upon the addition of alcohols to the catalyst, and (b) the recovery of the starting alcohols upon hydrolysis with water and that may occur as shown in equation 17.

$$(RCH_2O)_3Al + 3\,H_2O \rightarrow 3\,RCH_2OH + Al(OH)_3 \qquad 17$$

Second, the interaction between secondary and tertiary alcohols and the catalyst and that should be different from the case with primary alcohols. Accordingly, it is proposed that the initial step in the reaction with a

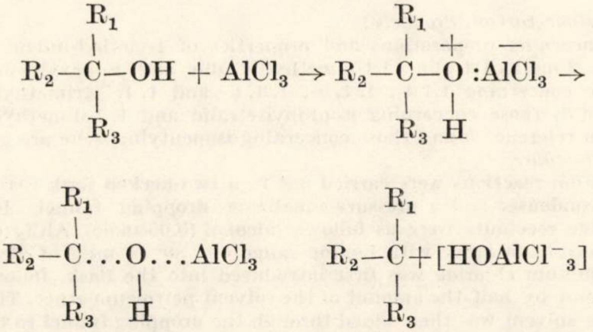
18	$PhCH_2CH_2CH(Ph)CH_2C(OH)(CH_3)_2$	82	1,1-Dimethyl-3-(B-phenylethyl) indan (100).

secondary or a tertiary alcohol is the combination of alcohol and aluminium chloride by a dative bond in which the unshared electrons of the alcohol complete the electron octet of the aluminum atom and that is followed by the formation of an alkyl cation as shown in equation 18. A similar proposition was placed before by Huston and Awuapara.[11]



$$R_2-\overset{R_1}{\underset{R_3}{C}}-OH + AlCl_3 \rightarrow R_2-\overset{R_1}{\underset{R_3}{C}}-\overset{+}{\underset{H}{O}}:\overset{-}{AlCl_3} \rightarrow \qquad 18$$

$$R_2-\overset{R_1}{\underset{R_3}{C}}\ldots\underset{H}{O}\ldots AlCl_3 \quad R_2-\overset{R_1}{\underset{R_3}{C}}{}^{+}[HOAlCl_3^-]$$

It can be seen from the above general equation that the function of the catalyst is to loosen or break the carbon-oxygen bond in the alcohol, thus making the resulting species more electrophilic and hence a more effective attacking reagent for the aromatic ring.[12] In the light of the above mechanistic proposals, the difference in behaviour between primary alcohols on the one side and secondary and tertiary alcohols on the other side is primarily due to differences expected in the stabilities of the carbonium ions that may result from the cleavage of the carbon-oxygen bond. As it is known that, in general, the secondary and tertiary carbonium ions are much more stable than the primary ones, one need not be surprised that the formation of the latter is rendered more difficult.

EXPERIMENTAL

Analytical Procedures:

These were the same as those described in the preceding paper.[13]

Syntheses of Starting Materials and Final Products:

As all of the starting materials and final products needed for this study were either available from previous work or prepared according to formerly detailed procedures, it appeared sufficient here to refer to papers in which the original synthetic procedures are given.

Starting Mono- and Diarylalkanols: For synthetic procedures and physical properties of these alcohols see the references given in the following: 3-Phenyl-1-propanol (1) [11]; 4-phenyl-1-butanol (2) [1]; 5-phenyl-1-pentanol (3)[8b]; 3-methyl-3-phenyl-1-butanol (4) [2]; 3-methyl-3-p-tolyl-1-butanol (5) [3]; the two diastereomers of 2-methyl-4,5-diphenyl-1-pentanol

Final Authentic Hydrocarbon Products:

Details concerning preparations and properties of 1-methyl-indan, 1,1-dimethylindan, 1-methyltetralin, 2-methyltetralin, 1,1-dimethyltetralin and isohexylbenzene are given in reference 1, those concerning 1,1,4-, 1, 1, 5-, 1, 1, 6- and 1, 1, 7-trimethylindan isomers are given in reference 3, those concerning isopropyltetralin and 1, 1-dimethyl-3-(β-phenylethyl)-indan are given in reference 5 and those concerning isopentylbenzene are given in reference.[16]

Cyclialkylation Procedure:

Cyclialkylation reactions were carried out in a two-necked flask fitted with a magnetic stirrer, a reflux condenser and a pressure-equalizing dropping funnel. In all experiments the amounts of the reactants were as follows: alcohol (0.05 mole), $AlCl_3$ (0.06 mole)/CH_3NO_2 (0.6 mole) and petroleum ether with boiling range 60—80° (4 ml/g of alcohol). In a typical reaction, the aluminum chloride was first introduced into the flask, followed first by nitromethane and second by half the amount of the solvent petroleum ether. The alcohol dissolved in the rest of the solvent was then added through the dropping funnel to the stirred contents of the flask over a period of 15 to 20 min. at ambient temperature. After this, the reaction mixture was stirred for two hours at the same temperature then it was decomposed by pouring into icecold dilute hydrochloric acid and the organic layer was taken into ether. The ether layer was washed with 10% sodium bicarbonate solution and water followed by drying over anhydrous sodium sulfate. The solvent was distilled at atmospheric pressure and, with the exception of the product from alcohol 18 which was a solid, the residue was distilled under vacuum. The distillate was analyzed by vapour phase chromatography to determine its composition by comparison with authentic samples.

Data concerning yields and composition of products are given in Table 1 in the results and discussion section.

Received October 31, 1973

The configuration of 8-substituted tricyclo [7.3.1.0 ^{2,7}]tridecen-13-ols obtained by various methods was established, by correlating the IR data with the retention time on carbowax 20M chromatographic column and the NMR signals given by the hydrogen atom geminal to hydroxyl group.

INTRODUCTION

The two hydroxyl groups of the 8-substituted tricyclo[7.3.1.$0_{2,7}$] tridecane-2,13-diols (I), substituents : H, CH_3, C_2H_5, C_3H_7, C_6H_5, are both axial,[2,3] this configuration being stabilized by the intramolecular hydrogen bonding between these two groups.

The hydroxyl group of the 8-substituted tricyclo[7.3.1.$0_{2,7}$] tridecen-13-ols (V–VIII) can be *endo* or *exo* with respect to the fused six-membered ring.

The study of the 8-substituted tricyclo[7.3.1.$0_{2,7}$]tridecen-13-acetates (IX–X) substituents H and CH_3[4] obtained by acetylation and dehydration of the diols Ia and Ib using acetic anhydride and zinc chloride led to the conclusion that, for CH_3, the acetate with the double bond C_2–C_7 (IXb) could exist as well as its isomer with the double bond C_7–C_8 (Xb). The gas-liquid chromatographic analysis on carbowax 20M, showd two peaks : the first very well resolved and the second one larger; their area ratio is about 5.5 : 1. The acetate having the double bond C_7-C_8 was the major product, as the NMR spectrum of the mixture shows.

The examination of the IXa, b and Xb acetates NMR spectra by Hassner's method[5] does not allow to establish their configuration, due to the conformational modifications generated by the double bond introduction: a 13-acetate group in this system, which is axial or equatorial in the cyclohexane ring, is pseudo-equatorial or pseudo-axial to the cyclohexene ring respectively.

If the acidic medium, causing epimerization at the C_{13} carbon atom, is avoided during the acetylation and dehydration processes of diols Ia, b, the acetate group is pseudo-equatorial to the cyclohexene ring, and the resulted acetates are *endo*. Therefore after distilling continuonsly the acetic acid arised from the reaction, one expects to obtain the *endo*-acetates.

RESULTS AND DISCUSSION

The 8-substituted tricyclo[7.3.1.$0^{2,7}$]tridecen-13-ols (V—VIII), substituents H and CH_3 were obtained using three methods: the alkaline hydrolysis of unsaturated acetates IXa, b and Xb, the dehydration of the diols Ia, b with sulphuric acid, and the reduction of unsaturated ketones IIIa, b and IVa, b — resulted by dehydration of ketols IIa, b — with lithium aluminium hydride.

The hydrolysis of the acetate IXa leads to a crystalline product, melting point 68.4—69.3° after recrystallization from pentane. The gas-liquid chromatographic analysis on carbowax 20M shows one peak for the recrystallized alcohol as well as for the rough one. Its NMR spectrum (Figure 1) presents one complex absorption from $\delta = 1.00$ to 2.30 ppm, with an area corresponding to 19 protons, and one triplet at $\delta = 3.53$ ppm — $J = 3$ Hz — for the hydrogen atom attached to C_{13}.

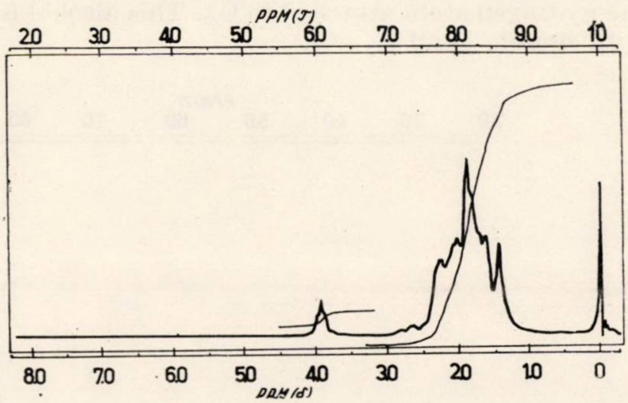

Fig. 1. — NMR spectrum of the tricyclo[7.3.1.$0^{2,7}$] trideca-2(7)-en-*endo*- 13-ol (Va).

The alcohol configuration assignment only on the basis of the coupling constant magnitude [6,7] is not sure, because the dihedral angles are almost equal, as Dreiding models show (57° for *endo* and 52°30′ for *exo*). The IR spectrum must, however, present distinct bands for the two isomers: the free hydroxyl group band for *exo*-isomer, and a band which shows intramolecular π-hydrogen bonding involving the hydroxyl group and the double bond for *endo*-isomer.[8,9]

The difference between the absortion bands of *anti*- and *syn*-1,5-dimethyl-bicyclo[3.3.1]non-2-en-9-ols is 56 cm^{-1}; *anti*- and *syn*-bicyclo[3.3.1]non-2-en-9-ols give for this difference the value 39 cm^{-1} [11];

syn-bicyclo[3.2.1]oct-2-en-8-01 presents a weak band at 3617 cm^{-1} and a stronger one at 3578 cm,$^{-1}$[12] the difference being 39 cm^{-1}; the association of hydroxyl group with benzene nucleus in *endo*-benzo-bicyclo[4.3.1] nonen-9-ol generates a shift of 30 cm.$^{-1}$ [13]

The IR spectrum of the unsaturated alcohol obtained by the acetate IXa hydrolysis exhibits a main band at 3588 cm^{-1}, with a shoulder at 3624 cm^{-1} (carbon tetrachloride solution, 2×10^{-2} mol/l). The difference of 36 cm^{-1} corresponds to the intramolecular association between the hydroxyl group and the double bond in the *endo*-epimer Va.

The gas-liquid chromatographic analysis of the IXb and Xb acetates mixture hydrolysis products, on a carbowax 20M column, shows two peaks in the 5.3 : 1 ratio. The NMR spectrum of the first peak, separated by gas-liquid preparative chromatography, presents the following signals (Figure 2) : one complex absorption from $\delta = 1.00$ to 2.90 ppm, on which the singlet specific for the $-\underline{CH}_3-Ar$ system at $\delta = 1.64$ ppm is superposed — for 21 protons; one triplet at $\delta = 3.57$ ppm, J = 3 Hz, for the hydrogen atom attached to C_{13}. This alcohol is then one of the epimers with double bond C_7-C_8.

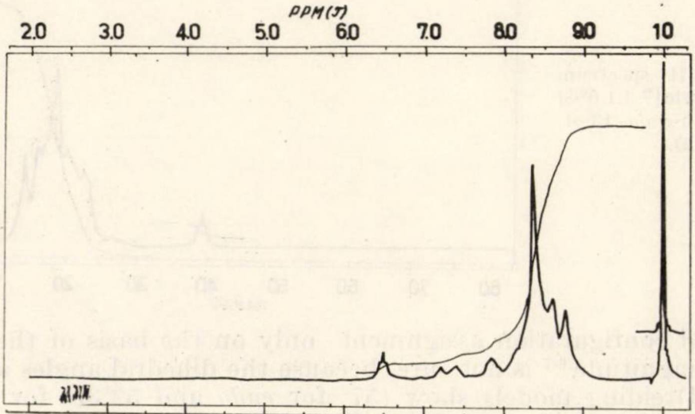

Fig. 2. — NMR spectrum of the 8-methyl-tricyclo[7.3.1.0 ^{2,7}] trideca-7(8)-en-*endo*-13-ol (VIIb).

Taking into account the ratio of the alcohols which, in the limits of the experimental errors, equalizes the ratio of the acetates, one can suppose that the second peak represents one of the epimeric alcohols with C_7-C_8 double bond. On the other hand, the NMR spectrum of the mixture of the alcohols presents also the methyl group doublet for the last alcohol at $\delta = 0.99$ ppm. The IR spectrum of this mixture (carbon tetrachloride solution, 4×10^{-2} mol/l) exhibits a main band at 3588 cm^{-1}, with a shoulder at 3624 cm^{-1}. It follows then that the first peak is the *endo*-alcohol VIIb and the second one the *endo*-alcohol Vb.

[12] N. A. LeBel and L. A. Spurlock, *Tetrahedron*, **20**, 215 (1964).

[13] H. Tanida and T. Irie, *J. Org. Chem.*, **36**, 2777 (1971).

The dehydration of the diol Ia with refluxing sulphuric acid 25% leads to two main components which are in the 1 : 1.58 ratio, as calculated from the chromatogram. The retention time of the second peak is identical with that of the alcohol Va. The two alcohols cannot be separated by chromatography on alumina and silicagel columns.

The NMR spectrum of the alcohol mixture (Figure 3) shows one multiplet from $\delta = 0.90$ to 2.90 ppm for 19 protons, one triplet at $\delta = 3.55$ ppm — $J = 3$ Hz — and one triplet centered at $\delta = 3.90$ ppm — — $J = 5$ Hz — for the hydrogen atom attached to C_{13}. The ratio of the two triplets area is 1.62 : 1.

There are a weak band at 3624 cm^{-1}, a main band at 3588 cm^{-1}, and a wide absorption from 3530 to 3425 cm^{-1}, the maximum being at 3480 cm^{-1},in the IR spectrum of the alcohol mixture (carbon tetrachloride solution, 4×10^{-2} mol/l). The wide band vanishes for 2.5×10^{-3} mol/l solution and the 3624 cm^{-1} band increases its intensity at the same time. Comparing the NMR spectrum (Figure 3) with that of the alcohol Va (Figure 1) one can reach the conclusion that the first peak, having the triplet at $\delta = 3.90$ ppm, represents the *exo*-alcohol VIa.

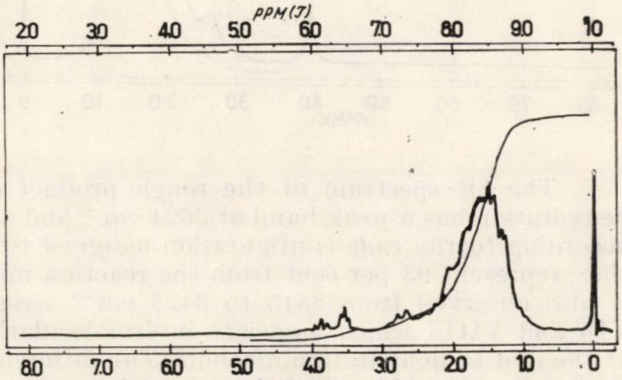

Fig. 3. — NMR spectrum of the mixture of *endo*- and *exo*-tricyclo [7.3.1.$0^{2,7}$]trideca-2(7)-en-13-ols (Va)and (VIa)respectively.

Some bicyclic [n.m.1] system epimers give also such shifts for the proton geminal to hydroxyl group : $\delta = 3.90$ ppm (triplet) for bicyclo-[3.2.1]oct-2-en-*syn*-8-ol and $\delta = 4.13$ ppm (singlet) for the *anti*-epimer [12], $\delta = 4.27$ ppm (singlet) for 7,8-benzo-bicyclo[4.2.1]nonen-endo-9-ol and $\delta = 4.72$ ppm (triplet) for the *anti*-epimer.[13] This can be explained by the more powerful screening, due to the double bond, of the hydrogen atom belonging to the *exo*- or *anti*-epimer, it being closer to the double bond and at a larger distance from its plane, as the Dreiding models show.

The wide absorption at 3480 cm^{-1} is produced by the alcohol VIa, which associates intramolecularly greater on steric grounds.

Dehydration of the diol Ib using sulphuric acid gives four peaks on chromatogram, with the following per cent concentrations : 5, 2, 50.8, and 42.2, respectively. The peak 3 has the same retention time as the alcohol VIIb, and the peak 4 the same as the alcohol Vb. The peaks 3 and 4 were separated by preparative gas-liquid chromatography on carbowax 20M and the NMR spectra were run, to verify the assignments. The peak 3 has the same spectrum as the alcohol VIIb (Figure 2), and the peak 4 (Figure 4) gives signals at : $\delta = 1.00$ ppm (doublet), $J = 7.5$ Hz, and $\delta = 3.65$ ppm (singlet) as the alcohol Vb does. A small quantity of a crystalline unsaturated alcohol, melting point 64—65°, was also obtained ; its NMR spectrum and retention time are identical with those of the alcohol Vb.

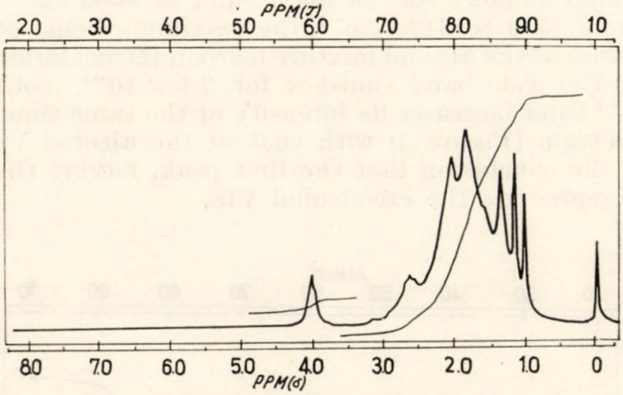

Fig. 4. — NMR spectrum of the 8-methyl-tricyclo-$[7.3.1.0^{2,7}]$trideca-2(7)-en-*endo*-13,-ol (Vb).

The IR spectrum of the rough product obtained by the diol Ib dehydration has a weak band at 3624 cm^{-1} and a strong one at 3588 cm^{-1}, according to the *endo* configuration assigned to the above two alcohols ; they represent 93 per cent from the reaction mixture. A very weak band is also observed from 3515 to 3425 cm^{-1}, assigned to the *exo* alcohols VIb and VIIIb which associate intermolecularly easier, on the analogy of the diol Ia dehydration alcohols. The difference of the retention times, similar to that of the alcohols Va and VIa, also support this assignment.

The stereochemistry of the carbonyl group reduction[14] does not allow to establish the configuration of the unsaturated alcohols, because of the conformational modification caused by the double bond introduction.

The dehydration of the ketol IIa leads to the mixture of unsaturated ketones IIIa and IVa. Their ratio is dependent on the dehydration agent.

The reduction of the mixture of unsaturated ketones with lithium aluminium hydride gives two alcohols : the first has the same retention time as the alcohol Va, and the second has a longer one. The NMR spectrum (Figure 5) presents the signals : one complex absorption from $\delta = 1.00$ to 2.60 ppm, one triplet at $\delta = 3.70$ ppm, $\delta = 3$ Hz, one singlet at $\delta = 3.93$ ppm and one doublet at $\delta = 5.27$ ppm, $J = 6.5$ Hz.

The IR spectrum exhibits a main band at 3630 cm^{-1} and a weak one at 3588 cm^{-1}. Repeated recrystallizations from ethyl alcohol give a crystalline alcohol, melting point 120.5—121.5°, having NMR signals at $\delta = 3.93$ and 5.27 ppm, a 3630 cm^{-1} IR band with a shoulder at 3588 cm^{-1}, and the same retention time as the second peak. On the basis of these data the structure Va was assigned to the first peak and the structure VIIIa to the second one.

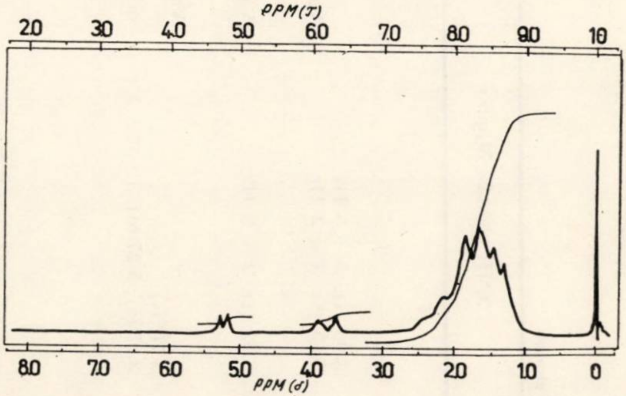

Fig. 5.—NMR spectrum of the alcohols obtained by the mixture of ketones IIIa and IVa reduction.

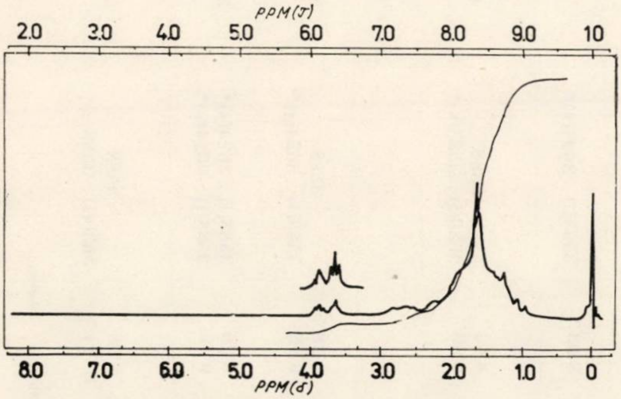

Fig. 6.—NMR spectrum of the alcohols obtained by the mixture of ketones IIIb and IVb reduction.

The dehydration of the ketol IIb gave also two ketones : IIIb and IVb. The reduction products of this mixture of ketones, analysed by gas-liquid chromatography, contain two peaks : the first with the same retention time as the alcohol VIIb and the second with a longer one. The following signals are superposed on the complex absorption of the NMR spectrum (Figure 6) : one doublet centered at $\delta = 1.01$ ppm specific for the $\underline{CH_3}—CH$ system, and the singlet of the $\underline{CH_3}—C =$ system at $\delta = 1.67$ ppm ; there are also : one triplet at $\delta = 3.67$ ppm, $J = 3$ Hz, and one triplet at $\delta = 3.89$ ppm, $J = 4$ Hz.

The IR spectrum shows two almost equal intense bands at 3630 and 3588 cm^{-1}. The crystalline alcohol, melting point 80—81°, separated

i – intense ; s* – shoulder ; d – doublet ; t – triple ; s – singlet.

from the mixture, presents the doublet at $\delta = 1.01$ and the triplet at $\delta = 3.89$ ppm in the NMR spectrum, and the band at 3630 cm^{-1} with a shoulder at 3588 cm^{-1} in the IR spectrum ; the retention time is identical with that of the second peak. Therefore, the first peak is the *endo*-alcohol VIIb, and the second one the *exo*-alcohol VIb.

The main characteristics of the unsaturated alcohols obtained by the above methods are summarized in Table 1.

CONCLUSIONS

The alkaline hydrolysis of the acetate IXa leads only to the tricyclo[$7.3.1.0^{2,7}$]trideca-2(7)-en-*endo*-13-ol Va. The hydrolysis of the mixture of acetates IXb and Xb gives the coresponding *endo*-alcohols : 8-methyl-tricyclo[$7.3.1.0^{2,7}$]trideca-2(7)-en-*endo*-13-ol Vb and 8-methyl-tricyclo[$7.3.1.0^{2,7}$]trideca-7(8)-en-*endo*-13-ol VIIb, in the 1 : 5.35 ratio.

The dehydration of the diol Ia using sulphuric acid 25% affords the mixture of *endo*- and *exo*-tricyclo[$7.3.1.0^{2,7}$]trideca-2(7)-13-ols Va and VIa, respectively. 50.8% 8-methyl-tricyclo[$7.3.1.0^{2,7}$]trideca-7(8)-en-*endo*-13-ol-VIIb, 42.2% 8-methyl-tricyclo [$7.3.1.0\lambda^{2,7}$]trideca-2(7)-en-*endo*-13-ol Vb and 7% mixture of *exo*-alcohols VIb and VIIIb were obtained by sulphuric acid dehydration of the diol Ib.

The reduction of unsaturated ketone IIIa using lithium aluminium hydride gives the *endo*-alcohol Va and that of ketone IVa the *exo*-alcohol VIIIa. The *exo*-alcohol VIb was obtained by lithium aluminium hydride reduction of ketone IIIb and the *endo*-alcohol VIIb by isomeric ketone IVb reduction.

EXPERIMENTAL PART

The preparation of the acetates IXa, b and Xb has been described in an earlier paper.[4]

Hydrolysis of the acetate IXa. a) 5.25 g acetate IXa were added to a stirred solution of natrium hydroxide (5 g) in methyl alcohol (50 ml) and water (20 ml); the stirring was continuated for 4 hours. The mixture was set aside overnight, then was diluted with water and extracted with ether (2 × 50 ml). The combined ethereal extracts were washed with water and dried on natrium sulphat. Removal of solvent gave 3.80 g (88.8% yield) white needles of unsaturated alcohol Va, m.p. 67–69°; recrystallization from pentane gives m.p. 68.4–69.3°.

b) 10.5 g acetate IXa and 100 ml solution of natrium hydroxyde in methyl alcohol (10%) were refluxed for 1 hour. 7.9 g (91.8% yield) white crystals, m.p. 66–69°, were obtained after cooling and dilution with water. Recrystallization from methyl alcohol-water gave 7.5 g unsaturated alcohol Va, m.p. 68–69°. Analytical gas-liquid chromatography on carbowax 20M gave one peak. NMR spectrum (CCl_4), δ : 3.53 ppm (t), $J = 3$ Hz ; IR spectrum CCl_4, 4×10^{-2} mol/l) : 3588 cm^{-1} (i), 3624 cm^{-1} (shoulder).

Hydrolysis of the isomeric acetates IXb and Xb. 10.2 g mixture of acetates IXb and Xb were worked as above, giving a semi-solid epimeric mixture (8.1 g, 96.4% yield) of the alcohols (VIIb and Vb). Analytical gas-liquid chromatography gave two peaks, which were separated by preparative chromatography. NMR spectrum of the mixture (CCl_4), δ : 0.99 ppm (d) $J = 7.5$ Hz, 1.65 ppm (s), 3.57 ppm (s) ; IR spectrum (CCl_4, 4×10^{-2} mol/l) : 3588 cm^{-1} (i), 3624 cm^{-1} (shoulder).

Dehydration of the diol Ia with sulphuric acid 25%. 20 g diol Ia was heated under reflux with 50 ml sulphuric acid 25%. The mixture was cooled and extracted with ether (3 ×

× 100 ml). The ethereal solution was washed with 10% sodium carbonate solution and dried on sodium carbonate. Removal of the ether gave 18.6 g (94% yield) row product which, by vacuum distillation, gave a semi-solid epimeric mixture. Analytical gas-liquid chromatography shows four peaks, two of them being of higher concentration. NMR spectrum (CCl_4), δ : 3.55 (t) J = 3 Hz, 3.90 ppm (t) J = 5Hz; IR spectrum (CCl_4) : 3624 cm^{-1} (weak), 3588 cm^{-1} (i).

Dehydration of the diol Ib with sulphuric acid 25%. 37 g diol Ib and 72 ml 25% sulphuric acid solution were heated under reflux as above. The mixture was worked up as above, giving 33 g (97% yield) row product which, by vacuum distillation, conducted to 24.8 g product, $n_D^{20} = 1.5350$. A semi-solid product was obtained by cooling and sitting aside. The chromatogram contains 4 peaks, two having higher concentration. Repeated recrystallization from pentane afforded a small quantity of crystalline alcohol, m.p. 64—65°, retention time the same as the last peak. NMR spectrum (CCl_4), δ : 0.99 ppm (d) J = 7.5 Hz, 3.62 ppm (s); IR spectrum (CCl_4) : 3588 cm^{-1} (i), 3624 cm^{-1} (shoulder).

Reduction of the mixture of ketones IIIa and IVa with lithium aluminium hydride. A solution of mixture of unsaturated ketones (5.04 g) in anhydrous ether (70 ml) was added within 1 hour to 30 ml anhydrous ether containing 1 g lithium aluminium hydride. The mixture was refluxed for 12 hours, then the aluminium alcoholate was decomposed by methyl alcohol (4 ml) and water (2 ml), and extracted with ether. Removal of the ether gave 4.77 g (94% yield) unsaturated alcohols. Reduction of unsaturated ketones obtained by dehydration of ketol IIa using sulphuric acid led to a semi-solid product. Gas-liquid chromatography, on carbowax 20M, showed the existence of 2 peaks, their ratio being 1 : 2.2. NMR spectrum of the mixture (CCl_4), δ : 0.85—2.90 ppm (m), 3.62 ppm (s), 3.82 ppm (s), 5.22 ppm (d) J = 6.5 Hz; IR spectrum (CCl_4) : 3630 cm^{-1}(i), 3588 cm^{-1} (weak). A solid product was obtained, m. p. 103—107°, when the ketones were obtained using the acetic anhydride-zinc chloride mixture as dehydration agent. Repeated recrystallization from ethyl alcohol gave white needle crystals, m. p. 120.5—121.5°. The chromatogram presented two compounds, 1.3 : 1 ratio, having the same retention times as above. NMR spectrum of the mixture is identical with the above one, but the doublet intensity increases; IR spectrum (CCl_4) : 3630 cm^{-1} (i), 3588 cm^{-1} (i).

Reduction of the mixture of ketones IIIb and IV b with lithium aluminium hydride. 6.71 g unsaturated ketones, obtained by sulphuric acid dehydration of the ketol IIb, gave at the reduction 6.50 g (94% yield) liquid product, in which needle crystals appeared in time. The chromatogram presented 2 peaks, 1 : 1 ratio. NMR spectrum (CCl_4), δ : 1.01 ppm (d) J = 7.5 Hz, 1.67 ppm (s), 3.60 ppm (t) J = 3 Hz, 3.80 ppm (s). By extracting the liquid portion on porous plate and recrystallizing from pentane, a crystalline compound, m. p. 80—81°, was obtained. IR spectrum (CCl_4) : 3630 cm^{-1}(i), 3588 cm^{-1}(shoulder). 3.5 g unsaturated ketones, obtained by acetic anhydride-zinc chloride dehydration of the ketol IIb, led to 3.35 g (94.2% yield) liquid product. The chromatogram shows 2 peaks, 2 : 1 ratio, the same retention time as above. NMR spectrum is identical with the above one; IR spectrum (CCl_4) : 3630 cm^{-1} (i), 3588 cm^{-1} (i).

Analytical chromatography has been performed on a Carlo Erba GT type gas-liquid chromatograph, using a 4 mm o. d. stainless steel column, 2 m in length. Packing material was 20% carbowax 20M on 60—80 mesh chromosorb W. The flame ionisation detector was used, with nitrogen as gas carrier. The conditions were as follows:

injection temperature	280°
column temperature	115—170°, 4°/min programing
detector temperature	280°
nitrogen flow rate	25 ml/min
injected quantity	0.6 µl

Preparative chromatography was carried out on a Carlo Erba GT type preparative chromatograph, equiped with peak discriminator, by employing a 10 mm o. d. stainless steel column, 2 m in length, and 20% carbowax 20M on 30—60 mesh chromosorb W was packing material. The thermal conductivity detector was used, with hydrogen as carrier gas. The conditions were:

injection temperature	280°
column temperature	195°
detector temperature	300°

hydrogen flow rate	650 ml/min
auxiliary gas flow rate	60 ml/min
injected quantity	100 μl

The purity verification of the collected samples was made using the above analytical column in the conditions :

injection temperature	240°
column temperature	120–180°, 6°/min programing
detector temperature	260°
nitrogen flow rate	30 ml/min
injected quantity	0.4 μl

using the flame ionisation detector.

ALTERNATING TENDENCY IN COPOLYMERIZATION. I

COPOLYMERIZATION OF BUTYL VINYL ETHERS WITH ACRYLIC MONOMERS

DAN SORIN VASILESCU
Laboratory of Macromolecular Chemistry, Polytechnical Institute,
Calea Victoriei 149, Bucharest, Romania

Received November 14, 1973

The copolymerization of *n*-butyl vinyl ether, *s*-butyl vinyl ether and *t*-butyl vinyl ether with methacrylonitrile, acrylonitrile and acrylamide was carried out. The reactivity ratios and the copolymerization rates for all binary systems, except those containing acrylamide, were determined. Also, the "Q" and "e" values for *s*-butyl vinyl ether were established. The calculated reactivity ratios are strongly dependent on the chemical structure of the monomer pair; some pairs show an alternating tendency. The structure of copolymers was evidenced by performed analyses.

1. INTRODUCTION

Vinyl ethers are known as monomers with strong electron donor substituents; they cannot polymerize by radicalic way. Polyvinyl ethers are usually produced working with Lewis acids as catalysts. However, vinyl ethers may be copolymerized, by radicalic way, with vinyl monomers containing electron attractive substituents. Several copolymers with maleic anhydride [1] or acrylate esters are better known; copolymers of ethyl acrylate with 2-chloroethylvinyl ether have been used as rubbers.[2] In such copolymerization vinyl ethers show a tendency towards an alternating structure; for instance, for the pair acrylonitrile-*t*-butyl vinyl ether, the values $r_1 = 0.14$ and $r_2 = 0.0032$, were reported.[3] The alternating copolymer results due to the formation of a molecular complex between the electron donor monomer and the electron acceptor monomer; this complex is assumed to have an important contribution in the free radicalic alternating copolymerization of many monomer pairs.[4]

Iwatsuki and Yamashita [5] have provided evidence for the participation of a charge transfer complex in the formation of alternating copolymers from the free radical copolymerization of *p*-dioxene or vinyl ethers with maleic anhydride. Terpolymerization of the monomer pairs which form alternating copolymers with a third monomer which had little interaction with either monomer of the pair, indicated that the polymerization was actually a copolymerization of the third monomer with the complex.[5] Similar results have been noted in terpolymerizations involving vinyl ether-fumaronitrile [6] monomer pair.

When a charge transfer complex does not form, the r_1 and r_2 values are very different (e.g. for the N-vinyl succinimide — *n*-butyl vinyl ether system, Furukawa and co-workers [7] found $r_1 = 15$ and $r_2 = 0$).

H. Gilbert [8] reported some data about the behaviour of vinylidene cyanide-vinyl ethers systems; no copolymerization occurred, but two homopolymers, polyvinylidene cyanide and polyvinyl ether were produced by cross initiation.

Although several copolymers with vinyl ethers are prepared on a large scale, our theoretical knowledge about the behaviour of vinyl ethers in copolymerization processes is still poor.

In this paper we present the data concerning the copolymerization of *n*-butyl vinyl ether (nBVE), *s*-butyl vinyl ether (sBVE) and *t*-butyl vinyl ether (tBVE) with acrylic monomers; also we carried out tests upon obtained polymers in order to elucidate their structure.

2. EXPERIMENTAL

2.1. MATERIALS

Butyl vinyl ethers (BVE) were obtained by vinylation of butyl alcohols with acetylene in the presence of potassium alkoxide according to the methods described by Shostakovskii [9] and other authors [10]; crude products were washed with water to remove the unreacted alcohol. The monomers were dried and distilled on metallic sodium; the purity was tested by refractive index and chromatographic methods.

Acrylonitrile (AN) and methacrylonitrile (MAN) — provenience Schuchard — were purified according to the usual methods.

Acrylamide (AA) — provenience BDH — was twice recrystallized from ethyl acetate [11] and dried in vacuum.

Toluene (T), acetone (Ac), N, N-dimethyl formamide (DMF) and chloroform (CL) were purified by conventional ways; methanol and petroleum ether — reagents grade — were used without purifications.

Azobisisobutyronitrile (AIBN) as radicalic initiator was recrystallized from ethanol.

2.2. COPOLYMERIZATION PROCEDURE

The copolymerization reactions were carried out in the absence of air in glass ampoules with two charging arms[12]; after filling, one arm was closed and the ampoules were connected to a short vacuum assembly. The ampoules were frozen in liquid nitrogen, air-removed at

10^{-2} mm.Hg, filled with purified argon and warmed at 30°; this cycle was accomplished three times.

Finally, the ampoules were sealed; the tubes were put at the desired temperature in a thermostated bath and rapidly mixed. The copolymerizations were carried out in such a manner, in order to obtain small conversions. The copolymerization process was stopped by abrupt freezing; the ampoules were opened and the polymer was precipitated by pouring the solution into a large amount of nonsolvent (methanol or petroleum ether). After filtration, polymers were dried and weighted; some copolymers were reprecipitated.

2.3. Analyses of polymers

The composition of copolymers was determined by their nitrogen content (Dumas classical micromethod); copolymers with high content in AN, generally infusible, were reprecipitated to obtain fine powdered products.

Intrinsic viscosities of copolymers were calculated using the data obtained on diluted solutions (copolymer concentration less than 0.2 g/dl) with an Ubbelohde viscometer at 25° As solvents we used CL and DMF.

I.R. absorption spectra were recorded on a PYE-Unicam, SP-200 spectrophotometer; the NMR spectra were performed using a VARIAN apparatus (60 MHz), solvent $CDCl_3$, internal reference TMS.

3. RESULTS AND DISCUSSION

The copolymerization tests of methacrylonitrile with nBVE, sBVE and tBVE were carried out at 60°, in homogeneous solution, using AIBN as initiator; the molar ratio monomer mixture/AIBN = 300, was kept constant. For a more precise and rapid dosage of the initiator, toluene solution of AIBN (1 ml in each ampoule) was used. Because the molecular weights and densities of each monomer are different, the total molar concentration of both monomers varies in the range 6.3–8.2 mole/l. (Table 1)

Table 1

Copolymerization of MAN (M_1) at 60°; solvent toluene; molar ratio $\frac{/M_1/ + /M_2/}{/AIBN/} = 300$

$/M_1/$ in monomers (mole %)	M_2	$/M_1/ + /M_2/$ (mole/l)	Reaction time (min.)	Conversion (%)	N% Dumas	$/m_1/$ in copolymer (mole fraction)

10	tBVE	6.3	360	3.36	8.47	0.504

AIBN was used as initiator, as in the literature it is assumed that the scission rate of this substance is not influenced by the nature of the reaction medium.[13] As the process was carried out to obtain small conversions (max. 5.6%) these tests could be used to establish initial copolymerization rates (Fig. 1).

Some kinetic data regarding the dependence of the initial rate on the feed composition are given in figure 1. It is evident that the rates increase when the initial molar fraction of MAN in monomer mixture increases; the more reactive monomer is MAN. The BVE act as retarders of the polymerization process; the copolymerization of the tBVE—MAN pair develops fastest.

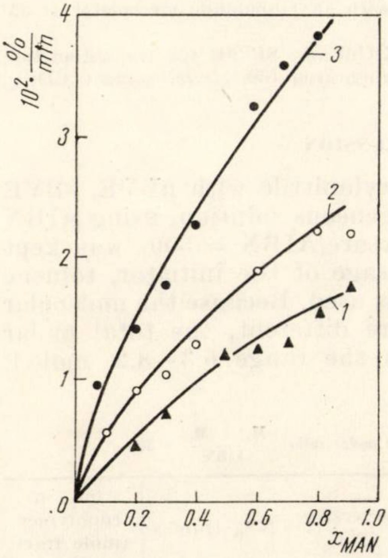

Fig. 1.—Dependence of the copolymerization rate upon the composition feed for the MAN — BVE systems; $M_1 + M_2 = 3.10^{-2}$ moles; AIBN $= 10^{-4}$ moles; solvent toluene (1 ml); temperature = 60° *1.* M_2=*n*BVE. *2.* M_2 = *s*BVE. *3.* M_2 = *t*BVE.

The precise computing of the copolymerization reactivity ratios has been tackled by several methods; but it is possible that a particular set of data lead to appreciably different values of the reactivity ratios.

To determine accurately r_1 and r_2 reactivity ratios the Fineman-Ross method [14] was chosen (linearization of the differential composition equation:)

$$Z = r_1 + Wr_2 \tag{1}$$

where: $Z = (Y - 1)/X$; $W = -Y/X^2$; $X = [M_1]/[M_2]$; $Y = [dm_1]/[dm_2]$.

Because of the possible errors of the method used to establish the copolymer composition (nitrogen content by the micro-Dumas method) it was utilized an analytic calculation — the least square method [15]:

$$r_1 = \frac{\Sigma W^2 \Sigma Z - \Sigma W \Sigma ZW}{n \Sigma W^2 - (\Sigma W)^2} \tag{2}$$

$$r_2 = \frac{n \Sigma WZ - \Sigma W \Sigma Z}{n \Sigma W^2 - (\Sigma W)^2} \tag{3}$$

where n is the number of accomplished tests.

The necessary data for the determination of the reactivity ratios at the MAN—BVE systems are given in Table 2.

X_1 – initial mole fraction of MAN in monomer mixture

Y_1 – mole fraction of MAN in copolymer.

The results are summarized in Table 3; the r_1 and r_2 values are in accordance to those predicted from the "Q–e" scheme.[16] The literature mentions no reactivity ratios for MAN – BVE systems.

---

[16] T. Alfrey and C. C. Price, *J. Polymer Sci.*, **2**, 101 (1947).

It is of interest to enquire whether the two r_1 and r_2 constants are alike meaningful. Moreover, it should be noticed that the obtained values have very different magnitudes ($r_1/r_2 = 10^3$); obviously, they were got with the same error. Supposing that r_1 value was obtained with an absolute error 0.01, this means that for r_2 values relative errors more than 100% may appear.

Table 3

Values of the copolymerization constants for the monomer pairs MAN (M_1) – BVE (M_2)

Monomer M_2	Least-squares method		Calculated from the Alfrey and Price's scheme	
	r_1	r_2	r_1	r_2
*n*BVE	2.47	0.0052	2.52	0.0069
*s*BVE	1.73	0.0001	—	—
*t*BVE	1.09	0.011	1.074	0.0031

Since this situation is not reasonable, it ought to consider practically $r_2 = 0$; we did this simplification and drew the curves from figure 2.

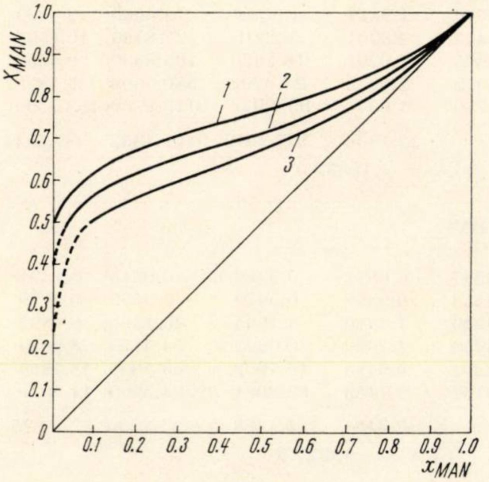

Fig. 2. — Monomer/copolymer composition curves for radical copolymerization of the MAN(M_1)—BVE (M_2) systems at 60°: *1.* M_2 = *n*BVE; *2.* M_2 = *s*BVE; *3.* M_2 = *t*BVE.

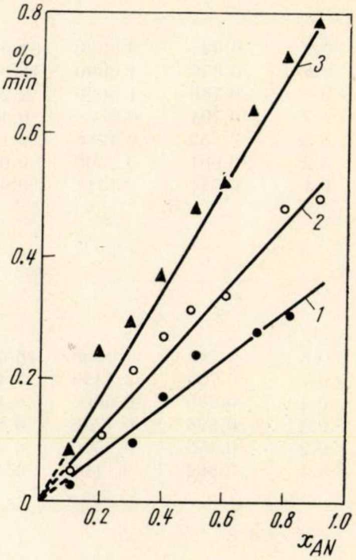

Fig. 3. — Copolymerization rate against composition feed for the AN-BVE systems; $M_1 + M_2 = 3.10^{-2}$ moles; AIBN = 10^{-4} moles; solvent toluene (1 ml); temperature = 60°. *1.* M_2 = *n*BVE. *2.* M_2 = *s*BVE. *3.* M_2 = *t*BVE.

As shown in figure 2, the molar fraction of MAN in copolymers has been always more than 50%; if MAN is M_1, as r_1 is smaller, the copolymerization process occurs faster (figure 1).

When instead of MAN was used AN in the same conditions, shorter polymerization times were necessary to obtain the same conversions (Table 4).

Table 4

AN is known as a monomer with a greater tendency towards alternation ("e" = + 1.20). The systems involving AN are more reactive than those containing MAN. This follows from figure 3 ; about the influence of the molar fraction of AN in initial monomer mixture, on the reaction rate, may be observed that when the AN content decreases, the rate drops sharply. This important shrinkage cannot be attributed to the reduction of total monomer concentration (from 11.5 to 9.3 mole/l), but to the great reactivity difference between monomers.

The same behaviour was observed by Tazuke [17] for the AN — isobutyl vinyl ether (iBVE) pair. Radicalic polymerization of AN is monotonously retarded by the addition of iBVE, when the system was initiated by AIBN in the dark. If the rate of initiation would be kept constant, therefore the change of the polymerization rate must be caused by a reduced rate of propagation or an enhanced rate of termination.[17]

---

X_1 – initial mole fraction of AN in monomer mixture.
Y_1 – mole fraction of AN in copolymer.

The reckoning of r_1 and r_2 values was made by two different methods : the least square method (Table 5) and the intersection method of Mayo and Lewis [18] (Figure 4). The copolymers of acrylonitrile with *t*-butyl vinyl ether, made at feeds rich in *t*BVE, have compositions neighbouring to the equimolecular one.

---

[18] F. R. MAYO and F. M. LEWIS, *J. Amer. Chem. Soc.*, **66**, 1594 (1944).

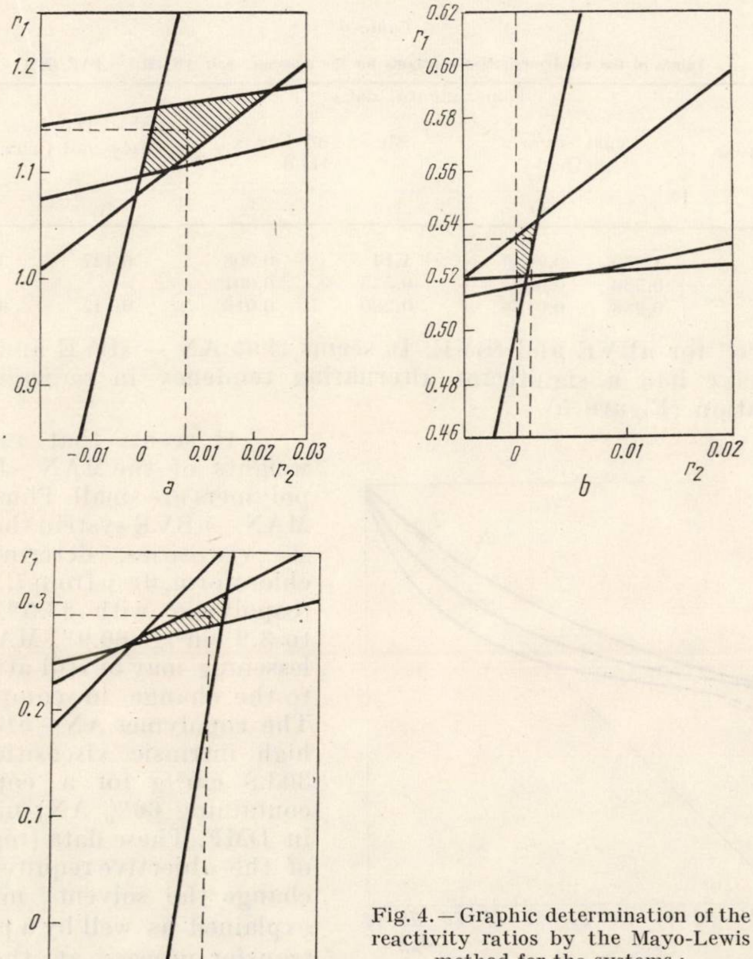

Fig. 4. — Graphic determination of the reactivity ratios by the Mayo-Lewis method for the systems :
*4*a) AN−*n*BVE ; $r_1 = 1.14$ $r_2=0.008$.
*4*b) AN−*s*BVE ; $r_1=0.535$ $r_2=0.001$.
*4*c) AN−*t*BVE ; $r_1 = 0.29$ $r_2=0.016$.

From the electronic point of view, the inductive effect decreases in the order *t*-butyl > *s*-butyl > *n*-butyl ; this appears obviously if we examine the r_1 and r_2 values. The experimental reactivity ratios are rather different from those calculated (by Alfrey and Price [16] scheme) and earlier reported data for the acrylonitrile *t*-butyl vinyl ether pair [3] ($r_1 = 0.14$ and $r_2 = 0.0032$). Therefore, the agreement with theoretical values is somewhat less satisfactory than that for the systems containing MAN.

The obtained data concerning the binary system involving *s*-butyl vinyl ether permitted us to calculate the values "Q" = 0.0417 and "e" = = − 1.54 for this monomer; the value "e" is placed between the known values "e" for *n*BVE and *t*BVE. It seems that AN − *s*BVE and AN − *t*BVE have had a significant alternating tendency in radicalic copolymerization (Figure 5).

Table 6

Values of the copolymerization constants for the monomer pair AN (M_1) − BVE (M_2)

Monomer M_2	Experimental data				Calculated data from the Alfrey and Price's scheme	
	Least-squares method		Mayo and Lewis method			
	r_1	r_2	r_1	r_2	r_1	r_2
nBVE	1.100	−0.0020	1.14	0.008	0.427	0.00897
sBVE	0.530	0.0007	0.535	0.001	—	—
tBVE	0.288	0.0178	0.290	0.016	0.142	0.00310

It seems that molecular weights of the MAN−BVE copolymers are small. Thus, at the MAN−*n*BVE system the intrinsic viscosities, determined in chloroform, drop from 7.12 cm³/g (copolymer with 83.5% MAN) to 3.9 cm³/g (60.9% MAN); this lessening may be still attributed to the change in composition. The copolymer AN−*n*BVE has high intrinsic viscosities (e.g. 303.8 cm³/g for a copolymer containing 66% AN) measured in DMF. These data (regardless of the objective requirement to change the solvent) might be explained as well by a powerful transfer process at the MAN BVE systems, as the participation of the charge transfer complexes of AN with BVE in copolymerization.

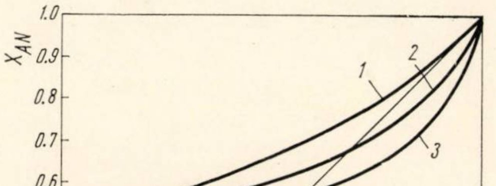

Fig. 5. — AN molar fraction in copolymer as a function of the AN molar fraction in initial monomer mixture at 60°. *1.* AN − *n*BVE pair; *2.* AN−*s*BVE pair; *3.* AN−*t*BVE pair.

To point out the presence of the vinyl ethers in the copolymer chain, IR absorption spectra were accomplished for the following copolymers: A = MAN (73.6%)−*n*BVE; B = MAN(60.1%)−*s*BVE; C = = MAN (55.3%)−*t*BVE; % represents the molar percentage, previous established by the nitrogen content. Characteristic vibration frequencies ν [cm^{-1}] are:

Compound A: 1085 s; 1190 m; 1385 m; 1460 s; 1755 m; 2240 m; 2960 vs.

Compound B : 1060 s ; 1380 s ; 1465 s ; 1730 m ; 2240 m ; 2910 vs.

Compound C : 1065 s ; 1195 s ; 1240 w ; 1365 s ; 1385 s ; 1460 s ; 1750 m ; 2235 m ; 2980 vs.

where : w-weak ; m-medium ; s-strong and vs-very strong.

A strong peak in the range 1060–1085 cm^{-1} (characteristic of the aliphatic ethers) and a medium absorption band at 2240 cm^{-1} may be attributed to the nitrile group.[19] Thus, the former analytical data regarding the copolymer composition, are confirmed.

Nuclear magnetic resonance spectroscopy (NMR) has lately become one of the polymer researcher's most important tools ; the use of NMR to study molecular composition and sequence distribution in copolymer has been more and more developed.[20] The NMR spectra of several copo-

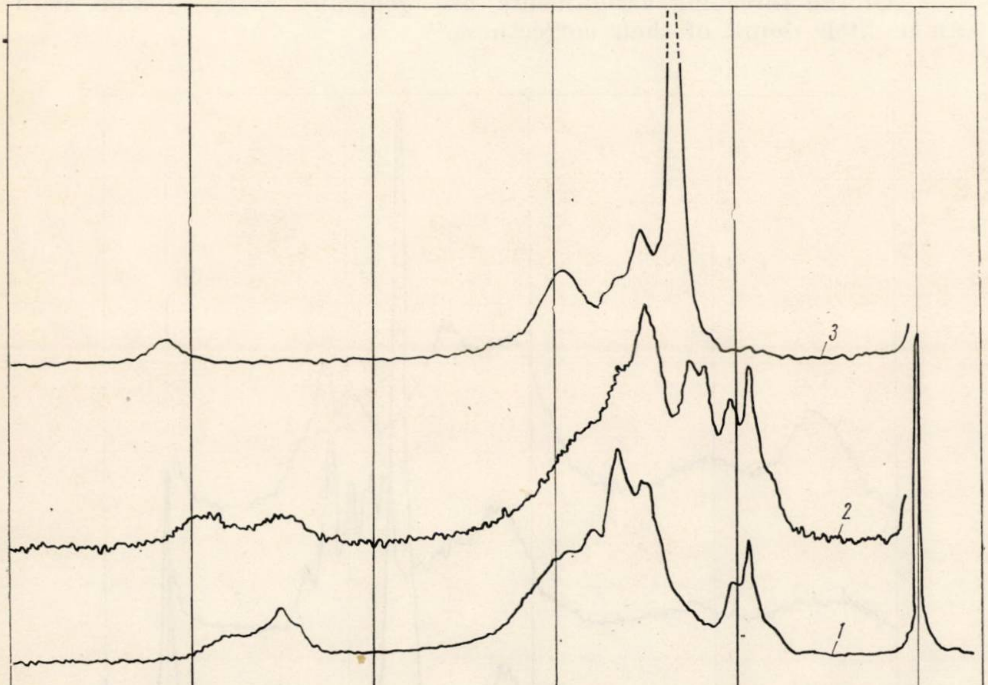

Fig. 6. — NMR spectra of the MAN-BVE copolymers.

[20] A. Pidcok, Nuclear Magnetic Resonance ; in : "Polymer Science — a Materials, Science Handbook", Editor A. D. Jenkins, vol. **2**, North-Holland Publishing Company, Amsterdam–London, 1972, p. 1383.

lymers of MAN and AN with BVE, having compositions nearby to equimolecular one, were carried out.

Figure 6 shows a comparison of spectra for three copolymers of MAN with various BVE ; the three spectra were recorded under the same conditions.

Thus, the chain methylene resonance are centered at 8.31 τ and the α-methyl (from MAN) resonance occurs in the neighbourhood of 9 τ. The large area at 8.67 τ (copolymer MAN−*t*BVE) is ascribed to the CH_3 protons, present in great number [20,21] and the intensity of this resonance is proportional to the *t*BVE fraction.

In figure 7, we present the NMR spectra for the AN−*n*BVE, AN−*s*BVE and AN−*t*BVE copolymers with nearly equimolecular compositions. Especially there is observed the strong peak at 8.78 τ corresponding to the methyl groups from *t*BVE.

All the foregoing assignments are generally accepted and there can be little doubt of their correctness.[21]

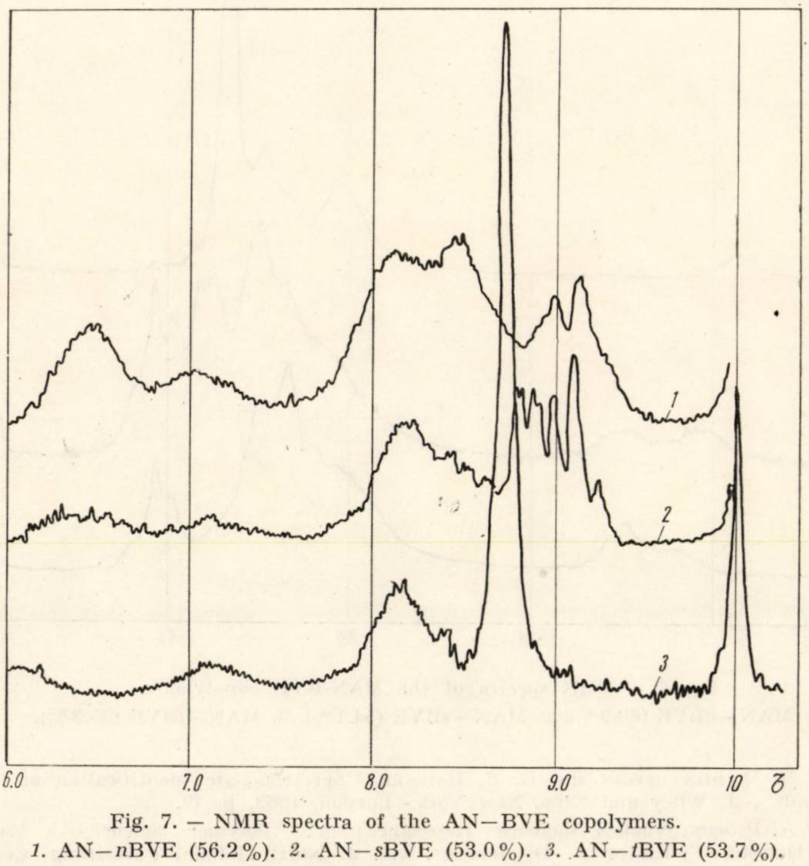

Fig. 7. — NMR spectra of the AN−BVE copolymers.

---

[21] B. Ke, "Newer Methods of Polymer Characterization", J. Wiley and sons, New York, 1964, p. 33.

In a copolymer of an acrylic monomer (A) with a vinyl ether (E) only the AE and AA diads and AAA, AEA and EAA triads are possible. The AE diad and AEA triad would be favoured at an equimolecular copolymer. Unfortunately, the lack of suitable standards did not permit us a complete interpretation of the NMR spectra, in order to establish the weight of each structure. Further study, with special emphasis on the sequence distribution, is needed.

AA acts in copolymerization processes with BVE in a different manner than MAN or AN. As the "e" value of acrylamide is +1.30,[4] then it would be expected that AA—BVE systems would show an increased alternating tendency.

The copolymerization tests were carried out in the same conditions as those described above, but acrylamide was poured in the ampoule with two arms, as a solution in acetone. Accordingly the concentration of both monomers (AA and BVE) varied in the range 2.0—4.2 mole/l.

The noticed polymerization rates were higher ($\simeq 0.6\%$/min.) than those observed at the MAN—BVE and AN—BVE systems; practically these rates do not depend on the feed composition.

The precipitated products are rather sticky and cause some difficulties in their analysis. Nevertheless, the nitrogen analyses showed that there was produced poly-AA. The polymer was dissolved in water and the solution evaporated to obtain pellicules. The IR absorption spectra were carried out on them and we acquired spectra alike to that reported by Hümmel[22] for polyacrylamide : 790 cm^{-1}(s) ; 1130 cm^{1} (w) ; 1420 cm^{-1} (m) ; 1660 cm^{-1} (vs) ; 2950 cm^{-1} (m) and 3340 cm^{-1} (s).

The lack of a strong peak at 1060—1080 cm^{-1} allows us to consider that BVE does not enter the chain.

On the other hand, the melting range of these products is high (200—220°) ; this fact may point a branched polymer due to the transfer reaction with the "dead" polymer.

The behaviour of AA—BVE systems might be explained in a similar manner to that of the styrene-vinyl acetate classical system.[4]

Further work is in progress.

The author wishes to thank to B. Mărculescu for the nitrogen analyses and expresses his gratitude to C. Drăghici for the NMR measurements.

THE EFFECT OF S-CHAMBER SHAPE ON THE SEPARATION OF ETHANOLAMINES BY THIN LAYER CHROMATOGRAPHY

H. NAȘCU and C. LITEANU

University of Cluj, Department of Analytical Chemistry

Received June 29, 1973

The effect of S-Chamber shape (profile) in the thin layer chromatographic separation of a test dyes mixture and some ethanolamines was studied. The "A" type chambers (wedge shaped) are more advantageous leading to a better separation. These are a new type of unsaturated chambers which give the same reproducibility as the S-Chambers. When the R_f values do not exceed 0.5, an optimum dimension of chamber for a given separation was found.

Recently, the influence of the shape of chromatographic chamber on the quality of thin layer chromatographic (TLC) separation was a problem of great interest in the field of thin layer chromatography (TLC). Thus, besides the usual chromatographic chamber (chromatographic tank) 21 × 21 × 9 cm known as "N-Chamber", Stahl[1] and Davies[2] introduced the "S-Chambers" which subsequently were improved.[3–7] The S-Chamber was used for both descending[8] and horizontal[9] chromatography. In addition, the KS-[10] and BN-[11] Chambers are special chromatographic chambers which permit the selection of optimum humidity conditions and assure highly reproducible results respectively. The S-Chambers for continuous chromatography have also been proposed.[12–14]

A recent work has shown that a chamber similar to the S-Chamber, but wedge shaped with 10 cm at its bottom may be also useful in some TLC separations.[15]

The purpose of the present paper is to study the influence of the shape (profile) of such chambers on certain TLC separations e.g. a test dyes mixture and some ethanolamines by using a single solvent in the first case and a mixture of polar solvents in the second.

MATERIALS

The chambers were constructed according to the procedure of Sherwood[13] i.e. by glueing by means of an epoxi adhesive two pieces (wedge shaped) and a strip of glass on the three sides of a 10 × 14 cm glass plates in such a manner as to get chambers of different shapes but with one constant dimension after grinding (Figure 1.). The opposite side dimension, L, is variable. In this way two types of chambers called "A" and "V" have been obtained. The L dimension varies from 2.5 to 18 mm for the A type chambers and from 2.5 to 14 mm for the V type chambers, respectively. This dimension permits to handle the chambers with the same easiness as the usual S-Chambers.

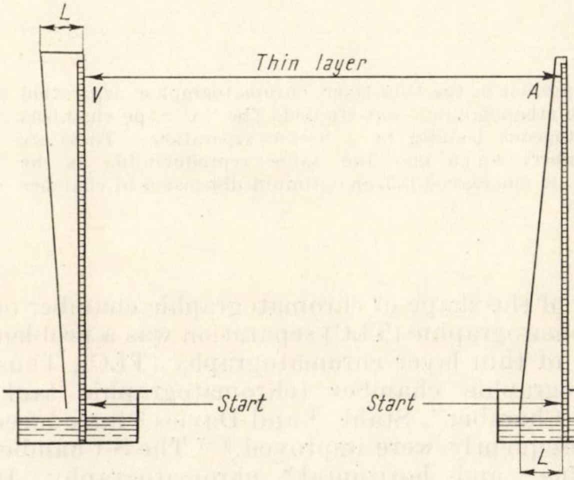

Fig. 1. — Schematic representation of the chambers :

A type chambers,
V type chambers

The L is the bottom and top width, respectively

Kieselgel H (Merck, Darmstadt, Germany) with 5% starch as binder was used to prepare 250 μ thick layers according to the procedure of Lees and De Muria.[16] The layers were air dried and kept above a saturated solution of potassium carbonate (45% relative humidity).

The solvents used were analytical grade reagents. Methil-ethilketone was purified by a distilling with potassium permanganate after a previousd rying with anhydrous potassium carbonate. Mono-(MEA), di-(DEA), and triethanolamines (TEA) (Merck, Darmstadt, Germany) were used as 2% aqueous solution. The test dyes mixture (Butter yellow, Sudan Red, and Indophenol) was used in the form supplied by Desaga (Heidelberg, Germany). A 0.2% ninhidrine in n-butanol (containing 2% acetic acid) was used as spray reagents for ethanolamines. Before and after spraying, the plate was kept for 10 minutes at 120°C in an oven.

RESULTS AND DISCUSSIONS

In order to check the effect of the chamber shape on the kinetics of the front and spot migration, the Desaga test dyes mixture as components and benzene as solvent were used. No essential modification in the equation of migration ($z^2 = \chi t$) as comparing with a S-Chamber ($10 \times 8 \times 0.25$ cm) was observed.

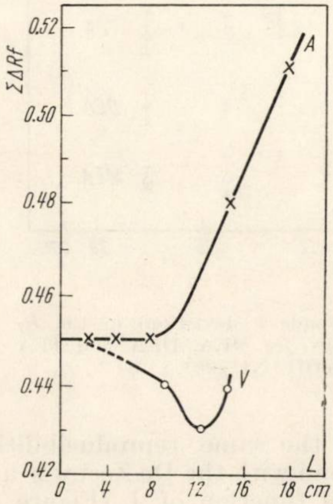

Fig. 2. — The plot of $\Sigma\Delta R_f$ vs. L for the test dyes mixture (Butter yellow, Sudan red and Indophenol). The length of migration at 10 cm.

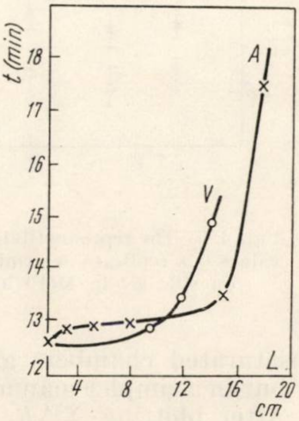

Fig. 3. — The plot of time of migration for benzene vs. chamber (shape A and V). Length of migration at 10 cm.

Taking into account the sum of differences between the R_f values ($\Sigma\Delta R_f$) at the same migration distance as a separation index, in the case of test dyes mixture and benzene, the graph in Figure 2 was obtained.

The plot of $\Sigma\Delta R_f$ vs. L shows an exponential increasing of the "separation" partly due to exponential increasing of the chamber volume. As for the V type chambers a better separation is noticed as compared to the S-Chamber.

The time required for the solvent to migrate 10 cm, was increasing with the L increase in both chambers, as shown in Figure 3.

Since the volume of these new studied chambers increases as compared to the S-Chambers and by increasing the volume, the reproducibility generally diminishes,[17] the effect of the A type chamber shape on reproducibility was tested. A solvent system in which MEA, DEA, and TEA are completely separated e.g. Me Et CO : MeOH : NH_3 (25%) 8 : 3 : 9 was used. As it can be seen from Figure 4, six replicate determinations of the R_f values give for the A type chambers reproducibilities (standard deviations) close and/or sometimes even better than those obtained in S-Chamber.

---

[17] F. Geiss, A. Schlitt and A. Klose, *Z. analyt. Chem.*, **213**, 331 (1965).

The F test proved that no signifiant differences exist between reproducibilities in the S-Chamber and the A type chamber. Thus, this new kind of unsaturated chambers gives the same reproducibilities as the S-Chamber but in a simpler manner than with the De Zeeuw's unsaturated chamber.[18] After plotting $\Sigma \Delta R_f$ as a function of L (Figure 5) only a correlation can be seen. The correlation coefficient $r = 0.57$ and the square of this, $r^2 = 0.33$ proves that 33% is the contribution of L to the distribution of these experimental points.

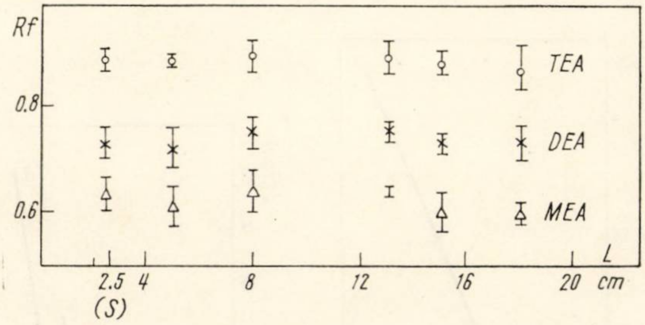

Fig. 4. — The reproductibility (standard deviation) of the R_f values (six replicate determinations) for MEA, DEA and TEA on silicagel in MeEtCO : MeOH : NH_3(25%), 8 : 3 : 9.

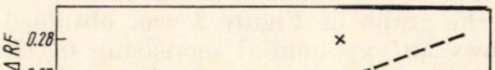

Fig. 5. — The plot of $\Sigma\Delta R_f$ vs. L for the separation of MEA, DEA and TEA on silicagel in MeEtCO : MeOH : NH_3(25%) 8 : 3 : 9. The correlation $r = 0.57$ ($r^2 = 0.33$).

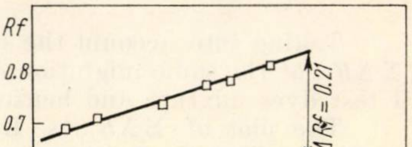

Fig. 6. — The plot of $\Sigma\Delta R_f$ vs. L for separation of MEA, DEA and TEA on silicagel with MeEtCO : MeOH : NH_3 (10%), 12 : 3 : 8. Time 30 min.

---

[18] R. A. DE ZEEUW and M. T. FEITSEMA, *Pharm. Weekblad*, **101**, 957 (1966).

Another solvent system used for quantitative determinations of TEA in DEA or MEA[19] was tested for its behaviour in the A type chambers (Figure 6.) In this case the new chambers are not more efficient than the S-Chamber, due to the fact that the real distance between these zones being smaller, the danger of contamination at elution from the plate increases.

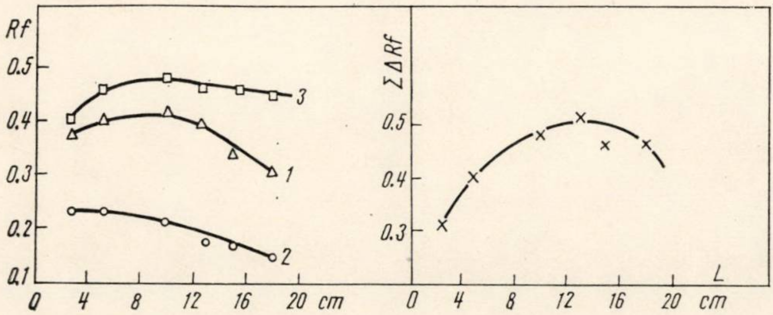

Fig. 7. — The plot of $\Sigma\Delta R_f$ vs. L for the separation of MEA, DEA and TEA on silicagel in MeEtCO : MeOH : NH_3(25%) 7 : 2 : 1. The length of migration at 10 cm.

In a solvent system which gives lower R_f values, a better separation can be obtained (Figure 7); thus there is an optimum chamber for a given separation.

CONCLUSIONS

The A type chambers may give better separations which are dependent upon the chromatographic system used. The reproducibility in these chambers does not differ significantly from the classical S-Chamber. They are unsaturated chambers easy to built and use. In the case of the TLC separations of ethanolamines when a solvent system gives low R_f values (<0.5) the "A" type chambers give better separations. The equation of front and zone migration is similar to that in the S-Chamber ($z^2 = \chi t$).

Revue Roumaine de Chimie, **19**, *8*, 1407–1411 (1974)

Structure and bonding. 15. Springer Verlag, Berlin, Heidelberg, New York, 1973, 188 p.

The volume is devoted to various topics concerning the coordination interactions.

In the first chapter dealing with the complexes of chelating olefin-group V ligands, D. I. Hall, J. H. Ling and R. S. Nyholm describe the results of their studies aimed at stabilizing the complexes of a wide range of metals, investigating the effect of the metal on the reactions of the olefinic group. The stabilization is achieved, using the olefinic group as a part of a molecule containing a "b" class donor atom, usually P or As, occasionally O^- or S^-. The strongest effect results when two or three carbon atoms are present between the heavy atom and the vinyl group. Besides valuable information on the properties of olefin complexes produced, new synthetic routes have been achieved. The structures of the complexes mentioned above are often of interest themselves. Some mechanistic and structural considerations concerning the ability of the ligand to chelate, the possibility of isomerization of terminal olefins and the formation of metal-carbon σ bonds are also suggested.

In the following chapter, E. C. Baughan discusses a new system of ionic radii obtained from diamagnetism : the root-mean-square electron-cloud radii. Their comparison with the structural radii, shows that for ionic and van der Waals bonds, the structural radii are about twice the root-mean-square electron-cloud radius, but for localized covalent bonds they are only nearly equal. This distinction between electron-cloud radii and structural radii is further used to refine the system of ionic radii due to Pauling and Goldschmidt. A short discussion of solvation energies pleads that here also the electron-cloud radii are the less suitable.

Another chapter concerns the Lewis acid-base interactions. The author, R. S. Drago begins by showing that in almost any chemical reaction Lewis acid-base interactions are involved, in at least a certain step of the process. A discussion of the data to be obtained follows in order to account for the strength of the bonding. Next, a quantitative model is presented with the view to predict and correlate the enthalpies of the adduct formation. The interpretation of the resulting parameters, the exceptions to the above correlation, as well as their valid transformations are considered in the light of hard-soft acid-base and donor strength models of acid-base chemistry. Both concepts are shown to be incomplete models of coordination. The relationship between the new parameters and the $\sigma-\rho$ Hammett ones is quantitatively demonstrated. Potential uses and extension of this approach to acid-base chemistry are presented. Some indications are given concerning the attempts to deduce the magnitude of interaction from changes in the spectroscopic properties of donors and acceptors on coordination.

In the fourth chapter of the compendium, V. Gutman, based on a functional approach to chemical interactions aimed to account for the relations between redox-properties and coordination, considers that the redox potential is decisively influenced by differences in the actual net charges at the redox active centers of the oxidized and reduced species. In agreement with this concept, the author relates the oxidizing properties and the complex stability for cations, anions and by back-donation.

The volume closes with S. Ahrtand's article concerning the thermodynamics of stepwise formation of metal-ion complexes in aqueous solution. The hard acceptors and donors are postulated to be electrovalent ; the soft ones, to be covalent. The thermodynamic functions found for the stepwise formation of complexes in aqueous solution, are in very good agreement with the models proposed for complexes of different character. The models applied are based on evidence from several fields, both thermodynamic and non-thermodynamic. The fact that many characteristics related to the consecutive steps agree with the models, is a supplementary support for this plausibility.

NOTE POUR LES AUTEURS

La *Revue Roumaine de Chimie* publie des articles en anglais, français, russe, allemand ou espagnol. Les auteurs sont priés d'envoyer des articles, notes, communications et comptes rendus inédits.

Les manuscrits seront dactylographiés à deux intervalles. Les tableaux seront dactylographiés sur des feuilles séparées, de même que la légende des figures. Les diagrammes seront tracés à l'encre de Chine sur papier calque. Les tableaux et les figures seront numérotés par des chiffres arabes, en nombre strictement nécessaire. Prière de ne pas inscrire les mêmes données dans les tableaux et les figures. Les formules chimiques seront incluses dans le texte ; en outre, elles seront transcrites sur des feuilles séparées. Les auteurs sont priés d'indiquer les caractères italiques (en soulignant les lettres au crayon), ainsi que tout autre caractère spécial. L'ordre des références bibliographiques sera celui de leur mention dans le texte ; le nom de l'auteur sera précédé de l'initiale du prénom ; les publications périodiques seront présentées suivant les prescriptions internationales. Les références seront ajoutées à la fin de l'article ; elles paraîtront comme des notes, au bas de la page. Le texte sera précédé d'un résumé comprenant 15 lignes au maximum.

L'entière responsabilité du contenu des articles appartient aux auteurs. On publie des articles dus aux collaborateurs roumains ou étrangers.

ON THE VISCOSITY OF MOLTEN METALS. II[1]

I. G. MURGULESCU and MARILENA ŞERBAN
Physical Chemistry Department, Bucharest University,
Bd. Republicii 13, Bucharest, Romania

Received April 10, 1974

It is proposed a calculation relation for viscosity, starting from one of Eyring's equations. According to the cell pattern, it is supposed that all the molecules perform harmonic vibratory motion with constant frequencies. The lattice parameters are function of atomic volume and packing coefficient. Mott's relation for the evaluation of the vibration frequency of the liquid particles is proposed; the vibration frequency of the solid particles is evaluated with Lindemann's relation. In the result equation there are two parameters, one being a function of atomic mass, melting temperature and atomic volume and the other — the activation energy — remaining an adjustable parameter. The equation is satisfied by a series of normal metals.

INTRODUCTION

In a previous work[1] we studied the applicability of Batschinski's relation for the viscosity of molten metals and liquified rare gases, both of which having constituent particles with spheric symmetry. At the same time, it was established the molecular significance of the limiting molecular volume in this equation and the possibility of its estimation from the corresponding atomic radii. Thus, in Batschinski's relation remained only one parameter adjustable by the variation of experimental values of viscosity.

In the present paper we try to derive another expression for metal viscosity, with one adjustable parameter too. Thus, we shall start from the equation:

$$\eta = h \frac{\lambda_1}{\lambda_2 \lambda_3 \lambda^2} \frac{F}{\overset{*}{F}} \mathrm{e}^{E/RT}, \qquad (1)$$

which was deduced by Eyring[2], using the transition state theory at the viscous flow of liquids; we shall develop now this theory in a different way. In this equation, λ_1, λ_2, λ_3, are lattice parameters, λ is the equilibrium separation while F and $\overset{*}{F}$ are partition functions, per cm^3, of the normal and activated particles; E is activation energy of viscous flow. The other magnitudes in the equation have known significances.

---

[1] I.G. Murgulescu and M. Şerban, *Rev. Roumaine Chim.*, **17**, 431 (1972).

[2] S. Glasstone, K.J. Laidler and H. Eyring, "The Theory of Rate Processes", New York, London 1941, p. 483.

If we accept the valability of cell pattern for the metallic liquids, we can write the equation :

$$\lambda^2 \ \lambda_2 \ \lambda_3 \ / \ \lambda_1 = a^3 = \gamma \ V/N,$$

in which a represents the nearest neighbours separation while V is the atomic volume. The factor γ can be 1, $\frac{3}{4}\sqrt{3}$ or $\sqrt{2}$ as the structures are : cubic, cubic with centred body or cubic with centred faces and hexagonal close packed respectively. In conformity with the X-ray diffraction studies, the last value is in better agreement with experimental data, and is the very one we used in the sequel. Taking into account the last equation, the viscosity coefficient equation becomes :

$$\eta = \frac{Nh}{\gamma V} \frac{F}{\overset{*}{F}} e^{E/RT} . \tag{2}$$

According to the same cell pattern, we supposed that liquid monoatomic particles have only harmonic vibratory motion round their lattice points, which may be considered equilibrium positions. The transition state partition function $\overset{*}{F}$ has one freedom degree less than F ; therefore, the ratio of the two partition function becomes equal to the partition function of an harmonic oscillator :

$$\frac{F}{\overset{*}{F}} = \left(1 - e^{-h\nu/KT}\right)^{-1},$$

where ν is the vibration frequency of the oscillator. The viscosity coefficient equation becomes thus:

$$\eta = \frac{Nh}{\gamma M} \frac{\rho e^{h\nu/KT}}{e^{h\nu/KT} - 1} e^{E/RT} , \tag{3}$$

where V was substituted by the ratio between the atomic mass M and the density ρ.

At high temperatures, which are characteristic for the metallic liquid, the harmonic oscillator partition function may be well approximated by the well-known relation :

$$kT/h\nu.$$

With this simplification, equation (3) takes the form of :

$$\eta = \frac{R}{\gamma M} \frac{\rho T}{\nu} e^{E/RT} . \tag{4}$$

The difference between the results of equations (3) and (4) remains much under the limit of experimental errors of the viscosity measurements. Therefore, we would prefer, in the sequel, the equation (4). Besides, the frequency ν is supposed constant in the temperature ranges for which we found experimental viscosity coefficients.

The determination of the vibration frequency is very accessible for the solid state of metals. By melting, the vibration frequency ν_s of the solid decreases. The vibration frequency of the corresponding liquid particles is connected with ν_s by Mott's relation[3] :

$$\frac{\nu_s}{\nu} = e^{L/3RT_m},$$

where T_m and L are the melting temperature and heat. Due to this relation, the solid state vibration frequencies may be successfully turned to account in equations (3) and (4).

In table 1, the $e^{L/3RT_m}$ values are given for the elements with normal metallic character. We used the averages of the temperature T_m and the heat L values, found in references. [4–6] The results (4th column) are near enough to justify the use of their average for the frequency correction.

Table 1

The ν_s/ν ratio for the normal metals

Element	T_m, °K	L, cal/gatom	$e^{L/3RT_m}$
Li	453.7	720	1.305
Na	371	659	1.347
K	336.6	581	1.336
Rb	312.0	537	1.335
Cs	301.8	505	1.324
Cu	1356.2	3157	1.478
Ag	1234	2726	1.449
Au	1336.2	3105	1.477
Mg	924.2	2170	1.483
Zn	692.7	1660	1.495
Cd	594.2	1394	1.482
Hg	234.3	557	1.490
Al	933.3	2449	1.553
Pb	600.6	1143	1.376
Fe	1809	3720	1.412
Co	1765	3736	1.426
Ni	1726	4032	1.480
			Av :1.427

The average —1.427 — is near the value of $\sqrt{2}$ in the above equations of viscosity coefficient, with which it is thus simplified. The equation (4) becomes :

$$\eta = \frac{R}{M}\frac{\rho T}{\nu_s} e^{E/RT} \tag{5}$$

---

[3] N.F. Mott , *Proc. Roy. Soc.*, **146**, 465 (1934).

[4] K. Jellinek, "Lehrbuch der physikalischen Chemie", II, Stuttgart, 1928, p. 232.

[5] "American Institute of Physics Handbook", New York, Toronto, London, 1957, p. 131.

[6] Landolt-Börnstein, "Physikalisch-Chemische Tabellen", IV Band, Technik, 2 Teil, Bandte 1 a (1963), b (1964), c (1965).

In the table 2 there are the $e^{L/3RT_m}$ values for some elements without normal metallic character. As we expected, the results have considerable deviations from the average in table 1.

Table 2

The ν_s/ν ratio for the abnormal metals

Element	T_m, °K	L, cal/g atom	$e^{L/3RT_m}$
Ga	303.0	1338	2.098
Sn	505.1	1676	1.745
Sb	903.7	4797	2.437
Bi	544.2	2510	2.168

The viscosity coefficients of these elements cannot be expressed by the equation (5) but only in the more elaborate equation :

$$\eta = \frac{R}{\gamma M}\,\frac{\rho T e^{L/3RT_m}}{\nu_s}\,e^{E/RT}, \tag{6}$$

where for each element is introduced the correction given by the peculiar exponential value.

The frequency ν_s for the corresponding solid metal is to be deduced with sufficient accuracy according to the well-known Lindemann's relation[7] :

$$\nu_s = 2.8 \times 10^{12}\sqrt{\frac{T_m}{M V_m^{2/3}}}, \tag{7}$$

where T_m is, as above, the melting temperature while V_m is the atomic volume of the solid substance at this temperature.

Substituting ν_s in equations (5) and (6), we obtained successively :

$$\eta = 3.57 \times 10^{-13}\,\frac{R V_m^{1/3}}{M^{1/2} T_m^{1/2}}\,\rho\, T e^{E/RT} \tag{8}$$

for meltings of the normal metals, and

$$\eta = 3.57 \times 10^{-13}\,\frac{R V_m^{1/3}}{\gamma\, M^{1/2}\, T_m^{1/2}}\,e^{L/3RT_m}\,\rho T e^{E/RT} \tag{9}$$

for meltings of the abnormal metals.

---

RESULTS AND DISCUSSIONS

In order to verify equations (8) and (9), it is necessary to know the density ρ function of temperature and the activation energy E.

In most cases, the densities are specified in the same papers in which are given the viscosity measurement results, and which are indicated in tables 3 and 4.

The activation energy E can be obtained from the experimental data, plotting log $\eta/\rho\ T$ against $1/T$. For the temperature range which exceeds only with some hundred degrees the melting point, straight lines are to be obtained, as we can see in figures 1 and 2, whose slopes lead to the activation energies. In more expanded temperature range, like in the case of Na and K, abnormal metallic elements and Hg, a slight departure from the linearity takes place. In these cases, we take the temperature ranges closer to the melting temperature, where the applicability of the cell pattern, on which our equations are based, is justified; beyond this range, the activation energy increases.

In order to verify the valability of equations (8) and (9), we calculated out of the corresponding physical magnitudes the preexponential

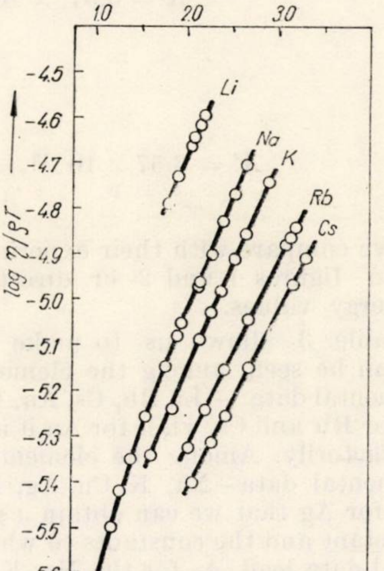

Fig. 1. — Dependence of log $\eta/\rho\, T$ on $1/T$ for the alkali metals.

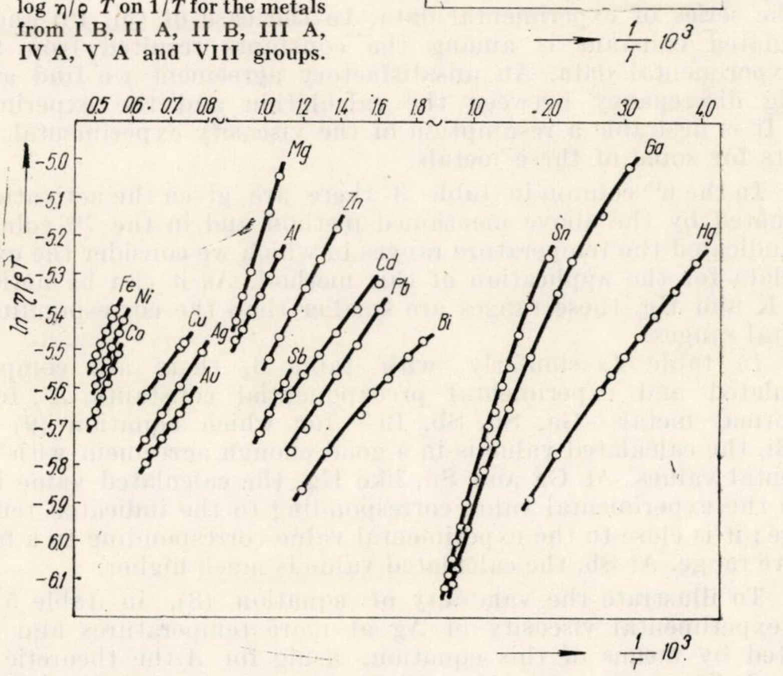

Fig. 2. — Dependence of log $\eta/\rho\, T$ on $1/T$ for the metals from I B, II A, II B, III A, IV A, V A and VIII groups.

constants :

$$A = 3.57 \times 10^{-13} \frac{RV_m^{1/3}}{M^{1/2}\, T_m^{1/2}} \tag{8'}$$

and

$$A' = 3.57 \times 10^{-13} \frac{RV_m^{1/3}}{\gamma M^{1/2}\, T_m^{1/2}} e^{L/3RT_m} , \tag{9'}$$

which we compare with their experimental values, that can be obtained either in figures 1 and 2 or directly, from the viscosity and activation energy values.

Table 3 allows us to make this comparison for normal metals. As it can be seen, among the elements for which we have one series of experimental data — Li, Rb, Cs, Au, Cd, Hg — there is a very good agreement for Rb and Cs, while for Au it is acceptable and for Li, Cd and Hg — unsatisfactorily. Among the elements for which we have more series of experimental data—Na, K, Cu, Ag, Mg, Zn, Al, Pb, Fe, Co, Ni — there is only for Ag that we can obtain a good agreement between the calculated constant and the constants to which the three series of available experimental data lead. As for the Na, K, Zn, Al, Ni, the calculated constant is in good or in satisfactory agreement only with that obtained from one of the series of experimental data. In the case of Cu, Pb and Fe, the calculated constant is among the constants resulted from the series of experimental data. An unsatisfactory agreement we find at Co and a big discrepancy between the calculation and the experiment — at Mg. It is desirable a resumption of the viscosity experimental measurements for some of these metals.

In the 6th column in table 3 there are given the activation energy evaluated by the above mentioned method and in the 7th column there are indicated the temperature ranges in which we consider the experimental data for the application of this method. As it can be noticed, with Na, K and Hg, these ranges are smaller than the corresponding experimental ranges.

In table 4, similarly with table 3, there are compared the calculated and experimental preexponential constants A', for several abnormal metals—Ga, Sn, Sb, Bi — for which equation (9) is valid. At Bi, the calculated value is in a good enough agreement with the experimental values. At Ga and Sn, like Hg, the calculated value is smaller than the experimental value corresponding to the indicated temperature range; it is close to the experimental value corresponding to a far temperature range. At Sb, the calculated value is much higher.

To illustrate the valability of equation (8), in table 5 we give the experimental viscosity of Ag at more temperatures and that calculated by means of this equation, using for A the theoretic value in table 3. The agreement between the two sets of values in the last two columns is good.

There is to be mentioned at least, that for the normal metals, the melting atomic volume V_m being nearly equal to the limiting atomic volume in the Bathschinski's equation, may be deduced from the atomic radii too :

$$V_m = 6.02\ \mathrm{N}r^3,$$

as it was established in the previous work.[1]

Table 4

Preexponential constants for abnormal metals

Bi	544.2	21.58	2.168	3.756	3.483 3.039	2453 2573	544 – 633 ; 833 577 – 673 ; 873	[30] [31,11]

The V_m values in tables 3 and 4 are those we used in ref. [1] (tab. 4)

Table 5

The viscosity coefficients of silver

$A = 1.804 \times 10^{-7}$ (cm²s⁻¹ grad⁻¹) ; $E = 7{,}303$ (cal/gatom)

T, °K	ρ, g/cm³	$\eta \times 10^2$ Poise Experim.	$\eta \times 10^2$ Poise Calcd.
1273.1	9.26	3.89	3.82
1323.1	9.22	3.62	3.54
1373.1	9.18	3.39	3.31
1423.1	9.135	3.18	3.11
1473.1	9.09	2.99	2.93
1523.1	9.05	2.83	2.78

Starting with the equation (1), Eyring[2] obtained in another way his well-known viscosity coefficient expression :

$$\eta = 1.09 \times 10^{-3} \frac{M^{1/2}\ T^{3/2}}{\Delta E_{\mathrm{vap}}\ V^{2/3}}\ \mathrm{e}^{E/RT}\ , \tag{10}$$

where ΔEvap is the vaporization heat. The other magnitudes have known significance. The equation (10), as the equations (8) and (9), has only one adjustable parameter : the activation energy E. The preexponential constant A has now the expression :

$$A = 1.09 \times 10^{-3} \frac{M^{1/2}}{\Delta E\text{vap}},$$

which obviously differs from the A and A' in equations (8) and (9). The activation energy may be evaluated by plotting log $\eta V^{2/3} \; / T^{3/2}$ against $1/T$, as the usual method. The calculated activation energy is also different from that evaluated by means of the equations (8) and (9).

To illustrate the applicability of Eyring's equation, we give in the table 6 the results for several metals. Comparing them with the corresponding data in the tables 3 and 4, we can see that the equation (10) expresses the preexponential constant satisfactorily, but less correct than the equations (8) and (9). The last ones have one advantage more : the fusion temperatures, which are in preexponential constant expressions, are much more available and more correctly known than the vaporization heats. As far as the melting atomic volume is concerned, it can be evaluated from the atomic radii too, as we mentioned above.

Table 6

The preexponential constants and activation energies calculated by means of Eyring's equation

Element	ΔE_{vap}, cal/gatom	A × 10^8, $g^{1/3}$ cm s^{-1} grad$^{-3/2}$		E, cal/gatom

Co[23]	91,400[6]	0.605	0.281	13,842

Da C. Andrade[32] was the first who introduced in the viscous flow treatment the vibration of the liquid particles with constant frequencies, comparable with those of solid particles. He suggests the following relation for the viscosity calculation of simple liquids, at the melting point :

$$\eta_M = 5.7 \times 10^{-4}(A T_M)^{1/2} \, V_M{}^{-2/3} \tag{11}$$

A is atomic weight, while T_M and V_M are melting temperature and volume. In the numerical part there is contained the Lindemann's constant, taken by Andrade as 3.1×10^{12}. The equation (11) is obeyed by six normal metals and Ar; the abnormal metals — Sb, Bi and Ga — have deviations too.

---

[32] E.N. da C. Andrade, *Phyl. Mag.* **17**, 497 (1934) ; *Proc. Roy. Soc.*, **215 A**, 36(1952) ; ***Endeavour***, **13**, 117 (1954).

Starting from the Eyring's significant structures theory[33] and ascribing the vibratory motion to a fraction of the whole number of liquid particles and the translation motion for the rest, Misra[34] obtained a new equation for the liquid viscosity coefficient:

$$\eta = \eta_1 \left(\frac{T}{T_1} \right)^{1/2} \frac{1 - e^{-2\theta\left(T_1^{1/2} - T_m^{1/2}\right)}}{1 - e^{-2\theta\left(T^{1/2} - T_m^{1/2}\right)}}, \tag{12}$$

in which T_m and θ are two adjustable constants; T_m represents the temperature at which all the molecules have only vibratory motion and is slightly less than the ordinary melting point.

The equation (12) may be reduced to a simpler one, with only one adjustable parameter, T_m. The results for Na, Hg, Sn and Sb prove that the Misra's equation leads to values which are in good agreement with experimental ones.

Nachtrieb[35] also used the particle vibration in the treatment of the diffusion in liquid metals, to obtain a relation for calculating the melting selfdiffusion coefficient. More details are to be seen in the original work.

SUR LA VISCOSITÉ DES SYSTÈMES MIXTES : EAU-MONOÉTHYLÈNEGLYCOL, EAU-MONOÉTHANOLAMINE ET EAU-DIMÉTHYLESULFOXYDE

L'INFLUENCE DE LA TEMPÉRATURE ET DES SELS SUR LA VISCOSITÉ DE CES SYSTÈMES

ORTANSA LANDAUER, G. COSTEANU et CORNELIA MATEESCU
Chaire de Chimie Physique, Institut Polytechnique, Bucarest, 132, Calea Griviţei

Reçu le 1er novembre

Les auteurs ont étudié la viscosité des systèmes mixtes : eau-monoétylèneglycol, eau-monoéthanolamine et eau-diméthylesulfoxyde à différentes concentrations et à des températures de 20° à 50°. On a tiré des conclusions sur la variation de la viscosité avec la température, ainsi que sur l'influence des sels dissous.

Les solvants mixtes sont souvent utilisés comme milieu de réaction pour l'étude de l'influence de la constante diélectrique et de la viscosité du solvant sur la vitesse de réaction. Ils sont également utilisés comme agents de réfrigération.

La viscosité étant une des propriétés les plus importantes des liquides, parce qu'elle permet de tirer des conclusions sur leur structure, il nous a semblé intéressant d'étudier les systèmes mixtes mentionnés plus haut.

Les substances étudiées par nous, bien purifiées par distillation fractionnée, ont les caractéristiques suivantes :

	P. ébull°C	n_{20}^{D}
Monoéthylèneglycol-MEG	197,4	1,4318
Monoéthanolamine -MEA	171,0	1,4539
Diméthylesulfoxyde-DMSO	189,0	1,4785

Les mesures des viscosités ont été réalisées avec un viscosimètre Ubbelohde pour différentes concentrations des systèmes eau-constituant organique, aux températures de 20°, 30°, 40° et 50°.

Pour le calcul des viscosités en valeurs absolues, évaluées en cP, nous avons déterminé aussi les densités des différents mélanges aux températures déjà mentionnées.

Les énergies d'activation de l'écoulement visqueux ont été calculées par la méthode des moindres carrés.

Les viscosités des mélanges des systèmes étudiés par nous, ainsi que les énergies d'activation sont réunies dans les tableaux 1, 2 et 3.

La variation de la viscosité des mélanges liquides est en rapport principalement avec le changement de volume au moment du mélange. C'est pourquoi il nous a semblé intéressant de calculer les volumes molaires des systèmes eau-MEG et eau-MEA à 20°, dont les valeurs sont réunies dans les tableaux 6 et 7.

Tableau 6

Valeurs des densités et des volumes molaires du système eau-MEG à 20°

X_{MEG}	$d_{20^\circ \text{g/ml}}$	V cm^3
0,035	1,0124	19,416
0,074	1,0266	20,727
0,120	1,0402	22,431
0,176	1,0551	24,390
0,322	1,0776	29,868
0,556	1,0976	38,725

Tableau 7

Valeurs des densités et des volumes molaires du système eau-MEA à 20°

X_{MEA}	$d_{20^\circ \text{g/ml}}$	V cm^3
0,070	1,0070	20,863
0,165	1,0179	24,666
0,304	1,262	30,302
0,620	1,0255	42,975
0,803	1,0403	50,556

Nous avons calculé aussi les volumes partiels molaires d'excès des systèmes eau-MEG et eau-MEA en fonction de la fraction molaire, dont les valeurs sont portées sur les figures 1 et 2.

On voit que $\overline{V}^E_{\mathrm{MEA}} > \overline{V}^E_{\mathrm{MEG}}$.

L'influence de la composition des solvants mixtes sur l'énergie d'activation de l'écoulement visqueux est représentée graphiquement dans les fig. 3, 4 et 5.

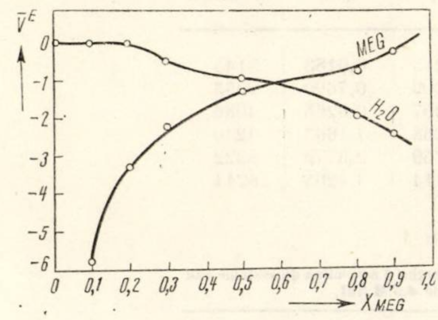

Fig. 1. — Volumes partiels molaires d'excès des mélanges eau-MEG en fonction de X_{MEG}.

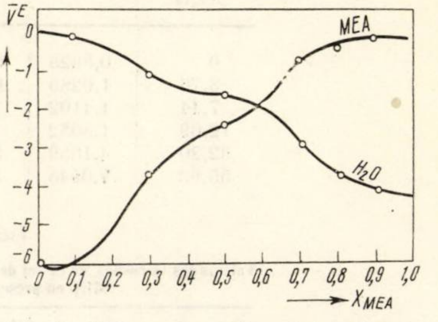

Fig. 2. — Volumes partiels molaires d'excès des mélanges eau — MEA en fonction de X_{MEA}.

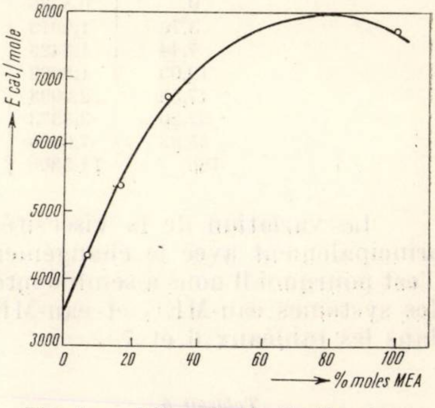

Fig. 4. — L'énergie d'activation du système eau-MEA en fonction de X_{MEA}.

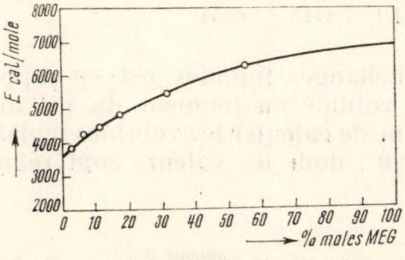

Fig. 3. — L'énergie d'activation du système eau-MEG en fonction de X_{MEG}.

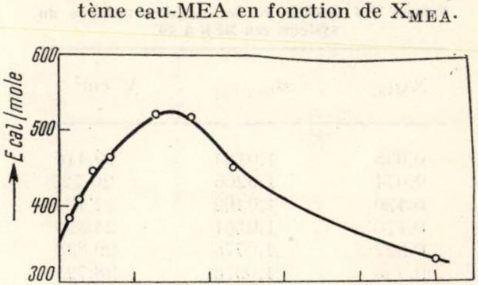

Fig. 5. — L'énergie d'activation du système eau-DMSO en fonction de X_{DMSO}.

On voit sur les tableaux 1, 2 et 3 que la viscosité du système eau-MEG croît régulièrement avec la concentration du constituant organique du solvant mixte, alors que pour les systèmes eau-MEA et eau-

DMSO elle passe par un maximum, d'autant plus marqué que la température est plus basse. Ce maximum est attribué à des interactions assez fortes entre les molécules de l'eau et les molécules du constituant organique du système. Une élévation de température, qui favorise l'agitation thermique, diminue dans tous les cas ces interactions.

L'existence de ces interactions dans le système eau-DMSO a été mise en évidence aussi par d'autres méthodes, à savoir la densité d'excès, l'indice de réfraction [1,2] et la cinétique chimique.[3]

Nous pouvons donc admettre que le système eau-MEA doit présenter également, au maximum de la viscosité, une structure privilégiée à laquelle on attribue le maximum de la courbe $E=f\ (X_{\mathrm{MEA}})$.

La variation toujours croissante de la courbe $E=f\ (X_{\mathrm{MEG}})$, du système eau-MEG, ne justifie pas l'existence d'une structure spécifique des molécules, comme on l'admet pour le système eau-MEA.

On voit, d'autre part, d'après l'allure des courbes $\bar{V}^E=f(X)$ qu'il y a une différence assez nette entre les deux systèmes.

On constate aussi, d'après les valeurs des énergies d'activation, que les interactions eau-MEA sont bien plus fortes que les interactions eau-MEG ; on a donc $E_{\mathrm{MEA}} > E_{\mathrm{MEG}}$.

En admettant que seules les molécules libres rendent compte de l'écoulement visqueux, et que d'après Miller[4,5] ces molécules représentent «le volume libre», on peut supposer qu'au maximum de la viscosité il y a un très petit nombre de molécules libres dans le système.

La viscosité toujours croissante du système eau-MEG pourrait être attribuée à une augmentation des molécules liées.

La présence des sels-NaCl et NaI — dans le système eau-MEG ne modifie pas sensiblement la viscosité du système.

HIGH-TEMPERATURE THERMODYNAMIC DATA FOR SOME URANIUM OXIDES WITHIN THE RANGE $UO_{2.25}-UO_{2.60}$

D.I. MARCHIDAN and SPERANȚA TĂNĂSESCU
Institute of Physical Chemistry
str. Galati 31, Bucharest

Received April 22, 1974

The two-phase region $U_4O_9 + U_3O_{8-y}$ is investigated. The electromotive force measurements on solid electrolyte galvanic cells have been carried out in order to obtain thermodynamic data for $UO_{2.46}$ and $UO_{2.50}$ uranium oxides. The partial molar free energies, enthalpies and entropies of solution of oxygen in uranium oxides and the corresponding integral quantities as a function of temperature, as well as the equilibrium pressures of oxygen over the oxides have been calculated.

INTRODUCTION

The phase relationships in the uranium-oxygen system have been studied by many scientists. But, owing to the complexity of this system the numerical information is still incomplete.

A consistent set of thermodynamic values for nonstoichiometric uranium oxides and more data on the limits of the UO_{2+x}, U_4O_9, U_3O_{8-y} phases are required.

In previous papers[1-3] we have related the values of the thermodynamic properties of some uranium oxides with nonstoichiometric compositions which are found disproportioned in two phases within certain temperature ranges. The method used was that of electromotive force measurements on high temperature galvanic cells with solid electrolyte.

The present paper extends the study on some nonstoichiometric uranium oxides that are part of the two-phase region $U_4O_9 + U_3O_{8-y}$. Thus, the oxides $UO_{2.46}$ and $UO_{2.50}$ were studied within a 1123–1373 K temperature range. The determinations were made with a high-temperature galvanic cell of the type :

Fe, wüstite/(0.85 ZrO_2 + 0.15 CaO) / uranium oxide.

[2] D.I. Marchidan and S. Matei, *Rev. Roumaine Chim.*, **17**, 9 (1972).

[3] D.I. Marchidan and S. Matei-Tănăsescu, *Rev. Roumaine Chim.*, **18**, 1681 (1973).

EXPERIMENTAL

The cell assembly consisting of the electrolyte tablet between the two electrode tablets was inserted into a quartz cell, the form and construction of which have been previously shown[4,5].

The electromotive force measurements were carried out in a vacuum installation at the residual gas pressure of about 133.322×10^{-6}N.m^{-2}. The apparatus, the experimental procedure and the techniques of preparing the tablets were also minutely described in the above mentioned papers[4,5].

RESULTS AND DISCUSSIONS

The nonstoichiometric oxides $UO_{2.46}$ and $UO_{2.50}$ were studied in the temperature range of 1123–1373 K. The electromotive force values for these compositions were practically identical indicating the presence of a two-phase region.

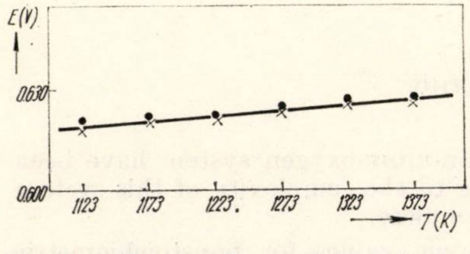

Fig. 1. — The variation of EMF with the temperature for $UO_{2.46}$ and $UO_{2.50}$

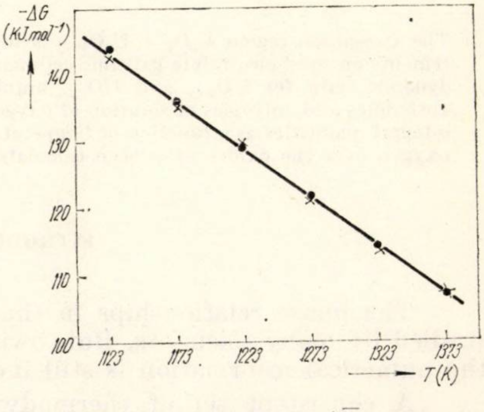

Fig. 2. — The variation of $\Delta\overline{G}_{O_2}$ with the temperature for $UO_{2.46}$ and $UO_{2.50}$

The partial molar free energy of oxygen in equilibrium with the uranium oxide $\Delta\overline{G}_{O_2}$ may be calculated by combining equations (1) and (2):

$$\Delta G_{cell} = -4\mathscr{F}E \tag{1}$$

$$\Delta G_{cell} = 2\,\Delta G^\circ \text{ wüstite } - \Delta\overline{G}_{O_2} \tag{2}$$

where ΔG° wüstite is the standard Gibbs free energy of formation of wüstite in equilibrium with iron and ΔG_{cell} is the measured free energy change of the cell.

[4] D.I. Marchidan and S. Matei, *Rev. Roumaine Chim.*, **15**, 1491 (1970).

[5] D.I. Marchidan and S. Matei, *Studii şi Cercetări Chim. Acad. R.S.R.*, **18**, 617 (1970).

Figure 2 illustrates that the shape of the curve obtained when $\Delta\overline{G}_{O_2}$ is plotted against T for the two-phase region is the same for these oxides. As the phase diagram of uranium-oxygen system[6,7] shows, this is the two-phase region $U_4O_9 + U_3O_{8-y}$. Considering the components in uranium oxide of any composition as UO_2 and O_2, the composition of the oxide is determined by the mole faction N_{UO_2} or N_{O_2}. The evaluation of the relative integral molar free energy ΔG and of the relative integral molar free energy per gram atom of uranium was made numerically from equation :

$$\Delta G = (1-N_{O_2})\int_{O}^{N_{O_2}} \frac{\Delta\overline{G}_{O_2}}{(1-N_{O_2})^2}\, dN_{O_2} \tag{3}$$

[6] L.E.J. ROBERTS and A. WALTER, *J. Inorg. Nuclear Chem.*, **22**, 213 (1961).

[7] M.H. RAND and O. KUBASCHEWSKI, "The Thermochemical Properties of Uranium Compounds" Oliver and Boyd, Edinburgh, 1963, p. 26.

In tables 1 and 2 the thermodynamic data for $UO_{2.46}$ and $UO_{2.50}$ uranium oxides are presented. One observes that similar to the two-phase region $UO_{2+x}+U_4O_9$, the values of partial molar free energies practically do not change with composition.

The data on the thermodynamic properties of $UO_{2.28}$, $UO_{2.30}$, $UO_{2.371}$, $UO_{2.53}$ uranium oxides were reported in previous papers[1,3]. The values obtained for $UO_{2.46}$ and $UO_{2.50}$ are practically identical with those obtained for the above mentioned oxides indicating that the six oxides are part of the same two-phase region.

To ilustrate this, the values of relative partial molar free energy and of equilibrium oxygen partial pressure as a function of composition at 1073 K are plotted in fig. 3.

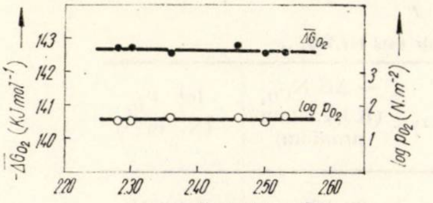

Fig. 3. — The variation with uranium oxide composition of relative partial molar free energy $\Delta\overline{G}_{O_2}$ and equilibrium oxygen partial pressure at 1073 K.

A considerable number of experimental measurements have been made by different methods on the two-phase regions and on their phase limits.

A concluding discussion on the $U_4O_9 - U_3O_8$ two-phase region may characterize this region. Although the upper and lower limits are not yet precisely known, the results for the two-phase regions tend to be in better agreement than those for single-phase regions because very small composition differences do not influence the thermodynamic properties.

Rand and Kubaschewski[7] studied the $U_4O_9-U_3O_8$ region from 298—1395 K. They accepted the results of Roberts and Walter [6] who had showen that the U_4O_9 phase decomposes peritectically at 1396 ± 5 K into U_3O_8 and UO_{2+x}.

Later results by Markin[8] and by Kiukkola[9] are in excellent agreement up to 1373 K. The region close to U_4O_9 has been studied by Kiukkola, who interprets his results as showing the U_4O_9 phase persisting up to 1488 K.

Kiukkola places the upper limit of the U_4O_9 phase at $O/U = 2.250$ because the results regarding this composition and $O/U = 2.300$ were identical, and in excellent agreement with Roberts and Walter's, who measured the identical pressures for the compositions $O/U = 2.250$, 2.257, 2.279 and 2.303. Blackburn's rather scattered results[10] for this phase limit determined by the interpolation of the effusion-cell measurements give higher values.

---

[8] T.L. Markin, L.E.J. Roberts and A. Walter, "Thermodynamics of Nuclear Materials", Ed. IAEA, Vienna, 1962, p. 693.

[9] K. Kiukkola, *Acta Chem. Scand.*, **16**, 327 (1962).

[10] P.E. Blackburn, *J. Phys. Chem.*, **62**, 897 (1958).

The lower limit of the U_3O_{8-y} phase is not much affected by the changes in temperature from 870 to 2000 K and it was reported by Biltz and Müller[11] as $UO_{2.607}$ at 1273 K and by Blackburn[10] as $UO_{2.607}$ to $UO_{2.616}$ at 1125 K to 1399 K, as suggested by the equilibrium measurements.

The results of Markin and Roberts indicate that the limiting composition is constant from 1396 to 873 K and probably nearly so from 1723 to 873. We have accepted the limit as $UO_{2,61}$ from 873 to 1473K[8].

The thermodynamic values given by Rand and Kubaschewski for this region are : At 298–1395 K ($U_4O_9-UO_{2.6}$) :
$\Delta\bar{H}_{O_2} = -304.595$ KJ. mol.$^{-1}$; $\Delta\bar{S}_{O_2} = -0.147$ KJ. mol^{-1} grad^{-1} and at 1395 – 1750 K ($UO_{2+x}-UO_{2.6}$) :
$\Delta\bar{H}_{O_2} = -313.381$ KJ.mol^{-1}; $\Delta\bar{S}_{O_2} = -0.153$ KJ. mol.$^{-1}$ grad^{-1}

Markin's values were combined with earlier values to give (from 873 to 1395 K) :
$\Delta\bar{H}_{O_2} = -328.862$ KJ mol.$^{-1}$; $\Delta\bar{S}_{O_2} = -0.164$ KJ. mol.$^{-1}$ grad^{-1} which are in excellent agreement with Kiukkola's[9] values who finds(from 1073 to 1473 K) :
$\Delta\bar{H}_{O_2} = -322.586$ KJ mol.$^{-1}$; $\Delta\bar{S}_{O_2} = 0.161$ KJ. mol.$^{-1}$ grad^{-1}

Acomparison of these data to our values over $U_4O_9-UO_{2.6}$ region, shows that our results are close to Rand and Kubaschewski's data.

Anyway more data are required on partial molar quantities in the region close to U_4O_9 up to 1473 K and in U_3O_{8-y} region at all temperatures.

We wish to express our deep gratitude to Professor I.G. Murgulescu for his interest in our work and to C. Volcovici, for his help in the construction of equipment.

SPECTRAL STUDY OF DIOXOURANIUM (VI) COMPLEXES WITH AROMATIC SCHIFF BASES

N.S. BIRADAR and T.R. GOUDAR,
Department of Chemistry, Karnatak University, Dharwar-3, India

Received June 26, 1973

A few complexes of dioxouranium (VI) have been prepared with aromatic Schiff bases and characterised by the elemental analysis. With the aid of infrared spectra it has been shown that O—U—O bonds of UO$_2^2$ ion are linear. These complexes are non-electrolytes in DMF and appear to have coordination number six.

INTRODUCTION

In the previous paper on dioxouranium (VI) Schiff base adducts[1] it has been shown that the O-U-O bonds are almost linear. In this paper, we have extended the study to the other aromatic Schiff bases shown below (I—X). While this work was in progress a few papers appeared on the same subject.[2-8] Yamada and Takeuchi[2] have shown that dioxouranium (VI) forms adducts in which the *o*-hydroxy group is the donor.

The present paper deals with the synthesis and spectral studies of dioxouranium (VI) Schiff base adducts.

EXPERIMENTAL

The Schiff bases (I–X) were prepared according to the methods reported elsewhere.[9] Uranyl chloride in ethyl acetate was treated with a slight excess of Schiff base in the same solvent with vigorous shaking. Sufficient time was allowed for the complex to settle. The complex was filtered, washed free from the reagent and dried in vacuum over fused calcium chloride. The dry mass was powdered and extracted in a soxhlet apparatus with ethyl acetate and dried in vacuum over fused calcium chloride.

The complexes were analysed for their uranium, nitrogen and chloride contents.

PHYSICAL MEASUREMENTS

Conductance measurements were made using an ELICO, CM-82, conductivity bridge with a cell having cell constant 0.829 cm^{-1}, manufactured by Electronic and Industrial Instruments Co., Hyderabad. The solutions were prepared in DMF and diluted to the required strength (10^{-3}M).

The i.r. spectra of the ligands and the complexes were obtained on a Perkin Elmer infracord.

RESULTS AND DISCUSSION

The elemental analyses (table 1) show that the Schiff base I—VII form the complexes of 1 : 2 stoichiometry whereas VIII—X form complexes of 1 : 1 stoichiometry.

Table 1

Elemental analysis of the complexes

Lig.N°	Comp.	N° Complex	% U	% N	% Cl

IX	XIX	$(C_{27}H_{22}N_2O_2)UO_2Cl_2$	30.92 (32.51)	3.74 (3.74)	10.15 (9.96)
X	XX	$(C_{29}H_{26}N_2O_2)UO_2Cl_2$	29.90 (30.20)	3.94 (3.59)	8.10 (8.29)

The values given in the parenthesis are calculated values.

All the complexes are intense coloured amorphous substances, insoluble in most of the organic solvents. These are soluble to a limited extent in DMF and DMSO. This limited solubility of the complexes in organic solvents did not permit the determination of the molecular weight. The molar conductance values determined in DMF at the concentration 10^{-3}M indicate that these are non-electrolytes in DMF.

The infrared frequencies along with their assignments are listed in table 2.

In the Schiff bases, the C=N stretch is reported[9] to occur in the region 1630—1600 cm^{-1}. We have assigned a strong band in the region 1620—1600 cm^{-1} to the C=N stretch in the case of Schiff bases I—VI and VIII—X. In the Schiff base VII one can expect to find the stretching frequencies due to C=N, N=N, and C=C. LeFevre and coworkers[10]

have found that aromatic azocompounds show an absorption band around 1570 cm^{-1} and 1406 cm^{-1}. It may be pointed out that the specific assignment of the band to the N=N stretch in aromatic azocompounds is rather cumbersome and it is more difficult in the Schiff base containing N=N group such as VII. It is possible for one to expect bands for N=N, C=N, and C=C stretching vibrations. They may be found as a mixture of C=N + N=N or N=N + C=C. Taking into consideration the assignments done for the Schiff bases, we have assigned the band at 1610 cm^{-1} to ν(C=N) vibration and the band at 1565 cm^{-1} to the mixture of ν (N=N)+ ν(C=C) vibrations. In the complex, the first band appears at 1650 cm^{-1}, while the second is little affected.

In the complexes XI–XX, the band due to the stretch is found around 1645 cm^{-1}. The shift towards the higher frequency observed in all these complexes may be interpreted as a consequence of coordination of azomethine nitrogen to the metal ion. This results in an increase in the bond-order of carbon-nitrogen link.

The broad weak band due to the H-bonded –OH in the region 2700–2600 cm^{-1} of the Schiff bases is retained in the complexes, XI–XIV and XVI–XX. The absence of this band in the ligand V and its complex XV supports our assignments. The phenolic C–O vibration of the bases is not affected even after the complex formation. These observations show that the orthohydroxy group of the Schiff bases has not taken part in the complex formation.

It is known from the literature that uranyl ion possesses three characteristic vibrations,[11] viz., ν_1 sym. 860 cm^{-1}, ν_3 asy. 930 cm^{-1} and ν_2 bend. 210 cm^{-1}.

If UO_2 is not linear, all the three frequencies become active in Raman as well as infrared regions. And if, the UO_2 is linear, ν_2 and ν_3 are infrared active and ν_1 is Raman active. Sacconi *et al.*[12] have studied a number

---

[1] J. Selbin, *Angew, Chem. Internat. Edn.*, **5**, 712 (1966).

[2] L. Sacconi, G. Caroti and P. Paoletti, *J. Chem. Soc.*, 4257 (1958).

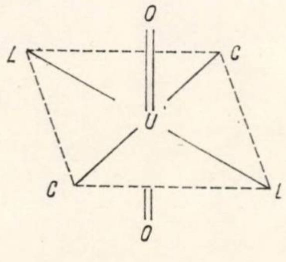
of uranyl salts and complexes. They observed a band in the region 830–828 cm^{-1} and they have assigned it to ν_1 vibration.

Invariably we observe a strong band in all the complexes in the region 925–900 cm^{-1} and it has been assigned to ν_3 vibration. Along with ν_3 band, another band of variable intensity is also found in the region 877–854 cm^{-1}. This band is weak in the complexes XI–XIV, XVIII and is not at all observed in the remaining complexes. This band is assigned to ν_1 vibration. It is in close agreement with the theoretical prediction that the intensity of the ν_3 band should be more than the intensity of ν_1 band.[12]

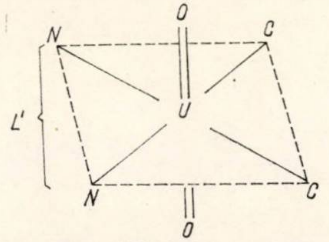
These observations agree well with the concept of almost linear uranyl group disturbed by strong local field.

The Schiff bases V and VI contain two coordinating centres, NH and C=N. It is of interest to know which of the coordination sites takes part in the coordinate bond formation. The infrared spectra of these Schiff bases show a band due to secondary NH vibration around 3330 cm^{-1}. This band in the complexes XV and XVI does not show any splitting indicating that the –NH– of the Schiff bases has not taken part in the complex formation. Similar observations have been made by previous workers in the transition metal complexes.[13,14] By analogy with these observations, it may be concluded that the N=N has not formed the coordinate bond in the case of base VII.

The complexes (XI–XVII) have 1 : 2 stoichiometry and the remaining complexes (XVIII–XX) have 1 :1 stoichiometry. All the complexes are non-electrolytes in DMF. All these observations taken together with spectral data lead to the conclusion that in all the complexes uranium has coordination number six. The complexes may, therefore, be represented in the following way.



L=I–VII



L=VIII–X

ELECTROCHEMICAL BEHAVIOUR OF 18Cr–10Ni STAINLESS STEEL IN ORGANIC ACID SOLUTIONS. I

FORMIC ACID

I. ATANASIU and TEODORA BADEA

Laboratory of Electrochemistry and Corrosion, Polytechnic Institute, str. Polizu 1,
Bucharest, Romania

Received October 26, 1973

Anodic, cathodic and potential/time studies for 18Cr – 10Ni stainless steel in formic acid of 10–80% concentration in aerated and deaerated solutions have been made by the potentiostatic method. The corrosion stability of 18Cr–10Ni stainless steel decreases with increasing formic acid concentration to a minimum value at 40% and then increases again. At 40% formic acid the characteristic currents – i_{corr}, i_{crit}, i_p – have shown maximum values.

The organic acids are used today in the chemical industry both in synthesis and for acid pickling of metal surfaces.

However, experimental data on the corrosion resistance of metals and alloys to organic acids as well as on the corrosion mechanism in their solutions are rather scarce.

The corrosion problems associated with the production and use of organic acids have been investigated by Bourrat,[1] Dillon [2] and Teeple.[3] The use of organic acid solutions for the pickling of ferrous materials and for the chemical cleaning of plants has been discussed by several authors.[4,5,6]

The corrosion behaviour of stainless steels in aqueous solutions is characterized by the marked tendency of the alloys to exhibit passivity. The anodic polarization measurements under potentiostatic conditions, including the primary passive potential, E_p, the critical anodic current density, i_{crit}, and the passive current density, i_p, are very important for the evaluation of the corrosion resistance of metallic materials.

Although the anodic behaviour of stainless steel has been studied in a wide variety of electrolyte solutions, there appears to be little evidence of studies using organic acids.[7,8]

The anodic polarization curve supplies information on the rate of anodic dissolution on the active-passive transitions, on the stability of the passive state and the behaviour of the materials in oxidizing medium. However, this information alone is insufficient to determine the active corrosion of the materials. In such a case, the cathodic polarization curve becomes indispensable, since the effect of the hydrogen overvoltage may become the decisive factor in determining the rate of active corrosion.

The present study has been confined to the effect of formic acid solutions of various concentrations on anodic and cathodic behaviour of 18Cr – 10Ni stainless steel under potentiostatic conditions.

EXPERIMENTAL

The stainless steel electrodes (18 %Cr ; 10 %Ni ; 0.04 % C ; 0.33 % Si), having the form and size indicated in fig. 1, were prepared from a band which was homogenized at 1050° for one hour and water-quenched. Specimens were wet polished with 3/0 emery paper, washed with carbon tetrachloride, followed by pickling for 5 minutes in a solution containing 15 % HNO_3, 2 % HF by volume at 60°. [9]

The solutions were prepared using chemically pure reagents and doubly-distilled water. The concentration of solutions of formic acid are expressed as % vol. For polarization studies in the absence of oxygen, the solutions were deaerated for 3 hours using prepurified nitrogen.

An all-glass cell was used for polarization studies (fig. 1).

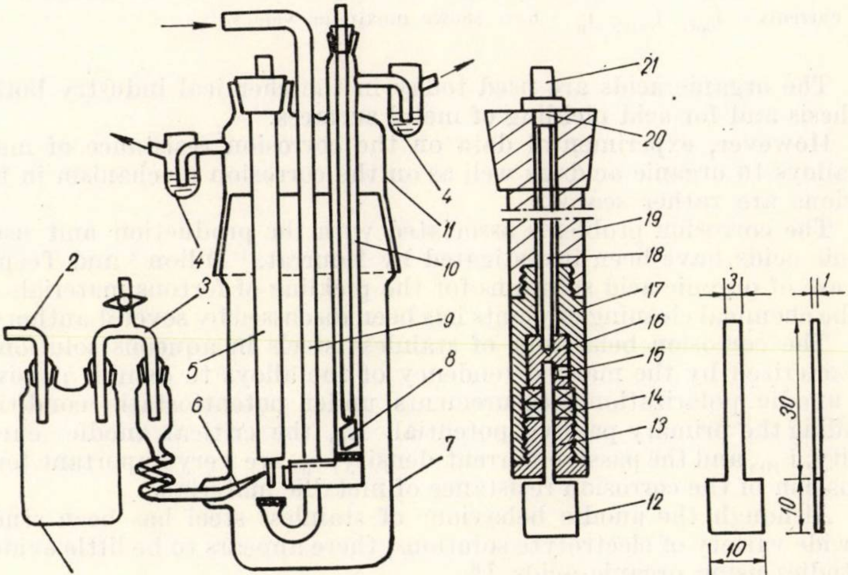

Fig. 1. – Schematic diagram of polarization cell (*a*) and electrode assembly (*b*) : *1*, intermediate vase with working solution ; *2*, electrolytic bridge with a saturated solution of KCl and agar-agar ; *3*, electrolytic bridge with working solution ; *4*, hydraulic close ; *5*, working electrode assembly ; *6*, Luggin probe ; *7*, cell ; *8*, Pt electrode ; *9*, gas bubbler ; *10*, counter-electrode space ; *11*, cover of the cell ; *12*, working electrode ; *13*, *17*, Teflon cap and rod ; *14*, rubber seal ; *15*, screen ; *16*, copper part ; *18*, copper rod ; *19*, polymethylmethacrylate cone to fit ; *20*, nut ; *21*, contact part.

---

[9] H. P. Leckie and H. H. Uhlig, *J. Electrochem. Soc.*, **113**, 1262 (1966).

The working electrode assembly was eccentrically mounted in the cover of the cell. Thus, the distance between electrode and Luggin capillary probe can be easily adjusted within rather wide limits. The tip of the Luggin probe was positioned about 1 mm from the electrode face. This distance was selected as a compromise designed to avoid shielding of the electrode surface (resulting in potential error) while minimizing the potential drop (IR) between the reference electrode and specimen during testing.

The electrode assembly was made of Teflon (fig. 1*b*) so that the solution studied was in contact only with glass, Teflon and electrode under investigation; this avoided eventual error sources associated with the mounting technique.[10]

For polarization measurements a PS 2 potentiostat was employed using stepwise technique of 40 mV/3 minutes. A standard activation was adopted for all specimens; this consisted of cathodic polarization at −0.8 V for five minutes.

Potential/time measurements have been made with a potentiometer Feussner using as zero instrument a Multiflex Galvanometer with a sensibility of 10^{-9} A/mm. The potentials were determined with reference to a saturated calomel electrode (SCE). All measurements were made at room temperature (23 ± 1°).

EXPERIMENTAL RESULTS

1. *Anodic polarization curves.* The effect of acid concentration on the anodic behaviour of 18Cr − 10Ni stainless steel is shown in fig. 2.

The anodic potentiostatic curves indicate the existence of the three characteristic regions : active, passive and transpassive, for 18Cr − 10Ni stainless steel in all tested solutions. In diluted solutions, 10 and 20% (curves *1* and *2*), one ascertains even the appearance of the secondary passivity at potentials nobler than + 0.850 V/SCE.

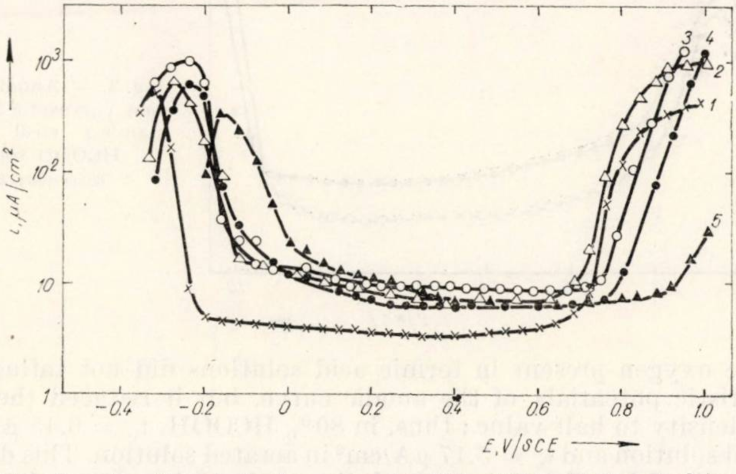

Fig. 2. − Anodic polarization curves for 18Cr—10Ni stainless steel in deaerated formic acid solutions :
1, 10% ; *2*, 20% ; *3*, 40% ; *4*, 60% ; *5*, 80%.

The passivation potential, E_p, showed a pronounced dependence on formic acid concentration, increasing with acid concentration. A similar shift of potential in positive direction was observed also in the transpassive region. Thus, the width of the stable passive region of 18Cr–10Ni stainless steel had the same absolute value in all formic acid solutions, but shifted in the noble potential direction at higher concentrations.

---

[10] N. D. Greene, W. D. France Jr. and B. E. Wilde, *Corrosion*, **21**, 275 (1965).

The critical current density, i_{crit}, increased with increasing acid concentration only over 10% – 40% HCOOH. A decrease in i_{crit} occurred as the acid concentration was increasing from 40 to 80% formic acid.

The passive current density, i_p, registered the minimum value of 3.65 μA/cm² in 10% HCOOH and the maximum value of 8.90 μA/cm² in 40% HCOOH (at the potential of + 0.400 V/SCE).

Thus, in 40% HCOOH solution, 18Cr–10Ni stainless steel showed the maximum current density both in active and in passive state; that is, the solution of 40% HCOOH was found to be the most aggressive. The i_{crit} value of 960 μA/cm² obtained in 40% HCOOH is comparable to the i_{crit} value of 1090 μA/cm² obtained for 18Cr–10Ni stainless steel in 1 N H_2SO_4,[11] while the i_p value in formic acid solution is four times grater than i_p in 1 N H_2SO_4. Accordingly, the passive state of 18Cr–10Ni stainless steel is less stable in formic acid solutions than in sulphuric acid solutions.

In order to evidence the role of oxygen in the corrosion of 18Cr–10Ni stainless steel, potentiostatic anodic curves in aerated formic acid solutions were determined. The general aspect of these curves was similar to the one presented in fig. 3.

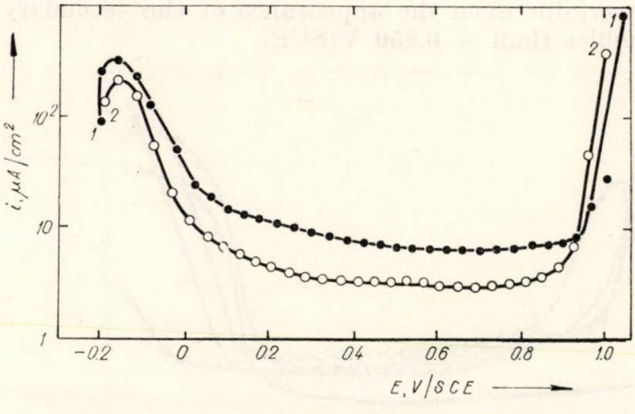

Fig. 3. — Anodic polarization curves for 18Cr–10Ni stainless steel in 80% HCOOH solution: *1*, deaerated; *2*, aerated.

The oxygen present in formic acid solutions did not influence the characteristic potentials of the anodic curve, but it reduced the passive current density to half value; thus, in 80% HCOOH, $i_p = 6.45$ μA/cm² in deaerated solution and $i_p = 3.17$ μA/cm² in aerated solution. This difference was maintained for all formic acid solutions, which shows that the presence of oxygen leads to an increased stability of the passive state of 18Cr–10Ni stainless steel.

2. *Cathodic polarization curves*. Fig. 4 presents the cathodic polarization curves obtained under potentiostatic conditions, in deaerated formic solutions of various concentrations.

---

[11] I. Atanasiu and T. Badea, *Revista de Coroziune*, **2**, 14 (1972).

The cathodic polarization curves have permitted the estimation of active corrosion rate expressed in current units, after Stern's method [12] — the extrapolation of the cathodic polarization curve in the Tafel region by the corrosion potential.

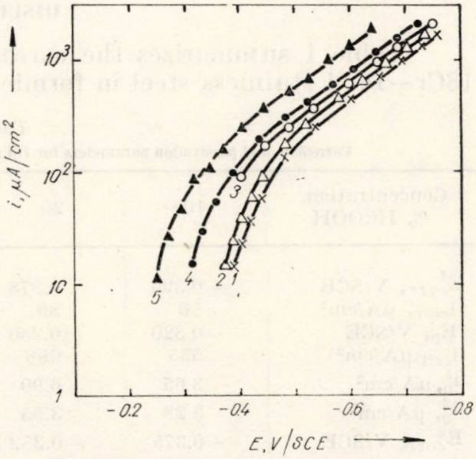

Fig. 4. — Cathodic polarization curves for 18Cr—10Ni stainless steel in deaerated HCOOH solutions :

1, 10% ; *2*, 20% ; *3*, 40% *4*, 60% ; *5*, 80%.

The current corrosion values thus obtained are high (table 1), indicating an appreciable active corrosion of 18Cr—10Ni stainless steel in formic acid solutions. The dependence of the active corrosion rate on formic acid concentration shows a maximum at 40%.

3. *Potential/time curves.* In order to characterize the behaviour of 18Cr—10Ni stainless steel at long immersion there was determined the corrosion potential dependence on time. The results are shown in fig. 5.

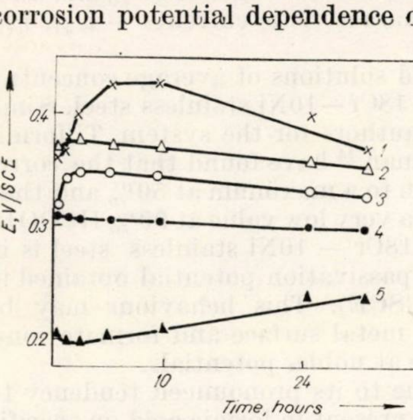

Fig. 5. — Potential/time relationships for 18Cr—10Ni stainless steel in aerated formic acid solutions :

1, 10% ; *2*, 20% ; *3*, 40% ; *4*, 60% ; *5*, 80%.

In the first hours after immersion, the electrode potential shifts to more negative values, indicating a supplementary activation of the 18Cr—10Ni stainless steel surface. After ten hours the potential reaches a minimum value and then it increases slightly, stabilizing itself after approximately 24 hours of immersion.

---

[12] M. Stern, *J. Electrochem. Soc.*, **102**, 363 (1965).

The corrosion potentials for 18Cr–10Ni stainless steel after 72 hours of immersion in 10–80% HCOOH have shown active values lower than the passivation potentials in solutions of the same concentration.

DISCUSSION

Table 1 summarizes the corrosion and passivation parameters for 18Cr–10Ni stainless steel in formic acid solutions.

Table 1

Corrosion and passivation parameters for 18Cr–10Ni stainless steel in formic acid solutions

Concentration, % HCOOH	10	20	40	60	80
E^1_{corr}, V/SCE	−0.390	−0.378	−0.365	−0.300	−0.240
i_{corr}, μA/cm²	56	89	112	75	45
E_p, V/SCE	−0.320	−0.280	−0.240	−0.240	−0.160
i_{crit}, μA/cm²	535	668	960	600	336
i^1_p, μA/cm²	3.65	6.90	8.90	6.50	6.45
i^2_p, μA/cm²	3.28	3.55	4.50	3.24	3.17
E^2_{corr}, V/SCE	−0.375	−0.352	−0.335	−0.305	−0.265

E^1_{corr} – corrosion potential in deaerated solutions; i_{corr} – corrosion current density; E_p – passivation potential; i_{crit} – critical current density; i^1_p – passive current density at E = +0.400 V/SCE in deaerated solutions; i^2_p – passive current density at E = + 0.400 V/SCE in aerated solutions; E^2_{corr} – corrosion potential after 72 hours of immersion in aerated solution.

The corrosion stability of 18Cr–10Ni stainless steel decreases with increasing formic acid concentration to a minimum value at 40% and then increases again. At 40% HCOOH the characteristic currents – i_{corr}, i_{crit}, i_p – have shown maximum values.

The high aggressivity of formic acid solutions of average concentration is not exceptional in the case of the 18Cr–10Ni stainless steel. Similar results were also obtained by other authors for the system Ti/formic acid. [13,14] Thus, Lane, Golden and Acherman [14] have found that the corrosion rate of Ti increases with concentration to a maximum at 50% and then falls rapidly with concentration, reaching a very low value at 90% HCOOH.

In the formic acid solutions the 18Cr – 10Ni stainless steel is in active state at potentials nobler than the passivation potential obtained in sulphuric acid solutions[9] ($E_p = 0.360$ V/SCE). This behaviour may be caused by a certain interaction between metal surface and formate ions, which maintains the metal in active state at nobler potentials.

The stability of stainless steel is due to its pronounced tendency to become passive and adsorption of species present in formic acid on specific metal sites may be important in inhibiting adsorption of species which react to give a passive film. There are considerable evidences for adsorption of formic acid and formates on metal surfaces. [15,16,17]

[17] M. W. Breiter, *Electrochim. Acta*, **8**, 447, 457 (1963).

The nature of formic acid is complex; Martin and Rossotti [18] have obtained equilibrium constants for various species (HA, HA_2^-, H_2A_2, A^-) which exist in solution. For $H^+ + HCOO^- = HCOOH$, $K = 10^{3.9}$ so that undissociated molecules will predominate at low concentration. Increase in concentration of formic acid will increase the concentration of A^-, HA_2^- and H_2A_2 (hydrogen bounded dimers).

It is possible that the specific electrochemical behaviour of 18Cr—10Ni stainless steel is due to the action of different species present in formic acid. It is apparent, therefore, that $HCOO^-$ must be active in the corrosion process and it is significant that the maximum aggressivity was obtained at 40% HCOOH — the concentration which has the highest conductivity.

Although the role of the other species in formic acid solutions is not clear, it is possible that they play an active part in the film-forming process in both the active and passive region. In particular, specific adsorption of formic acid dimers, which becomes more significant with increase in concentration of formic acid, may be important in preventing adsorption of $HCOO^-$.

These considerations might explain why the 40% HCOOH solution has shown the most aggressive character on 18Cr — 10Ni stainless steel.

CONTRIBUTIONS TO THE BISMUTH HYDROLYSIS STUDY. III[1]. ELECTROMETRIC INVESTIGATIONS ON BISMUTHYL PERCHLORATE HYDROLYSIS

C. DRĂGULESCU, ANA NIMARĂ and I. JULEAN
Chemical Research Centre, Bd. Mihai Viteazul, No. 24, Timişoara, Romania

Received February 4, 1974

The equilibria between $Bi_6\ (OH)_{12}^{6+}$ – NaOH, in the pH range 3–10, were studied. The obtained data were rationalized by the direct analysis of the titration curves and by the method of the formation function. On these conditions the presence of the following compounds with the stability constants was identified :

$$9[Bi(OH)_2^+ + 0.44\ OH^-] \rightleftharpoons [Bi_9(OH)_{22}]^{5+} \quad \log K_1 = -2{,}765$$

$$9[Bi(OH)_2^+ + 0.54\ OH^-] \rightleftharpoons [Bi_9(OH)_{23}]^{4+} \quad \log K_2 = -5{,}928$$

$$9[Bi(OH)_2^+ + 0.76\ OH^-] \rightleftharpoons [Bi_9(OH)_{25}]^{2+} \quad \log K_3 = -6{,}701$$

In a previous note[1] we had in view the hydrolysis process which was the result of the pH modification by the simple replacement of the hydrogen ions with sodium in sodium perchlorate medium only till pH 3.

In order to study further the hydrolysis at a greater pH, we followed the effect of the addition of OH^- ions on the bismuthyl perchlorate solutions in the range of pH 3–10.

EXPERIMENTAL

REAGENTS AND APPARATUS

The used reagents were bismuthyl perchlorate, which was obtained by means of the described procedure[2], and sodium hydroxide, Merck *p.a.*

The experimental investigations were carried out with several bismuth concentrations (0.5 –1 M Bi^{3+}) in 0.1 M sodium perchlorate medium.

The determinations consisted in a series of pH-metric and conductometric titrations between bismuthyl perchlorate and sodium hydroxide.

The measurements were carried out on a " Radiometer" pH-meter PHM-25 with a G–202 C glass electrode and on a "Methrom" conductoscop E 369.

[1] Part II : C. DRĂGULESCU, A. NIMARĂ and I. JULEAN., *Rev. Roumaine de Chim.*, **17**, 1181 (1972).

[2] Part I : C. DRĂGULESCU, A. NIMARĂ and I. JULEAN, *Chem. Analit.*, **17**, 631 (1972).

DISCUSSION AND RESULTS

a) The direct analysis of the titration curves.

The results of the pH-metric and conductometric titrations are shown in figs 1 and 2.

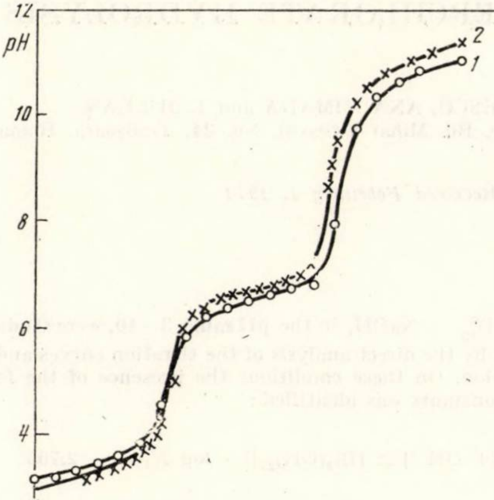

Fig. 1. — pH-titration curves of $BiOClO_4$ with 0.1 M NaOH, $NaClO_4$ 0.1M : 1 — 1M $BiOClO_4$; 2 — 5.10^{-1} M $BiOClO_4$.

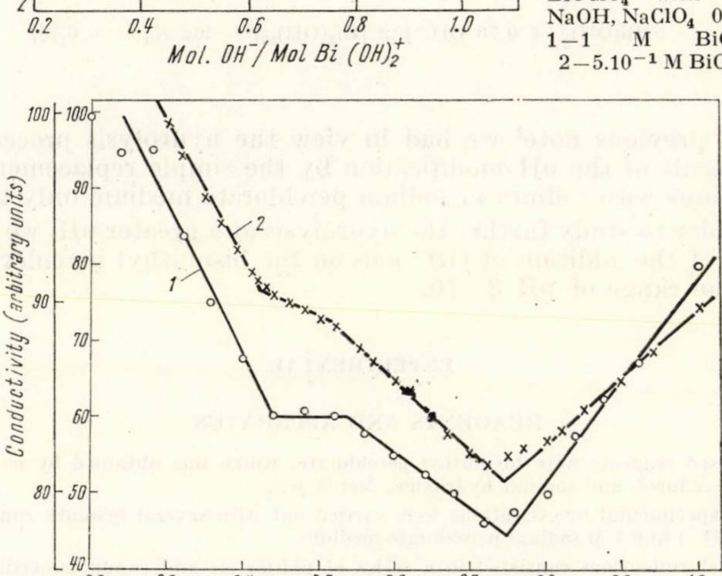

Fig. 2. — Conductometric titration curves of $BiOClO_4$ with 0.1 M NaOH, $NaClO_4$ 0.1 M : 1—1 M $BiOClO_4$; 2—5.10^{-1} M $BiOClO_4$.

It can be seen in fig. 1. the appearance of two inflexions in the ratio $OH^-/Bi(OH)_2^+ = 0.46$ and 0.76 showing the existence of at least two compounds in equilibrium.

The conductometric titration curves (fig. 2) give further information. Until a ratio of 0.42 $OH^-/Bi(OH)_2^+$ is reached, the solution remains clear, the conductibility decreases much enough, perhaps due to the neutralization of the hydrogen ions, which results from the bismuthyl hydrolysis.

Starting with a ratio of 0.44 $OH^-/Bi(OH)_2^+$ one can notice the appearance of an opalescence that increases with the addition of NaOH, the conductibility remaining either constant or decreasing a little to a ratio of 0.54 $OH^-/Bi(OH)_2^+$. In this interval, there is probably an equilibrium between two compounds, one turning into the other. A net precipitation follows, the conductibility decreases to a ratio of 0.76 $OH^-/Bi\ (OH)_2^+$, and it begins to increase thereafter due to the reagent excess.

From the direct analysis of the titration curves we may notice the following facts :

— the general aspect of the titration curves is the same, irrespective of the bismuthyl concentration, this showing that the reactions which take place in the system are also the same ;

— a characteristic feature of the curves of conductometric titration is the fact they have three inflexion points which correspond to the existence of three equilibrium compounds. The pH-metric curves have only two inflexion points, that could be explained by admitting that two of these compounds have close stability constants.

For simplification, considering the bismuthyl in a simple uncondensed form, we may write the following formation reactions :

$$Bi(OH)_2^+ + 0.44\ OH^- \rightleftharpoons [Bi(OH)_{2.44}]^{+0.56} \qquad (1)$$

$$Bi(OH)_2^+ + 0.54\ OH^- \rightleftharpoons [Bi(OH)_{2.54}]^{+0.46} \qquad (2)$$

$$Bi(OH)_2^+ + 0.76\ OH^- \rightleftharpoons [Bi(OH)_{2.76}]^{+0.24} \qquad (3)$$

These compounds correspond to the series[3] :

$$Bi_9(OH)_{22}^{5+} \rightleftharpoons Bi_9(OH)_{23}^{4+} \rightleftharpoons Bi_9(OH)_{25}^{2+}$$

b) The method of the formation curve.

In the case of the polynuclear compounds formation, it is known that the average number of ligands is both $[H^+]$ and $[M]$ dependent.

In the case of hydroxocomplexes, the method of the formation curve developed by Bjerrum[4] and adapted by Ahrland[5] for the special case of the hydrolysis reactions, allows a mathematical treatment of the experimental data.

---

[3] A. Olin, *Acta Chem. Scand.* , **13**, 1791 (1959).

[4] J. Bjerrum, "Metal Ammine Formation", P. Hase and Son, Copenhaga, 1957.

[5] S. Ahrland, *Acta Chem. Scand.*, **3**, 374 (1949).

The average number of ligands, $\bar{n}$, will be determined with the help of relation :

$$\bar{n} = \frac{C_{OH}}{C_M}$$

C_{OH} = the OH ion concentration which is consumed by the formation of the complexes. At a given moment of the titration C_{OH} is given by the relation :

$$C_{OH} = B - C_H + [H^+]$$

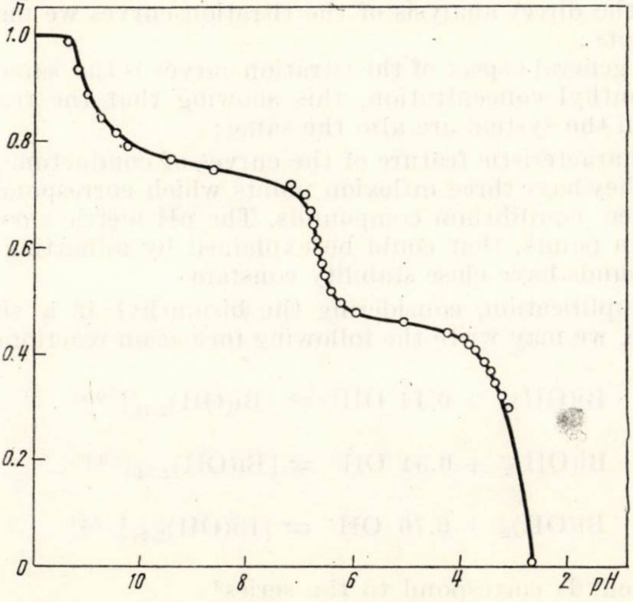

Fig. 3 — The formation curve for the bysmuthyl — OH^- ions in 0.1 M $NaClO_4$.

B = the total amount of the added base,

C_H = initial acid concentration of the solution which can be determined knowing the pH value,

$[H^+]$ = the concentration of the hydrogen ion resulting from the hydrolysis = the concentration of the free OH ions. Taking into consideration that the studied hydrolysis reaction occurs in the pH range 3—10, the concentration of the OH^- ions may be neglected as compared with the amount of the base added.

The experimental data allowed the calculation of $\bar{n}$, by means of which the formation curve $\bar{n} = f$ (pH) was built, as shown in fig. 3.

The approximate values of the stability constants may be read out directly from the diagram at half of the inflexion point.

These approximate constants were then refined with the help of the convergency formula deduced for N = 3[6]:

$$K_1 = [\mathrm{H}^+]\,\frac{\bar{n}}{0.44 - \bar{n}}, \tag{I}$$

$$K_2 = [\mathrm{H}^+]\,\frac{(\bar{n} - 0.44) + \dfrac{\bar{n}[\mathrm{H}^+]}{K_1}}{(0.54 - \bar{n})}, \tag{II}$$

$$K_3 = [\mathrm{H}^+]\,\frac{(n - 0{,}54) + \dfrac{(n - 0.54)\,[\mathrm{H}^+]}{\mathrm{K}_2} + \dfrac{\bar{n}[\mathrm{H}^+]}{\mathrm{K}_1\mathrm{K}_2}}{(0.76 - \bar{n})}. \tag{III}$$

The values of the successive stability constants are shown in table 1.

Table 1

The values of the stability constants as read out of the formation curve compared with the calculated values

Log. Stability constants	Values read out of the formation curve	Calculated value
K_1	− 2.90	− 2.765
K_2	− 5.90	− 5.928
K_3	− 6.70	− 6.701

In conclusion three compounds were identified in solution by pH-metric and conductometric method.

The first compound $Bi_9(OH)_{22}^{5+}$ is already known, the value of the stability constant established in the present paper, being identical with the one given in the literature.

CONTRIBUTION À L'ÉTUDE DE L'HYDROLYSE DE L'URANIUM (VI) EN MILIEU AZOTIQUE

MARIA MAVRODIN-TĂRĂBÎC
Centre de Chimie Physique, 31, str. Galaţi, Bucarest

Reçu le 30 juillet 1973

On étudie, par voie pH-métrique (la méthode de l'analyse mathématique des courbes pH-métriques différentielles, la méthode de la fonction de formation et la méthode « core and links »), la nature et la stabilité des espèces ioniques formées par l'hydrolyse de l'uranium (VI) en milieu azotique. On tire la conclusion que l'hydrolyse de l'uranium en milieu azotique a lieu par une série de réactions dépendantes du pH qui conduisent à la formation des complexes polynucléaires du type « core and links », les espèces ioniques formées étant moins stables dans le milieu azotique que dans le milieu inerte d'acide perchlorique.

Dans des publications antérieures[1,2] on a exposé les résultats obtenus dans l'étude de l'hydrolyse de l'ion UO_2^{2+} en milieu inerte d'acide perchlorique.

Tenant compte de l'importance du milieu azotique, dans ce travail nous nous proposons de déterminer, par voie pH-métrique, la nature et la stabilité des espèces ioniques qui se forment par l'hydrolyse de l'uranium (VI) en milieu complexant d'acide azotique. Il faut mentionner que, dans la littérature de spécialité il n'y a que peu de travaux qui s'occupent de ce domaine. Parmi les plus importants on cite les études sur l'hydrolyse de l'uranium (VI) en milieu de sulfate[3] et d'azotate de magnésium[4].

PARTIE EXPÉRIMENTALE

1. RÉACTIFS ET APPAREILS

— Azotate d'uranyle $UO_2(NO_3)_2 \cdot 6\,H_2O$ (*p.a.* Merck). On a préparé une solution « stock » approximativement 0,1 M, dont on a obtenu, en diluant avec de l'eau bidistillée, les solutions d'azotate d'uranyle de différentes concentrations : 0,05 M ; 0,02 M ; 0,01 M ; 0,001 M. Les concentrations de ces solutions ont été vérifiées par voie gravimétrique (évaporation et calcination à l'état d'oxyde U_3O_8).

— Hydroxide de sodium (*p.a.* Merck). Les solutions utilisées ont été préparées en diluant une solution « stock » approximativement 0,1 M. La concentration des solutions d'hydroxyde de sodium a été établie avec du phtalate acide de kalium.

---

[1] M. Mavrodin-Tărăbîc, *Rev. Roumaine Chim.*, **18**, 73 (1973).
[2] M. Mavrodin-Tărăbîc, *Rev. Roumaine Chim.*, **18**, 609 (1973).
[3] H.S. Dunsmore, S. Hietanen et L.G. Sillen, *Acta Chem. Scand.*, **22**, 2644 (1963).
[4] U. Schedin et M. Frydman, *Acta Chem. Scand.*, **22**, 115 (1968).

Pour les titrages pH-métriques on a utilisé un pH-mètre Radiometer-Copenhagen (électrodes de verre et de calomel). Les déterminations ont été faites dans une installation fermée spécialement construite.

2. MODE DE TRAVAIL

Les déterminations pH-métriques ont été effectuées en titrant les solutions d'azotate d'uranyle avec de l'hydroxyde de sodium. Pour tirer des conclusions sur l'influence de la concentration sur la nature des espèces ioniques qui se forment par l'hydrolyse, on a travaillé avec des solutions d'azotate d'uranyle de différentes concentrations, comprises entre 0,1 — 0,001 M. L'influence de la force ionique a été évaluée en effectuant des déterminations, pour chaque concentration, à quatre forces ioniques : $I = 0{,}5$; 1 ; 1,5 et 2.

Les déterminations ont été faites par le titrage direct de la solution d'azotate d'uranyle avec de l'hydroxyde de sodium. On a travaillé dans un large domaine de pH, les titrages pH-métriques étant considérés terminés à l'apparition d'un précipité stable, de couleur orange, de polyuranate. Les titrages ont été répétés trois fois, les valeurs du pH représentées graphiquement et utilisées dans les calculs étant des valeurs moyennes.

RÉSULTATS ET DISCUSSIONS

L'étude de la nature des espèces ioniques formées par l'hydrolyse de l'ion UO_2^{2+} en milieu azotique a été faite par trois méthodes :

— l'analyse mathématique des courbes pH-métriques différentielles[5] ;

— la méthode de la fonction de formation[6] et

— la méthode « core and links » (ion central — ponts de liaison), caractéristique des complexes polynucléaires [7,8].

1. L'ANALYSE MATHÉMATIQUE DES COURBES pH-MÉTRIQUES DIFFÉRENTIELLES

Tenant compte que les courbes pH-métriques obtenues par le titrage des solutions d'azotate d'uranyle caractérisées par des concentrations variant entre 0,001 — 0,05 M et par les forces ioniques $I = 0{,}5$; 1 ; 1,5 et 2 ont la même allure, on présentera seulement les courbes caractéristiques des solutions 0,02 M (fig. 1).

Ainsi qu'on observe de la figure 1, les courbes de titrage présentent, à toutes les concentrations et forces ioniques, deux points d'inflexion (situés au pH=4,5 — 5 et au pH 6) qui correspondent aux rapports mol. UO_2^{2+} : équivalents de NaOH = 1 : 1,68 (pour la première inflexion) et 1 : 2,36 (pour la deuxième inflexion).

Les rapports $UO_2^{2+} : OH^- = 3 : 5 : 7$ indiquent que les réactions d'hydrolyse en milieu azotique impliquent trois ions UO_2^{2+} et cinq ions OH^- (pour la première inflexion) et trois ions UO_2^{2+} et sept ions OH^- (pour la deuxième) et plaident pour un mécanisme d'hydrolyse qui conduit, à des pH 4,5 — 5, à la formation des ions polynucléaires : $U_2O_5^{2+}$; $U_3O_8^{2+}$; $U_3O_8(OH)^+$; $U_3O_8(OH)$; $U_3O_8(OH)^-$; $U_3O_8(OH)_2^-$ etc. (On mentionne qu'un mécanisme de réaction analogue a été mis en évidence en milieu inerte d'acide perchlorique[1].)

---

La stabilité des ions $U_2O_5^{2+}$ et $U_3O_8^{2+}$ en milieu azotique a été déterminée en utilisant les relations qui expriment le bilan de l'uranium et l'électroneutralité de la solution[1].

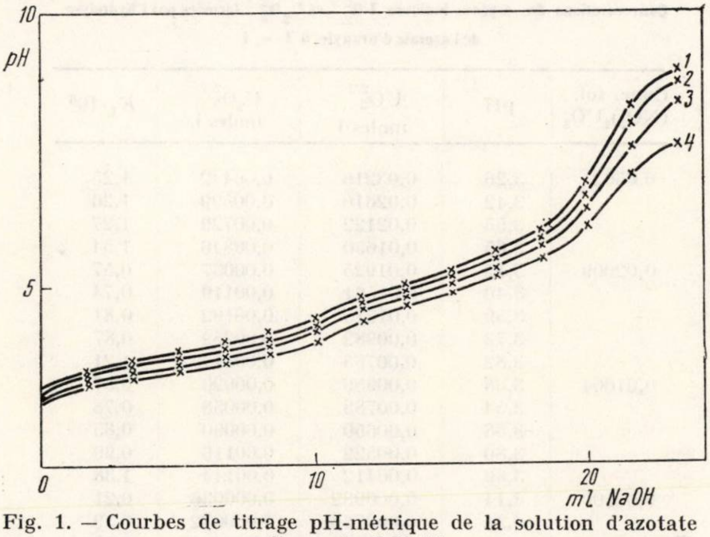

Fig. 1. — Courbes de titrage pH-métrique de la solution d'azotate d'uranyle 0,02 M
1 — I = 0,5 ; *2* — I = 1 ; *3* — I = 1,5 ; *4* — I = 2.

Les résultats obtenus pour différentes concentrations et forces ioniques sont présentés dans les tableaux 1—4.

Tel qu'on voit dans les tableaux 1—4, la stabilité de l'ion $U_2O_5^+$ est plus grande dans les solutions plus concentrées; la constante K_1 présente, dans le domaine de pH dans lequel on peut considérer que dans la solution coexistent seulement les ions UO_2^{2+} et $U_2O_5^{2+}$, une valeur moyenne d'environ 1.10^{-6}. A un certain pH (3,6—4) on constate une brusque augmentation de la valeur de K_1, ce qui démontre que dans ce domaine de pH il se forme aussi d'autres espèces ioniques qui ne peuvent être négligées.

Dans les figures 2 — 4 on présente quelques-unes des données qui caractérisent la stabilité des ions polynucléaires $U_2O_5^{2+}$ et $U_3O_8^{2+}$ en milieu azotique, en comparaison de la stabilité des mêmes espèces ioniques en milieu inerte[2].

De l'analyse comparative des courbes qui présentent les constantes K_1 et K_2, à différentes concentrations et forces ioniques, on tire la conclusion que la stabilité des polyions $U_2O_5^{2+}$ et $U_3O_8^{2+}$ est plus grande en milieu inerte.

2. L'ÉTUDE DU SYSTÈME AZOTATE D'URANYLE — EAU PAR LA MÉTHODE DE LA FONCTION DE FORMATION

Conformément à cette méthode, la détermination de la nature des espèces ioniques qui se forment par l'hydrolyse en milieu azotique a été faite en calculant $\bar{n}$, le nombre moyen de ligands OH^- liés à l'ion central d'uranyle et en analysant les courbes de la fonction de formation $\bar{n} = f(pH)$, pour les différentes concentrations de l'ion UO_2^{2+}.

La relation fondamentale utilisée dans le calcul a été la suivante :

$$\bar{n} = \frac{C_A - (A)}{C_M} \text{ dans laquelle}$$

C_A = la concentration totale du ligand OH^-, connue dès les données initiales du travail ; C_M=la concentration de l'ion central UO_2^{2+}, également connue dès les données initiales et A = la concentration du ligand « libre » déterminée par la méthode pH-métrique. On mentionne que les données déterminées expérimentalement se rapportent au ligand « libre » $(A) = (OH^-)$ d'une manière indirecte, la quantité mesurée directement étant la concentration des ions H^+ liée à OH^- par la relation : $(OH^-) = K_w(H^+)$.

Ainsi qu'on a démontré dans un travail antérieur[2], $\bar{n}$ dépend seulement de (H^+) si dans le système il ne se forme que des complexes mononucléaires ; $\bar{n}$ dépend tant de (H^+) que de (M) lorsque dans le système il se forme aussi des complexes polynucléaires.

Les données expérimentales et les résultats obtenus par le calcul pour les solutions d'azotate d'uranyle de différentes concentrations et forces ioniques sont présentés dans les tableaux 5 — 8.

	4,22	5,26	5,12	1,020
	4,60	7,02	5,03	1,390

De l'analyse des courbes de formation (fig. 5) qui ne coïncident ni même pour les moindres valeurs de C_M, on tire la conclusion que l'hydrolyse de l'uranium en milieu azotique implique la formation des complexes polynucléaires, ce processus se manifestant même à des dilutions très grandes.

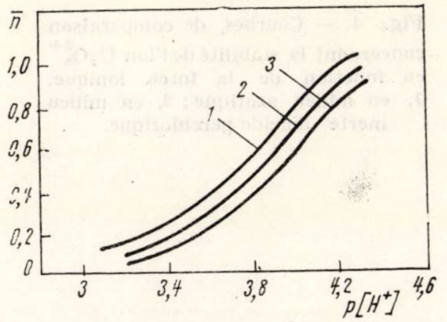

Fig. 5. — Courbes de formation déterminées pour différentes concentrations de la solution d'azotate d'uranyle, à I = 1.
1 — C = 0,05 M ; 2 — C = 0,02 M ; 3 — C = 0,01 M.

3. L'ÉTUDE DU SYSTÈME AZOTATE D'URANYLE – EAU PAR LA MÉTHODE « CORE AND LINKS »

Conformément à cette méthode [7,8], la nature des espèces ioniques formées par l'hydrolyse de l'uranium en milieu azotique a été déterminée en analysant les courbes $Z = f(\log h)_M$, analogues aux courbes $\bar{n} = f(\log h)_M$ (Z représente le nombre moyen d'ions OH^- liés à l'ion central d'uranyle ; h = la concentration des ions d'hydrogène « libres » ; M = la concentration totale des ions UO_2^{2+} libres ou liés dans les complexes).

Du fait que les courbes $Z = f(\log h)_M$ obtenues pour les solutions aqueuses d'azotate d'uranyle sont parallèles on tire la conclusion que l'ion UO_2^{2+} hydrolyse avec la formation des ions complexes polynucléaires du type « core and links » caractérisés par la formule générale $UO_2\,[(OH)_t\,UO_2]_n^{2+}$. La valeur de t ($t = -R = \log M/\log h$) a été établie à l'aide du diagramme $\log M = f(\log h)_Z$ (fig. 6).

Tel qu'on le voit dans la fig. 6, les droites sont parallèles et se caractérisent par une pente $\log M/\log h = 2$, ce qui mène à la conclusion que $t = -R = 2$, Z étant fonction de $X = \log M - 2 \log h$.

La valeur de t a été confirmée en représentant les données expérimentales dans le système de coordonnées $Y = Z/2 = f(X)$ (fig. 7).

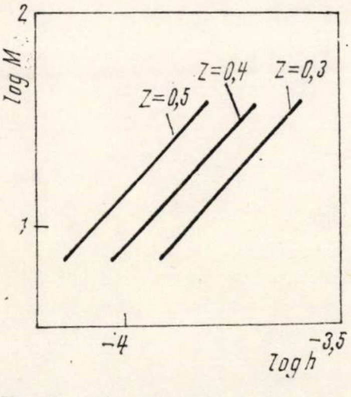

Fig. 6. — La détermination de la valeur de t caractéristique des complexes polynucléaires formés par l'hydrolyse de l'uranium en milieu azotique.

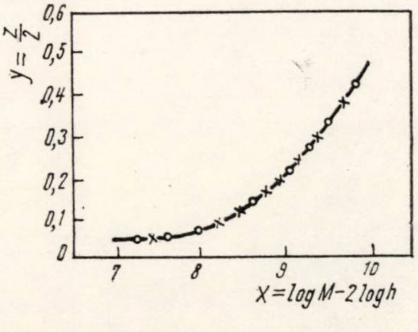

Fig. 7. — Diagramme $Y = f(X)$ caractéristique des complexes polynucléaires formés par l'hydrolyse de l'uranium en milieu azotique.
x – 0,05 M ; o – 0,025 M.

Du fait que les courbes $Y = f(X)$, obtenues pour les solutions d'azotate d'uranyle 0,05 et 0,025 M, se superposent, on tire la conclusion que la valeur de t est correcte et que la formule générale des complexes formés par l'hydrolyse de l'azotate d'uranyle est : $UO_2[(OH)_2UO_2]_n^{2+}$. (Ce processus est analogue à celui que nous avons mis en évidence, dans un travail antérieur, en milieu inerte.)

CONCLUSIONS

1. L'étude de l'hydrolyse de l'ion UO_2^{2+} en milieu azotique a démontré que cette réaction conduit à la formation d'une série de complexes polynucléaires caractérisés par la formule $UO_2[(OH)_2UO_2]_n^{2+}$.

2. Les premiers termes de cette série, les polyions $U_2O_5^{2+}$ et $U_3O_8^{2+}$, se caractérisent par les constantes de stabilité (valeurs moyennes) $K_1 = 1.10^{-6}$ et $K_2 = 1.10^{-7}$.

3. Les espèces ioniques $U_2O_5^{2+}$ et $U_3O_8^{2+}$ sont moins stables dans le milieu azotique que dans le milieu inerte d'acide perchlorique.

BONDING AND MAGNETIC PROPERTIES IN TETRAKIS PHOSPHINE COMPLEXES OF NICKEL

PATRICK CASSOUX, FERNAND GALLAIS, JEAN-FRANÇOIS LABARRE and
JEAN-MICHEL SAVARIAULT,
Laboratoire de Chimie de Coordination du CNRS, BP 4142, 31030 TOULOUSE CEDEX, France

Received March 8, 1974

The results of the studies on magnetic properties (^{31}P NMR, Faraday effect and Diamagnetism) of some 30 tetrakis phosphine complexes of nickel (0), NiL_4 (L = PXYZ; X, Y, Z = R, OR, F, Cl, Br, Ph, OPh; R = Me, Et, Pr, Bu, Am), are summarized and tentatively related with the bonding in such molecules. A semi quantitative analysis of the NMR data, based on LETCHER's and VAN WAZER's formalism alows approximate Ni-P bond orders to be estimated. The change in the coordination shift, $\Delta_P = \delta(NiL_4) - \delta(L)$, is discussed in terms of electronegativity and steric effect. The magnetooptical data place the complexes studied in the same qualitative order as the ^{31}P NMR studies — and as the magnetic susceptibilities measurements. The observed unexpected decrease of the Ni—P bond rotation may be explained by the following factors: a contribution of the free d-electrons of nickel and the magnetic rotary dispersion related with changes in the energy level on complexation.

For the last twenty years, a considerable number of studies have been devoted to evaluate the electron content of the dative nickel-phosphorus bond in nickel (0) phosphine complexes.

The studies on stability should be quoted first: the observed decreasing stability in the series $Ni(PF_3)_4 > Ni(PCl_3)_4 > Ni(PBr_3)_4$ made Wilkinson[1] suggest that the highly electronegative fluorine is more effective than the chlorine in freeing stable orbitals on phosphorus for use in forming π-bonds with the d-electrons of nickel. In contrast, although the alkoxy group OR is less electronegative than the fluorine, $Ni[P(OEt)_3]_4$ appears to be considerably more stable than $Ni(PF_3)_4$. Additionally to that, Basolo[2] demonstrated from the enthalpies of activation of Ni $[P(OMe)_3]_4$ and $Ni(CO)_4$ that these empirical stability considerations are not always consistent. Finally, Tolman[3] suggested on the basis of phosphorus ligand exchange equilibria studies the important rôle of the steric effects in determining the relative stability of such complexes. Numerous studies using infrared spectroscopy were carried out to throw light on the above problem: the substitution of CO in nickel carbonyl by a weaker π-bonding ligand increases the electron density on nickel which in turn induces a diminution of the CO force constant and frequency.[4] Such a correlation permits a quite consistent description of the π-acceptor character of many ligands, which can be arranged in the following order[5-11]: $PF_3 > PCl_3 > P(OR)Cl_2 > PR_2Cl > P(OPh)_3 > PPh_2Cl > P(OR)_3 > PPh_3 > PR_3$ (R = alkyl). This order rests on the assumption that the $\sigma(P \rightarrow Ni)$ charge transfer remains constant while the $\pi(Ni \rightarrow P)$ one varies. Bigorgne[12] and Angelici[13] adopt the reverse assumption : they obtain the same order as above, except that PF_3 is not the best π-acceptor ligand but the least basic one. Additionally, the anomalous place of the chlorine containing ligands in this series with respect to the electronegativity of chlorine may be noticed.

Some inconsistencies in all these results caused us to prepare and study some 30 nickel (0) phosphine compounds in order to discover whether their magnetic rotation could be related to the extent of the corresponding π-back coordination, i.e. to the multiplicity of the Ni-P bonds. For this purpose we carried out Faraday effect and ^{31}P NMR measurements, as well as magnetic susceptibilities determinations.

The preparation of the NiL_4 complexes ($L = PXYZ$; $X,Y,Z = R, OR, F, Cl, Br, Ph, OPh$; $R = Me, Et, Pr, Bu, Am$) was previously described[14-20] and most of the experimental data are published[14-24] (the data obtained by the various experimental methods for R = Me, Et, Pr, Bu, Am, vary so little to make a separate discussion not justifiable). The purpose of this paper is to summarize and extend the empirical explanations which have been put forward in the hope that they will bring a step nearer a really quantitative approach.

^{31}P NMR SPECTROSCOPY

The ^{31}P chemical shifts of the free ligands, δ(L), and of the complexes, δ(NiL_4), were determinated on a Perkin-Elmer R—10 spectrometer at 24.29 MHz, P_4O_6 being used as external reference. [20–23]

It might be expected on first consideration that the "coordination shift", $\Delta_p = \delta(NiL_4) - \delta(L)$ – which changes drastically throughout the series (Table 1) – should parallel the magnitude of the electronic shielding introduced by the coordination, which in turn should increase with the extent of the back-coordination. It is clear however that such an elementary interpretation is not valid for the following reasons :

Table 1

^{31}P coordination shift, $\Delta_p = \delta(NiL_4) - \delta(L)$, of NiL_4complexes

N°	COMPOUND	Δ_p	Ref.
1	$Ni(PMe_3)_4$	−41.1	3

* present work

a Δ_p not determined, because of extensive dissociation in solution.

(i) because Δ_p decreases steadily in the series $Ni(PBr_3)_4$, $Ni(PCl_3)_4$, $Ni[P(OR)_3]_4$, $Ni(PF_3)_4$* (figure 1) when the electronegativity of the atoms or groups linked to phosphorus increases, i.e. when the order of the Ni-P bond is also liable to increase ;

(ii) because even the Δ_p values of $Ni(PMeCl_2)_4$ and $Ni(PMe_3)_4$ do not fit the correlation (figure 1).

---

* The Δ_p values of the aromatic complexes were not plotted on figure 1 because the electronegativity of the aromatic group is not so well defined in the literature and is difficult to estimate ([21] and references quoted therein).

In fact, Δ_p is not only determined by the $d_\pi - d_\pi$ back-coordination (Ni→P) but also by the direct σ-coordination (P→Ni), by anisotropy, hybridization factors, etc ....[25-26]

Moreover, in the chemical shift itself, the screening constant, σ, appears to be the sum of three terms which may be called the diamagnetic, the paramagnetic and the anisotropy terms :

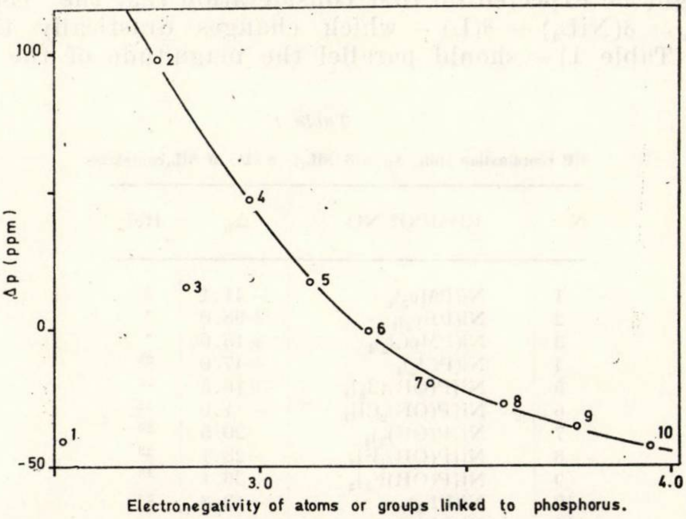

Fig. 1. — Plot of Δ_p, coordination shift of NiL_4 complexes vs. electronegativity of atoms or groups linked to phosphorus.

$$\sigma = \sigma_{dia} + \sigma_{para} + \sigma_{anisotropy}$$

According to Letcher and Van Wazer,[27] the diamagnetic term which accounts for the electronic shielding of the ^{31}P nucleus is by far less important than the paramagnetic one, the latter being due to the mixing of low lying excited states with the ground state; the third term (anisotropy) is negligible.

The formalism of Letcher and Van Wazer of the paramagnetic term leads to the following expression for the total number, n_π, of electrons in the phosphorus d orbitals :

$$n_\pi = \frac{-\delta + 11941.5 - 7940\,\zeta_1}{149.8};$$

δ is the chemical shift of a quadruply connected phosphorus nucleus (table 2) and 11941.5, 7940, 149.8 are semi-empirical coefficients.

[27] J.R. Van Wazer and J.H. Letcher "Topics in Phosphorus Chemistry", vol. 5, J. Wiley, New York, 1967, p 75—167.

The ζ_1 term is a function of two factors :

(i) the electronegativities of the atoms or groups linked to phosphorus,

(ii) the bond angles $\theta = ZPZ$ and they may be calculated or estimated from graphs.[27]

* present work.

The ζ_1 term cannot however be very accurately estimated, as the ZPZ angles are not accurately known, and hence, the n_π values we have calculated for five standard symmetrical NiL_4 molecules are only approximate. However, even when the values of θ vary somewhat from one complex to another (figure 2), the NMR results nevertheless permit a definite order of classification with regard to the n_π values and therefore to the multiplicity of the Ni-P bond, the PF_3 derivatives having the highest bond order and the PMe_3 derivatives the lowest. The total bond order approximately from 2 to 1.

Obviously, the negative n_π value for $Ni(PMe_3)_4$ is not significant and it results, as stated by Letcher and Van Wazer themselves[27] (p. 191), from the approximation of the method.

The overall picture is that which would be expected : the tendency of phosphorus to attract the d-electrons of nickel increases with the former's formal positive charge which is at its maximum when the electronegativity of the ligands is the highest ; i.e. in $Ni(PF_3)_4$.

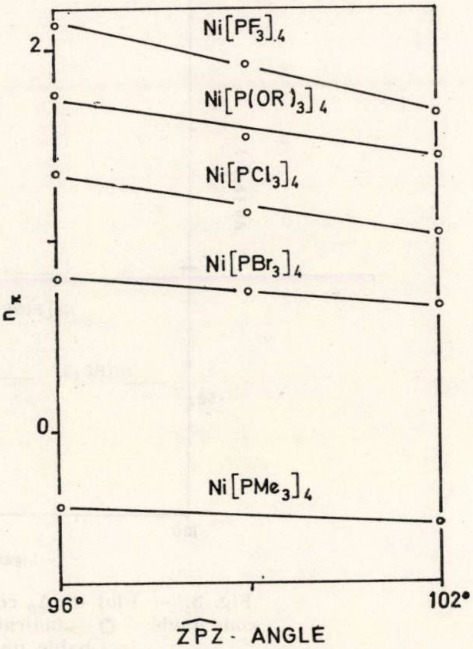

Fig. 2. — Plot of n_π values calculated for some $Ni(PZ_3)_4$ complexes vs. ZPZ angle.

It nevertheless remains true that the variations of the Δ_p values are not consistent with the results of the above semi-quantitative analysis. Reddy and Schmutzler suggested earlier that the surprising Δ_p value of $Ni(PCl_3)_4$ could be due to large changes in hybridization and bond angles on complexation[26]. This explanation was further extended by Tolman who emphasized (on the basis of ^{31}P NMR studies) the important role of steric effects in determining the ligand exchange equilibria in such complexes, and proposed a quantitative measure of these effects based on the determination of "ligand cone angles".[3] Similar ligand exchange equilibria studies, based on the ^{31}P NMR studies carried out by us,[21] led to the following classification of the aromatic complexes:

$$Ni[P(OPh)F_2]_4 > Ni(PPhF_2)_4$$

$$Ni[P(OPh)Cl_2]_4 > Ni(PCl_3)_4 > Ni(PPhCl_2)_4.$$

This confirms that the stability of these complexes decreases, with the increasing size of the ligand.

Moreover, UV spectroscopic[28] and NMR studies[3,20] show that $Ni(PPh_3)_4$ and $Ni(PPh_2Cl)_4$ (where its ligands are very large) are extensively dissociated in solution.

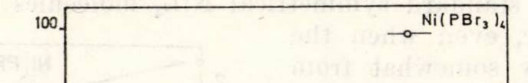

Fig. 3. — Plot of Δ_p coordination shift vs. ligand cone angle —O— indicates the magnitude of probable uncertainty.

We have attempted to correlate the Δ_p values with the ligand cone angles reported by Tolman[3] (figure 3). For many complexes, the greater the ligand cone angle is, the greater the corresponding value of Δ_p. However the surprisingly low Δ_p values for complexes, e.g. $Ni[P(OPh)_3]_4$ ($\Delta_p = -3$) and especially $Ni(PMe_3)_4$ ($\Delta_p = -41$), do not fit in this eventual correlation : Tolman has suggested that these ligands are bulky.[3] This anomalous behaviour of $Ni(PMe_3)_4$ may be due, as noticed by Verkade,[21a] to a possible metal-phosphorus bond shortening of trialkylphosphines complexes ; a shortening of a similar magnitude as for the more electronegative ligands.

FARADAY EFFECT MEASUREMENTS

The magnetic molecular rotations of the ligands, $[\rho]_M$ (L), and of the complexes, $[\rho]_M$ (NiL_4), have been measured, using a previously described apparatus,[29] at 20°C for the yellow wavelength ($\lambda = 578$ nm), either heat if the complexes are liquid, or in solution if they are solid.[14-21] Obviously, the coordination increment $\Delta\rho = \frac{1}{4}\{[\rho]_M(NiL_4) - 4[\rho]_M(L)\}$ is the result of all the electronic and geometric changes occurring on coordination and a classical magnetooptical analysis of these factors [30] leads to the following expansion of the "true" rotation of the Ni-P bond, ρ(Ni—P):

$$\rho(\mathrm{Ni.P}) = \Delta\rho + 2\,\rho(e)_p \pm \rho G \pm \delta\pi.$$

(i) $2\,\rho(e)$ is the contribution of the lone pair of electrons of the P(III) atom before σ-coordination has occurred. The values of $2\,\rho(e)_p$ were previously estimated.[31]

(ii) δG measures the changes of hybridization and ionic character : in fact, in contrast with the NMR results, the magnitude of the $\Delta\rho$ and $2\,\rho(e)_p$ values (table 3) allows this factor — the magnitude of which is far smaller [30] — to be neglected in this case.

(iii) $\delta\pi$ symbolizes the change in the π-character (where present) between the free and complexed ligand ; in particular the π-character of the P-F bond in the fluorophosphines has been repeatedly discussed.[32] The results of Faraday effect studies allowed us to suggest that this bond is a pure σ one.[31] This is confirmed by an *ab initio* calculation on PF_3[33], but is in contradiction with other calculations by Hillier and Saunders on the same molecule.[34]

Even if some δ-character is present in the P-F bonds it can be neglected for our present discussion, as its magnitude is so small : the electron diffraction studies on PF_3 and $Ni(PF_3)_4$ show indeed that the length of the P-F bond is unchanged[35] and the photoelectron spectroscopy studies state that the bonding in PF_3 is unaltered on coordination to nickel[36] It might be expected however that this $\delta\pi$ factor would be very important in the case of the aromatic complexes : the magnetooptical contribution of a phenyl group is rather variable[37] and may vary on the coordination of the aromatic ligands to nickel. Fortunately it has been shown[21] that these variations may be considered as second order perturbations.

Under these conditions, approximate values of the bond rotation $\rho(Ni.P)$ may thus be deduced from the experimental data (Table 3). These values, which range from $\simeq 500$ to $\simeq 2200$ μr are all extremely high : such high values have never been found in other branches of chemistry.[29] Moreover, these two characteristics, and especially the second one, provide good experimental proof of the multiplicity of the Ni-P bond and its variation with structure as only $(\sigma + \pi)$ bonds are liable to vary so widely with the molecular environment.[29] The Faraday effect results arrange the complexes in an order which is quite consistent with that obtained by the previous semi-quantitative analysis of the NMR data. The Faraday effect is again demonstrated as a property which may be

extremely useful to follow the changes in the bonding throughout a series of related chemical compounds. Additionally, the third specific bond modulus, $\varkappa$(Ni.P) we obtained by an analysis of the diamagnetic susceptibility of some NiL_4 complexes gives (Table 3) nearly the same order as the other two experimental methods [except for Ni $(PPhCl_2)_4$]. We note that as expected,[38] the highest diamagnetic contribution parallels the highest Ni-P bond order in the fluorine containing complexes.

The magnetooptical behaviour of these molecules containing a transition element offers a striking contrast to compounds containing no transition elements. In the latter the π-bonding gives rise to very large increments in the magnetic rotation, these increments rising sharply when the bond order increases.[29] This striking difference may be accounted for by the following:

The influence of the electronegativity is illustrated by the fairly good correlation in figure 4 between ρ(Ni.P) and the electronegativity of atoms of groups linked to phosphorus. Moreover, this correlation leads to predicted electronegativity values for the OPh group ($\simeq 3.0$) and for the Ph group ($\simeq 2.35$) which are in good agreement with the more recent values proposed in the literature ([21] and references therein reported) and allows all the studied aromatic complexes to fit into this correlation. (+ points in figure 4); $Ni(PMeCl_2)_4$ is however anomalous.

In figure 5, we have attempted to correlate the ρ(Ni.P) values with ligand cone angle[3] : the greater cone angles are associated with the greater ρ(Ni.P) values.

The unusual magnetooptical behaviour of the complexes studied can be directly related to the specific nature of the central atom i.e. a transition metal involving free d-electrons. The decrease of ρ(Ni.P), when the order of this bond increases, may indeed be interpreted in terms of a resulting decrease of the electron population in the nickel d-orbitals.

Finally, attention is drawn to the fact that the considerable changes of ρ (Ni.P) experimentally observed parallel the occurrence of an "anomalous" and variable rotary dispersion, i.e. that the ratios ρ^g/ρ^y and ρ^i/ρ^y of the values we obtain by measurements using the yellow ($\lambda^y = 578$ nm), green ($\lambda^g = 546$ nm) and indigo ($\lambda^i = 436$ nm) wavelengths are not equal to the normal values (1.13 and 1.86) and furthermore are variable. Table 4 summarizes these results and we notice that the order of the complexes considered is not by the value of the wavelength seem to be related with the position of the first UV absorption band (λ_0). It may be thus objected that these rotations must be analysed in terms of molecular energy levels, as for example Briat *dt la.* did in the case of $TiCl_4$.[39] However, because of the size of the molecules studied, such calculations, in as much as they are possible in the current state-of-art, would involve computations of such magnitude to put them outside the scope of the present study.

CONCLUSION

We attempted, by means of a critical discussion of the magnetic behaviour of some tetrakis phosphine complexes of nickel (0) to open a new view of bonding in such molecules. ^{31}P NMR and Faraday effect data — as well as the magnetic susceptibilities, permit a placing of these complexes in nearly the same order for all three methods, and this consistency is discussed in terms of the varying geometric or electronic factors.

The NMR results show that steric effects may be as important as electronic ones in determining the experimental coordination shifts; on the other hand, the semi-quantitative analysis of the chemical shifts themselves — based on Letcher's and Van Wazer's formalism — leads to approximate values of the total bond order of the nickel-phosphorus bond which are more dependent on the electronegativity of the atoms or groups linked to phosphorus than on the steric effects.

The Faraday effect results may be likewise discussed in terms of steric and electronegativity factors, but further complications may also result from the specific contribution of the free d-electrons of nickel, from “anomalous and variable rotary dispersion, from changes in energy levels on changing ligands — as shown by the changes in the first UV absorption band. All the above factors may contribute to why in such cases bond rotations do not fit into the general pattern which has proved to be so extremely useful in other branches of chemistry.

The authors are indebted to Professor R.A. SHAW, Birkbeck College, London, for his interest in this work, for stimulating the discussions and for the suggestions about the manuscript.

CALCIUM ALUMINOSULPHATE FORMATION AND HARDENING PROPERTIES

I. TEOREANU and MARCELA MUNTEAN
Polytechnic Institute
Str. Polizu, no. 1 — Bucharest — Romania

Received February 6, 1974

The present paper studies both the stability range and the properties of $3(CaO.Al_2O_3)CaSO_4$ and the changes induced by this compound in the mechanical strength value of the tricalcium silicate and of the dicalcium silicate. Calcium aluminosulphate starts being formed even et temperatures below 1000°, reaching a maximum formation rate around 1300°. Beyond 1300° its decomposition rate is higher than its formation rate. The calcium aluminosulphate shows a high interaction rate with water, developing slightly better mechanical strength than $3CaO.Al_2O_3$. The calcium aluminosulphate influences in a differentiated manner the hardening process of calcium silicates and their mechanical strength.

1. The formation of calcium aluminosulphate $3(CaO.Al_2O_3).CaSO_4$ in the systems $CaO-Al_2O_3$, $CaO-Al_2O_3-Fe_2O_3$, $CaO-Al_2O_3-SiO_2$ and $CaO-Al_2O_3-Fe_2O_3-SiO_2$ with additions of calcium sulphate and also in clinkers mineralized with gypsum or phosphogypsum has been previously reported.[1–16]

The hardening properties of clinkers containing calcium aluminosulphate are influenced by the latter which also influences the hardening

of the other mineralogical compounds of clinker, particularly the silicate compounds.

2. The present paper studied both the stability range and the properties of $3(CaO.Al_2O_3).CaSO_4$ and the changes induced by this compound in the mechanical strength of the hardened tricalcium silicate and β-dicalcium silicate. Chemically pure, finely ground $CaCO_3$, Al_2O_3 and $CaSO_4.2H_2O$ were used in order to obtain $3(CaO.Al_2O_3).CaSO_4$. Based on the data from the literature,[8,10] the synthesis temperature chosen was 1300°. The calcination processes are achieved with the maintenance for 4 hours at a maximum temperature followed by 2 hours of cooling in the furnace and then in the air. The roentgenogram of the resulted product is exhibited in figure 1. Figure 2 presents the microscopic image of the compound in transparent light.

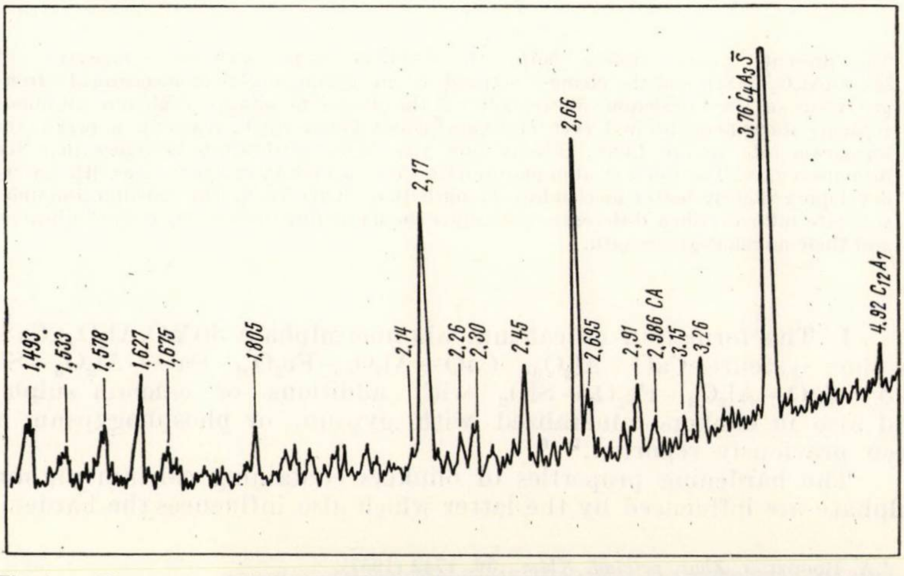

Fig. 1. — The roentgenogram of the calcium aluminosulphate synthesized at 1300°.

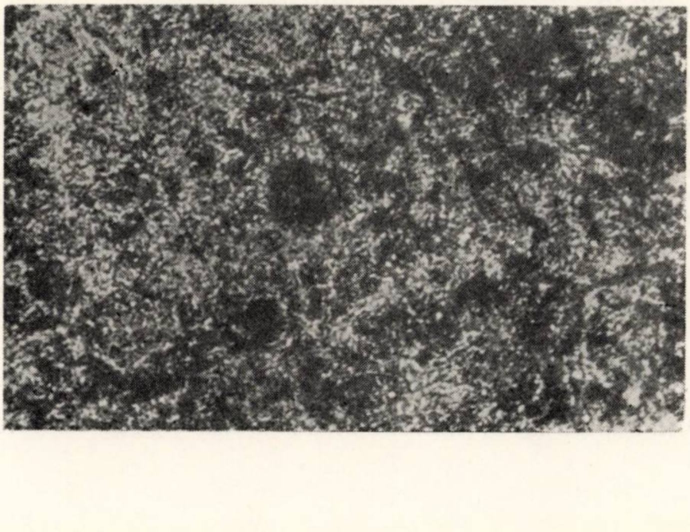

Fig. 2. — Microphotograph of calcium aluminosulphate synthesized at 1300° (× 300).

In order to follow the formation of calcium aluminosulphate at various synthesis temperatures and also its stability with the increase in the calcination temperature, the stoichiometric mixtures were also burnt at 800°, 900°, 1000°, 1100°, 1250°, 1380°, 1420° and 1500° allowing them to cool in the furnace up to roughly 800° and then in the air.

Since the roentgenogram presented in fig. 1 reveals the presence of $CaO.Al_2O_3$ and of $12CaO.7Al_2O_3$ together with $3(CaO.Al_2O_3).CaSO_4$ impulse measurements were made on the synthesized samples at various temperatures, by means of a X diffractometer corresponding to the diffraction lines $d = 2.97 Å$ – $CaO.Al_2O_3$, $d = 3.76$ Å – $3(CaO.Al_2O_3).CaSO_4$ and $d = 4.93$ Å – $12CaO.7Al_2O_3$. Similar measurements were also performed for $CaO.2Al_2O_3$ ($d = 3.51$ Å). The results obtained were plotted in figs. 3 and 4*. At the same time, determinations were made on the free CaO and SO_3 content of the synthesized samples (table 1 and table 2).

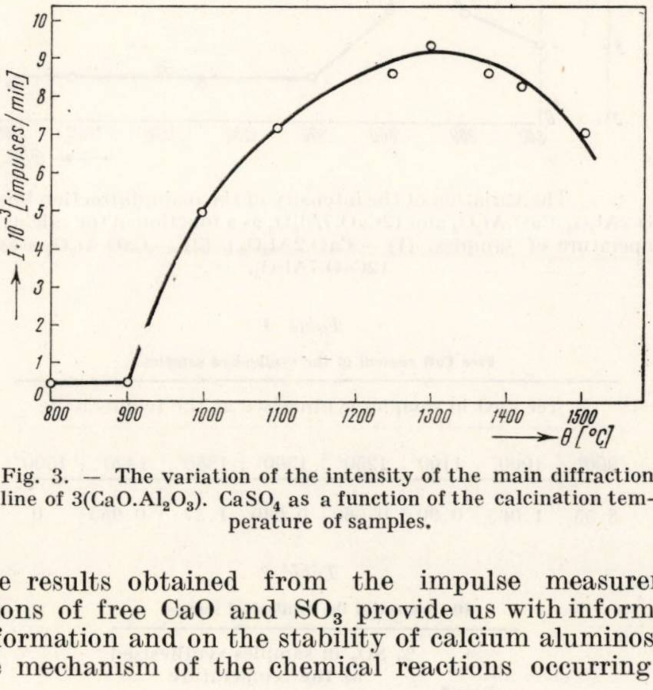

Fig. 3. – The variation of the intensity of the main diffraction line of $3(CaO.Al_2O_3).CaSO_4$ as a function of the calcination temperature of samples.

3. The results obtained from the impulse measurements and determinations of free CaO and SO_3 provide us with information on the kinetics of formation and on the stability of calcium aluminosulphate and also on the mechanism of the chemical reactions occurring during the calcination.

The positive existence of $CaO.2Al_2O_3$ and of $12CaO.7Al_2O_3$ is revealed at 800°. Beyond 900° the amount of $CaO.Al_2O_3$ and $3(CaO.Al_2O_3).CaSO_4$ from the mixture increases simultaneously, whereas the amount of $12CaO.7Al_2O_3$ and $CaO.2Al_2O_3$ decreases; beyond 1100°, the latter is practically absent from the synthesized samples. Since the formation of calcium aluminosulphate reaches a maximum at 1300°, the significant decrease of the $CaO.Al_2O_3$ proportion in samples calcined between 1000° and 1300° may be explained :

---

* The background impulse recording corresponds to approx. 350...400 impulses/min.

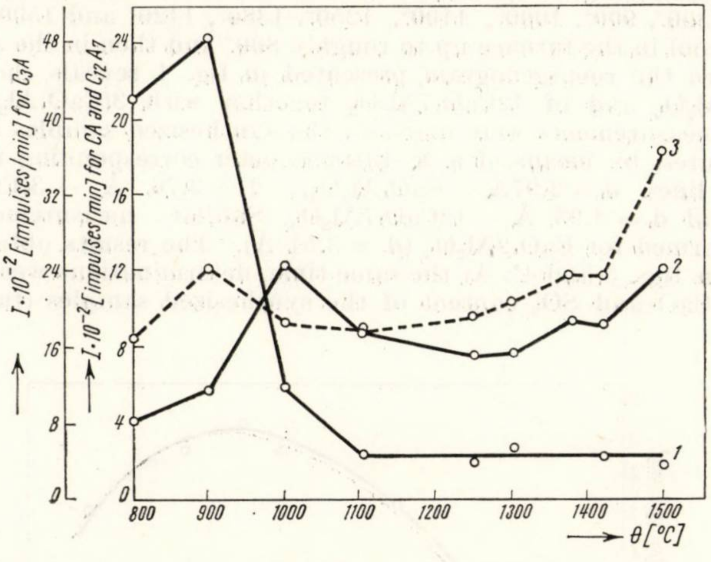

Fig. 4. — The variation of the intensity of the main diffraction lines of $CaO.2Al_2O_3$, $CaO.Al_2O_3$ and $12CaO.7Al_2O_3$ as a function of the calcination temperature of samples. (1) — $CaO.2Al_2O_3$; (2) — $CaO.Al_2O_3$; (3) — $12CaO.7Al_2O_3$.

Table 1

Free CaO content of the synthesized samples

% free CaO in samples synthesized at the temperature							
900°	1000°	1100°	1250°	1300°	1380°	1420°	1500°
8.55	1.065	0.90	0.060	0.040	1.37	0.955	0

Table 2

SO_3 content of the synthesized samples

% introduced SO_3	% SO_3 in samples synthesized at the temperature		
	1380°	1420°	1500°
13.11	10.63	10.76	6.32

$$3(Ca.O.Al_2O_3) + CaSO_4 \rightleftarrows 3(CaO.Al_2O_3).CaSO_4 \qquad (1)$$

The proportion of $CaO.Al_2O_3$ and also of $12CaO.7Al_2O_3$ is maintained within the mentioned temperature range at a relatively reduced level.

Beyond 1300°, the counter reaction rate illustrated by equation (1) becomes more important than the direct reaction rate : the calcium aluminosulphate becomes instable ; as a result of this instability in samples synthesized at 1500° the proportion of $CaO.Al_2O_3$ and $12CaO.7Al_2O_3$ obviously increases as compared to its value in the samples calcined at 1300°. The increase in the $12CaO.7Al_2O_3$ content when calcination takes place at very high temperatures may be explained by the saturation of $CaO.Al_2O_3$ resulted from the $3(CaO.Al_2O_3).CaSO_4$ decomposition. Indeed, the data reporting the SO_3 content of the synthesized samples attest an intense $CaSO_4$ decomposition at high temperatures (particularly in samples calcined at 1500°). An equilibrium of the process may be achieved at temperatures over 1500°, the equilibrium products being $CaO.Al_2O_3$ and $12CaO.7Al_2O_3$. The presence of the latter can be explained only if considering the relatively intense decomposition of $CaSO_4$ under these conditions, in addition to the high instability of the calcium sulphataluminate.

4. The hydration properties of $3(CaO.Al_2O_3).CaSO_4$ (a binder synthesized at 1300°) were investigated by mechanical strength tests on Kühl microprobes prepared of 1 : 3 mortar (binder : sand) with 13% water. Table 3 lists the data obtained as compared to those determined for $3CaO.Al_2O_3$. A comparison with the resistances of $3CaO.Al_2O_3$ is justified by the fact that the formation of $3(CaO.Al_2O_3) . CaSO_4$ in clinkers mineralized with gypsum blocks the formation of tricalcium aluminate. The results obtained show that the calcium aluminosulphate has somewhat better binding properties than $3CaO.Al_2O_3$.

Table 3

Relative mechanical strength of hardened $3CaO.Al_2O_3$ and $3(CaO.Al_2O_3) . CaSO_4$.

Binder	Relative strength of compression, after :			
	1 day	7 days	28 days	90 days
$3CaO . Al_2O_3$	100	187	209	194
$3(CaO.Al_2O_3).CaSO_4$	163	238	231	231

The roentgenographic study of hydrated calcium aluminosulphate showed that $3CaO.Al_2O_3.CaSO_4.12H_2O$ is formed after a day of hardening ; an increase in the hardening duration causes the occurrence of $3CaO.Al_2O_3.3CaSO_4.32H_2O$, its proportion increasing in the sample ; the only calcium aluminate sulphate hydrate existing in the binder hydrated for 28 days is ettringite.

5. Studies were also carried out on the mechanical properties of some mixture containing $3CaO.SiO_2$ with $3(CaO.Al_2O_3).CaSO_4$ and β-$2CaO.SiO_2$ with $3(CaO.Al_2O_3).CaSO_4$ (synthesized at 1300°). The mixtures were achieved in a proportion of 1 : 1, 2 : 1,3 : 1 and 10 : 1 calcium silicate/cal-

cium aluminosulphate. The determinations were again made on same Kühl microprobes using 1 : 3 mortar (binder : sand) with 13% water. The results of the tests are listed in table 4 (the obtained values were reported to the strength of compression of a $3CaO.Al_2O_3$ sample hardened for 1 day; the strength value of the latter sample was considered 100).

Table 4

Relative strength of mixtures containing calcium silicates and $3(CaO.Al_2O_3).CaSO_4$

Binder	Mixing ratio	Relative strength of compression, after: 1 day	7 days	28days	3 months
$3CaO.SiO_2$	—	318	650	1050	1470
β-$2CaO.SiO_2$	—	62.5	137	455	—
$3CaO.SiO_2$ / $3(CaO.Al_2O_3).CaSO_4$	1/1	209	635	975	1430
	2/1	244	672	1050	1460
	3/1	290	766	1290	1500
	10/1	351	1130	1760	1840
β-$2CaO.SiO_2$ / $3(CaO.Al_2O_3).CaSO_4$	1/1	395	830	1070	1230
	2/1	364	577	853	995
	3/1	216	520	680	905
	10/1	81.5	133	483	920

The calcium aluminosulphate is found to have an activating action on the hardening of β-$2CaO.SiO_2$ and this action becomes more intense as the aluminosulphate proportion in the mixture is higher. Conversely, the presence of the calcium aluminosulphate in a mixture with tricalcic silicate determines the decreases in the strength of the latter for short hardening periods; the reason must be sought in the internal tensions appearing in the hardening structure, due to high interaction rates of both compounds of the mixture with water. In the case of the longer hardening periods (7 days) this negative influence is attenuated and at 28 days and 3 months, the mechanical strength of hardened mixtures of tricalcic silicate and calcium aluminosulphate are significantly higher than those of the pure tricalcium silicate hardened for the corresponding periods of time; there seems to exist an optimum proportion of $3(CaO.Al_2O_3).CaSO_4$ in the mixture (shifted towards the low values).

For all the hardening periods of β-$2CaO.SiO_2$—$3(CaO.Al_2O_3).CaSO_4$ mixtures we can speak about an optimum ratio between the two components, which is however shifted towards large calcium aluminosulphate proportions.

It results from the data presented that the composition must be judiciously selected in clinkers mineralized with gypsum (phosphogypsum) calcined at low temperatures, so that to have an optimum $3CaO.SiO_2$/β-$2CaO.SiO_2$/$3(CaO.Al_2O_3).CaSO_4$ proportion from the point of view of the physical-mechanical properties of the hardened binder. To do this, the fact must be kept in mind that under the mentioned conditions, the formation of calcium aluminosulphate blocks the formation of tricalcium aluminate with the occurrence of an excess of CaO. The excess of calcium oxide may determine the formation of an increased amount of tricalcium silicate and the decrease of the β - $2CaO.SiO_2$ content in the final product compared to their potential value corresponding to the dosage used.

6. In conclusion, the investigations into the formation and the properties of calcium aluminosulphate result in the following findings :

a. The calcium aluminosulphate starts being formed even at temperatures below 1000°, its maximum formation rate being established at approx. 1300°.

b. At temperatures beyond 1300° the decomposition rate of calcium aluminosulphate is higher than its formation rate.

c. The formation of the calcium aluminosulphate in Portland cement clinkers calcined at lower temperatures may block the formation of tricalcium aluminate and favour the saturation of the dicalcium silicate in tricalcium silicate.

d. The calcium aluminosulphate shows a high interaction rate with water, developing somewhat better mechanical strength than those of tricalcium aluminate.

e. The calcium aluminosulphate has an intense activating action of β-$2CaO.SO_2$, which, accordingly, develops some relatively high initial strength. From the standpoint of the initial strength, the calcium aluminosulphate has a negative influence on the hardening of the tricalcium silicate. The above facts illustrate the need for a judicious choice of the composition of clinkers mineralized with gypsum or phosphogypsum, calcined at lower temperatures so that to obtain an optimum $3CaO.SiO_2/$ β-$2CaO.SiO_2$ / $(CaO.Al_2O_3).CaSO_4$ proportion from the point of view of the physical-mechanical properties of the hardened binder.

INFLUENCE OF OXIDES OF TRANSITIONAL ELEMENTS ON THE PROPERTIES OF MINERALOGICAL COMPONENTS OF CLINKERS OF CEMENTS

MARIA ENCULESCU

Institute for Research, Designing and Documentation in Binders and Asbestos Cement Industry,
Calea Victoriei No. 111, Bucharest, Romania

Received November 21, 1973

By carrying out our own investigations it was possible to establish the approximate values for the solubilization limits of some colouring oxides in calcium silicates and calcium aluminates. The solubilization degree of the chromophore ions, the manner in which they are included in the basic lattice, the binding energy with oxygen, the coordination explain the correlation with the basicity of calcium silicates and aluminates and their colour. By means of the ligand field theory we revealed the correlations between the colour characteristics and the basicity of calcium silicates and aluminates. Approaches were thus established for obtaining cements, mortars and concretes reinforced by high mechanical resistances and by a great colour stability. Cements of coloured Portland and aluminous clinkers were obtained in the laboratory and in factories, coloured on the base of raw materials for white cement and raw materials for ordinary cement, contributing thus to the production on scientific bases of cements falling in this category. Important results were obtained in achieving Portland cements with a high degree of whiteness.

1. INTRODUCTION

The utilization of finishing materials based on white and coloured cements has been largely extended in recent times. Considering some more limited investigations into coloured cements with superior characteristics obtained from coloured clinkers, our own studies[1–10] mainly focused on the influence of oxides of Fe, Mn, Cr, Co, Ni and Cu on the formation, stabilization and colouring of the principal mineralogical compounds of Portland and aluminous clinkers and also on their binding properties.

2. THE INFLUENCE OF THE OXIDES OF TRANSITIONAL ELEMENTS ON THE FORMATION OF CALCIUM SILICATES AND ALUMINATES

Using the results obtained from our personal studies,[1-10] and also the available information found in the speciality literature, we established with sufficient accuracy the solubilization limits of the oxides of transitional elements in clinker mineralogical compounds.

2.1. The main phase, highly important in clinkers of white and coloured cement, 3 $CaO.SiO_2$, has been the subject of a number of studies.[1,11-16] The isomorphism relations of tricalcium silicate with the oxides of transitional metals are of a great interest.

The *ferric oxides* are isomorphically added to the structure of tricalcium silicate. The tricalcium silicate samples with over 2% Fe_2O_3 revealed, in our own investigations,[1] the characteristic lines of C_2F (d = 2.71 Å and 2.81Å) and even of Fe_2O_3 (d = 2.68 Å and 2.79 Å), pointing to the fact that the solubilization limit is obviously exceeded, as illustrated in fig. 1.

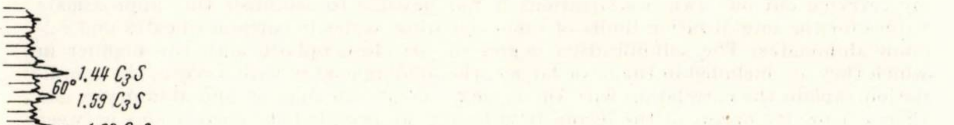

Fig. 1. — Diffractograms of pure anhydrous $3CaO.SiO_2$ and $3CaO.SiO_2$ with 0.5 – 2.0 – 4.0 – 8.0 % Fe_2O_3.

[13] M. Regourd, "Symposium International de la Chimie du Ciment", Tokyo, 6—11 oct. 1968., *Rev. des Mat. Construction*, **1969**, 643 ; **1969**, 644.

[14] A. Dietzel and L. Tscheischwili, *Ber. dtsch. Keram,. Ges.*, **30** (1953).

[15] L. Revay, *Epitoanyag*, **1968**, 3.

[16] E. Woermann, W. Eysel and Th. Hahn, *Zement, Kalk, Gips*, **1968**, 6.

The examinations based on electron microprobe,[1] indicate with an increased precision that this solubilization limit is 0.68–0.79%, very close to that indicated by Woermann[16]. The solid solutions of tricalcium silicate with Fe_2O_3 are described by the formula :

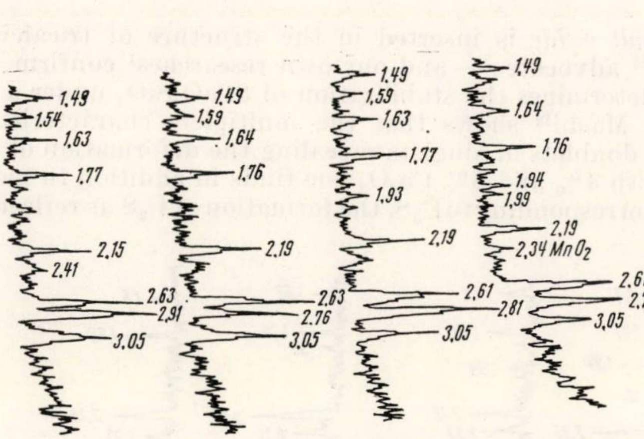
$$(Ca_{3-x}\,.\,Fe_x)\;(Si_{1-y}\,.\,Fe_y)O_{5-z} \qquad (1)$$

in which $z = x + 2y - \frac{u}{2}(x + y)$, u being the valence of the cation.

The *manganese dioxide* is included in the lattice of tricalcium silicate leading to the occurrence of a monoclinic polymorphic form[11,12]. The diffractometric analysis shows for $3CaO.SiO_2$ samples with 2%, 4% and 8% MnO_2 characteristic lines of MnO_2 at d = 2.1994 Å and at d = 2.3422 Å, as seen in figure 2. The MnO_2 solubility limit in tricalcium silicate is about 1 %. The solid solutions of $3CaO.SiO_2$ with MnO_2 may be described by formula :

$$(Ca_{3-x}\,.\,Mn_x)\;(Si_{1-y}\,.\,Mn_y)\;O_{5-z} \qquad (2)$$

in which $z = x + 2y - \frac{u}{2}(x + y)$, u being the valence of the metallic cation.



C_3S+0.5% MnO_2 C_3S+2.0% MnO_2 C_3S+4.0% MnO_2 C_3S+8.0% MnO_2

Fig. 2. — Diffractogram of tricalcium silicate with MnO_2.

The *chromium oxide* is included in the lattice of tricalcium silicate. Hornain[11] claims that it confers to the latter a hexagonal and monoclinic polymorphic form (MI_a), a fact confirmed by our own investigations in samples with 0.5 and 2% Cr_2O_3. In samples with 4% and 8% Cr_2O_3, the diffractograms in fig. 3 also reveal high intensity lines corresponding to $2CaO.SiO_2$, Cr_2O_3 (d = 2.2739 A) and calcium chromites (d = 3.65–3.90 Å).

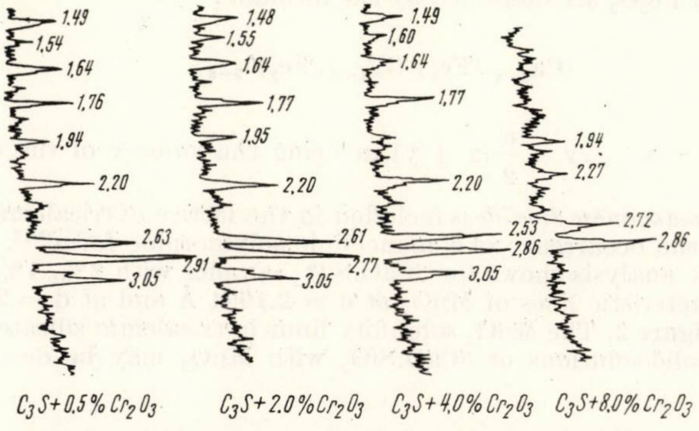


Fig. 3. — Diffractograms of tricalcium silicate with Cr_2O_3.

The solid solutions of $3CaO.SiO_2$ with Cr_2O_3 may be described by the formula:

$$(Ca_{3x} . Cr_x) (Si_{1-y} . Cr_y)O_{5-z} \quad (3)$$

The *cobalt oxide* is inserted in the structure of tricalcium silicate and Hornain[11] advocates — and our own researches[1] confirm — that the cobalt oxide determines the stabilization of $3CaO.SiO_2$ under a monoclinic form (M II). Maslîi[12] shows that the multiplets characteristic of pure C_3S pass into doublets or singlets revealing the deformation of C_3S lattice. In samples with 4% and 8% Co_2O_3 one finds in addition to maximum intensity lines corresponding to C_3S, the formation of C_2S as reflected in fig. 4.

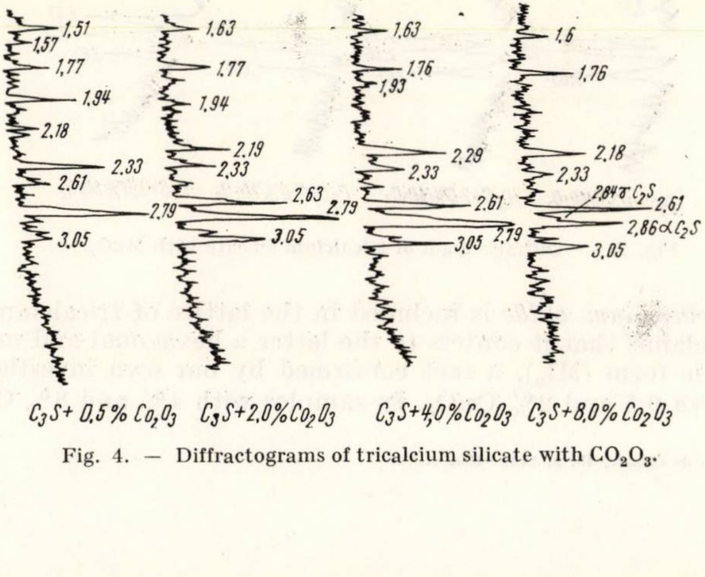

Fig. 4. — Diffractograms of tricalcium silicate with CO_2O_3.

The solid solutions of $3CaO.SiO_2$ with Co_2O_3 may be described by the formula :

$$(Ca_{3-x}.\ Co_x)\ (Si_{1-y}.\ Co_y)O_{5-z} \tag{4}$$

The *nickel oxide* confers to tricalcium silicate a monoclinic polymorphic form (M Ib) or hexagonal,[11] fact which was also confirmed by our own studies.[1] The solid solutions of tricalcium silicate with NiO may be described by the formula :

$$(Ca_{3-x}.Ni_x)SiO_5 \text{ in which } 0 \leqslant x \leqslant 0.04 \tag{5}$$

The *copper oxide* stabilizes the tricalcium silicate under a monoclinic form (M Ib), fact which was confirmed by Hornain's studies[11] and by our own investigations. For the systems with CuO additions, the solid solutions may be described by the formula :

$$(Ca_{3-x}.Cu_x)SiO_5 \text{ where } 0 \leqslant x \leqslant 0.04 \tag{6}$$

2.2. The *dicalcium silicate* represents one of the important crystalline phases in white and coloured Portland cement clinkers. They largely possess the property of forming solid solutions with the oxides of transitional elements.

The *ferric oxide* introduced in a proportion of 4% and 8% produces the probably physical stabilization of β $2CaO.SiO_2$. As a matter of fact, according to Dietzel and Tscheischwili[14] Fe^{3+} fails to stabilize crystallochemically β $2CaO.SiO_2$. The diffractograms in fig. 5 reveal the high intensity lines characteristic of β $2CaO.SiO_2$. However the line at d = 2.969 Å also appears, which is characteristic of Fe_2O_3. This fact proves that the solubilization limit of Fe_2O_3 has been exceeded by far in the dicalcium silicate.

The solid solutions of dicalcium silicate with ferric oxide may be described by the formula :

$$Ca_2[Fe_x.Si_{1-x}]O_4 - \frac{x}{2} \text{ where } 0 \leqslant x \leqslant 0.05 \tag{7}$$

The *manganese dioxide*, introduced up to 2% fails to stabilize the β $2CaO.SiO_2$ form ; diffractograms reflect the lines at d = 3.03 Å, 2.76 Å and 1.92 Å, characteristic of γ $2CaO.SiO_2$. By increasing the MnO_2 amount (from 2% to 4%) one observes an intensity of the main lines characteristic of β $2CaO.SiO_2$. The solid solutions of $2CaO.SiO_2$ may be described by the general formula :

$$(Ca_{2-x}.Mn_x)(Si_{1-x}\cdot Mn_x)O_{4-z} \text{ in which } z = x(3-n) \tag{8}$$

The *chromium oxide* introduced (like Cr^{6+} and Cr^{3+}) into the raw mixture of $2CaO.SiO_2$ and burnt at 1500° fails to lead to the stabilization of β $2CaO.SiO_2$. Chemical and electron spin resonance analyses[1] emphasized the fact that only Cr^{3+} exists at the working temperature involved and

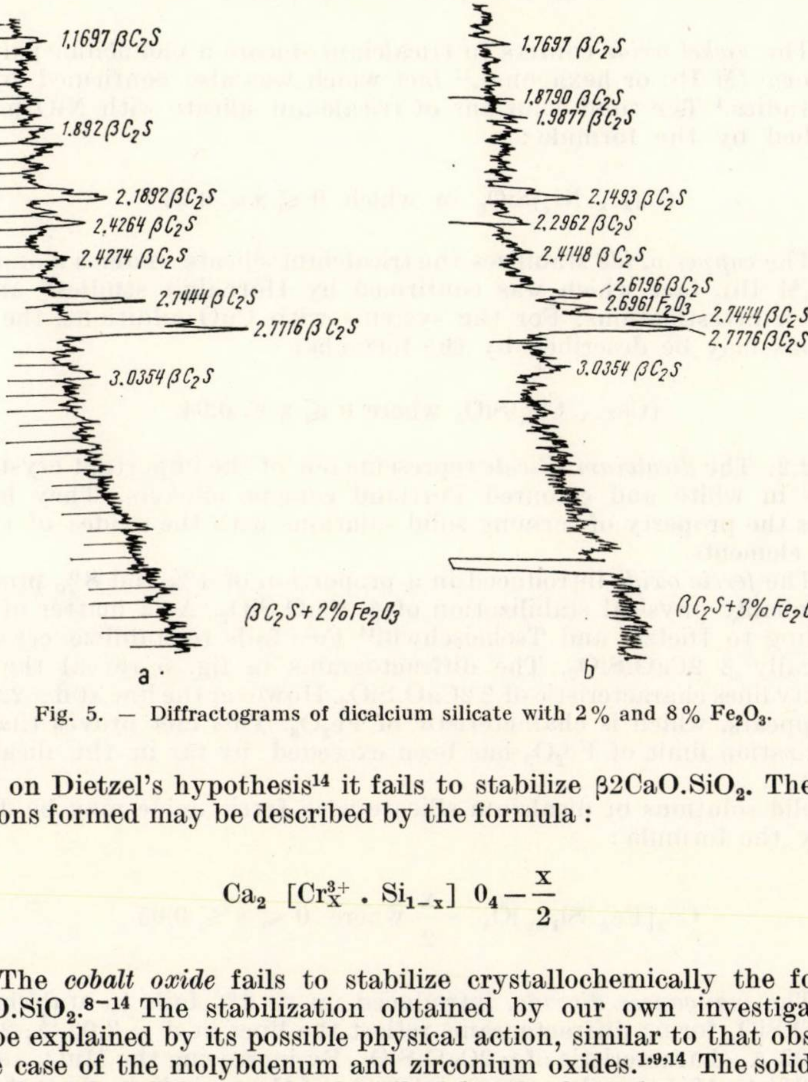

Fig. 5. — Diffractograms of dicalcium silicate with 2% and 8% Fe_2O_3.

based on Dietzel's hypothesis[14] it fails to stabilize $\beta 2CaO.SiO_2$. The solid solutions formed may be described by the formula :

$$Ca_2\ [Cr^{3+}_X\ .\ Si_{1-x}]\ 0_4 - \frac{x}{2} \qquad (9)$$

The *cobalt oxide* fails to stabilize crystallochemically the form β $\beta 2CaO.SiO_2$.[8-14] The stabilization obtained by our own investigations[1] may be explained by its possible physical action, similar to that observed in the case of the molybdenum and zirconium oxides.[1,9,14] The solid solutions of β $2CaO.SiO_2$ may be described by the formula :

$$(Ca_{2-x}.\ Co_x)\ (Si_{1-x}.\ Co_x)O_{4-z} \text{ in which } 0 \leqslant x \leqslant 0.06 \qquad (10)$$

The solid solutions of $\beta 2CaO.SiO_2$ with nickel oxide may be described by the formula :

$$(Ca_{2-x}.Ni_x)\ SiO_4 \qquad (11)$$

The formula of the solid solution of β $2CaO.SiO_2$ with copper oxide may be written down as follows:

$$(Ca_{2-x}.Cu_x)\ SiO_4 \qquad (12)$$

2.3. The *tricalcium aluminate* represents one of the crystalline phases which is always present in a proportion of at most 15% in white and coloured Portland cement clinkers. The penetration of the extraneous ions in the C_3A lattice leads to the modification of the parameters of the lattice.

The *ferric oxides* solubilize in the $3CaO.Al_2O_3$ lattice and for the corresponding solid solutions we may write the formula:

$$Ca_3\ [Al_{1-(0.02...0.03)} \cdot Fe_{(0.02...0.03)_2}]O_6 \qquad (13)$$

The *manganese dioxide* is included in a proportion below 2% in the $3CaO.Al_2O_3$ lattice; the formula of the solid solutions is:

$$Ca_3\ (Al_{1-x}.Mn_x)O_6 \text{ in which } 0 \geqslant x \geqslant 0.01 \ldots 0.02. \qquad (14)$$

The *chromium oxide and nickel oxide* are included as solid solutions in the lattice $3CaO.Al_2O_3$ producing modifications in the intensity of its characteristic lines.

2.4. The *monocalcium aluminate* is the basic constituent of white and coloured aluminous cement clinkers,[1,4,8,10,15] $CaO.Al_2O_3$ forms solid solutions with the oxides of the transitional elements.

The *ferric oxides* are included as solid solutions up to 2% in the $CaO.Al_2O_3$ lattice producing an intensification of characteristic lines; over 2 %, we find the obvious presence of C_4AF through line 2.6345 Å (2.6496 Å). Both in slowly cooled samples and in studdenly cooled ones there appear doublets or multiplets revealing the disturbance of the $CaO.Al_2O_3$ lattice. Considering that Fe^{3+} replaces Al^{3+}, the description of the formed solid solution may be made by the formula:

$$CaO\ (Al_2O_3)_{1-x}\ (Fe_2O_3)_x \text{ where } 0 \leqslant x \leqslant 0.015\ (0.02). \qquad (15)$$

The solubilization of the *manganese dioxide* in $CaO.\ Al_2O_3$ may be analyzed similarly to the solubilization of Fe_2O_3. The solubilization limit of MnO_2 in $CaO.Al_2O_3$ is far below 4% since new lines appear in the interval 2.5334 Å ... 2.8642 Å which may be assigned to some ternary compounds.

The *chromium oxide* forms solid solutions with $CaO.Al_2O_3$. The investigations carried out so far[1-15] show the existence in the $CaO.Al_2O_3$ system of some complex isomorphism relations. The solid solutions of $CaO.Al_2O_3$ with Cr_2O_3 may be expressed by the formula:

$$CaO.Al_2O_{3\ 1-x}.Cr_2O_3, \text{ in which: } 0 \leqslant x \geqslant 0.01\ (0.02). \qquad (16)$$

The studies made and the results obtained[1,4,7,10,15] indicate the possibility of including as a solid solution the cobalt oxide and the nickel oxide in the $CaO.Al_2O_3$ lattice under certain limits (1 – 2 %).

3. THE INFLUENCE OF THE OXIDES OF TRANSITIONAL ELEMENTS ON THE COLOURING OF CALCIUM SILICATES AND ALUMINATES

The ions of transitional metals which have free energetic levels allowing the passage of optically activated electrons present a large colouring capability. The colour of the calcium silicates depends on the nature of the chromophore ions, on the solubilization degree, on the manner in which they are included in the lattice, on the binding energy of the chromophore ions with oxygen, on their coordination. For this reason the colour saturation increases with the approach of the solubilization limit and is modified after exceeding it, as seen in figs. 6 and 7.

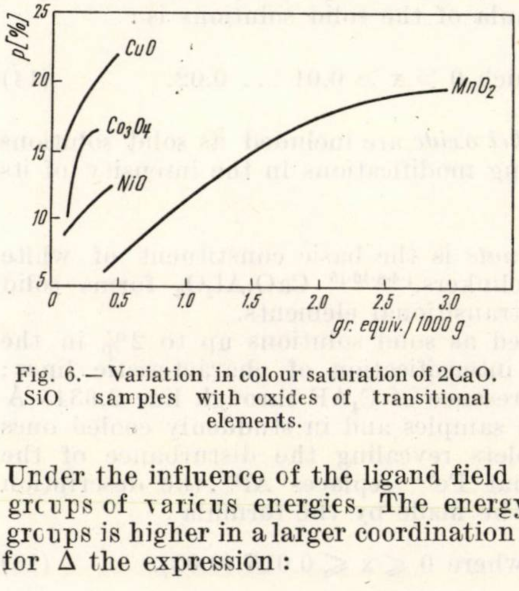

Fig. 6. — Variation in colour saturation of 2CaO. SiO samples with oxides of transitional elements.

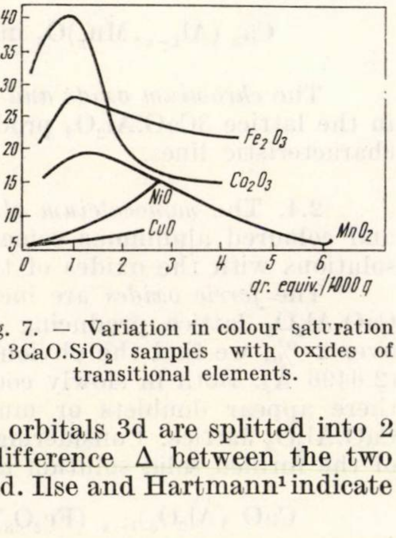

Fig. 7. — Variation in colour saturation of $3CaO.SiO_2$ samples with oxides of transitional elements.

Under the influence of the ligand field the orbitals 3d are splitted into 2 groups of various energies. The energy difference Δ between the two groups is higher in a larger coordination field. Ilse and Hartmann[1] indicate for Δ the expression :

$$\Delta = \frac{5.e.r.^{-4}}{3} \cdot \frac{q}{R} \text{ in which :} \qquad (17)$$

r = the average distance from the nucleus to the electrons 3d ;
e = the electron charge ;
q = the charge or the electric moment of the ligand ;
R = the ion-ligand distance.

The proportion of unbridged oxygen with high polarizability increases with the rise in the CaO concentration (q becomes higher and R becomes smaller) ; thus, in the case of $3CaO.SiO_2$ the absorption shifts towards the range of shorter wavelengths relative to β $2CaO.SiO_2$.[1] An inspection of the samples of $3CaO.SiO_2$ with Fe_2O_3, MnO_2, Cr_2O_3, Co_2O_3, NiO and

CuO by means of the ESR method (electron spin resonance) showed that the ion Fe^{3+} is also found as Fe^{2+}, Mn^{4+} is found as Mn^{2+}, Cr^{6+} is found as Cr^{3+}, Co^{3+} is found as Co^{2+} and the copper and nickel ions are divalent. Thus the plot of a function $\lambda = f(z/a^2)$ is a decreasing curve both in the case β $2CaO.SiO_2$ and in the case of $3CaO.SiO_2$ (fig. 8 and fig. 9). The dependences established between the colour saturation and the increase of the addition of colouring oxide, fig. 10 and fig. 11, and also between the wavelength and the intensity of the electrostatical field, fig. 12 and fig. 13, both for $CaO.Al_2O_3$ and for $3CaO.Al_2O_3$ are similar to those found with calcium silicates.[1]

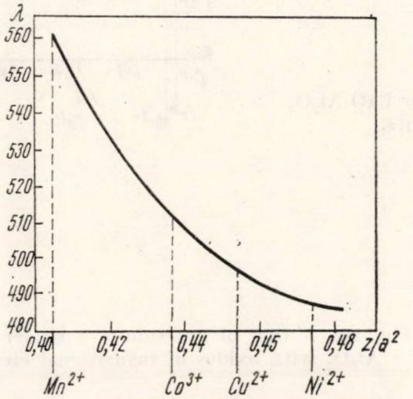

Fig. 8. — Plot of function $\lambda = f(z/a^2)$ for 2 $CaO.SiO_2$ with oxides of transitional elements.

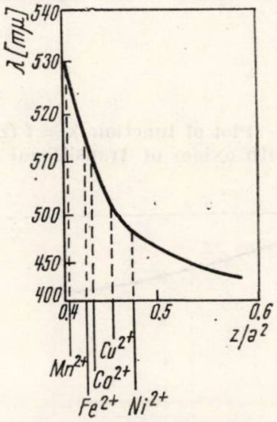

Fig. 9. — Plot of function $\lambda = f(z/a^2)$ for $3CaO.SiO_2$ with oxides of transitional elements.

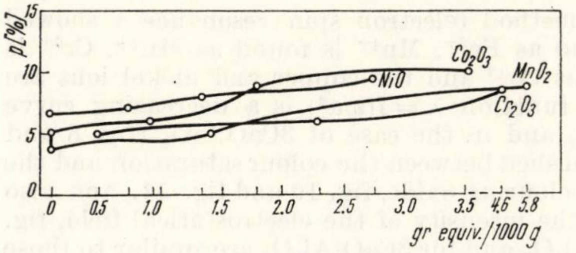

Fig. 11. — Variation in colour saturation of $3CaO.Al_2O_3$ samples with oxides of transitional elements.

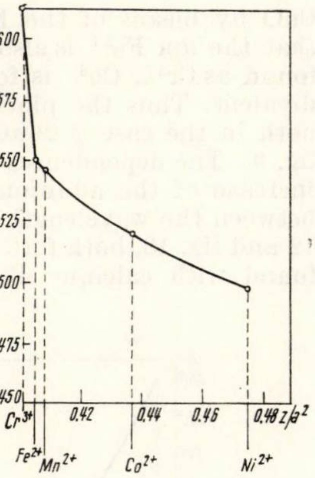

Fig. 12. — Plot of function $\lambda = f(z/a^2)$ for $CaO.Al_2O_3$ with oxides of transitional elements.

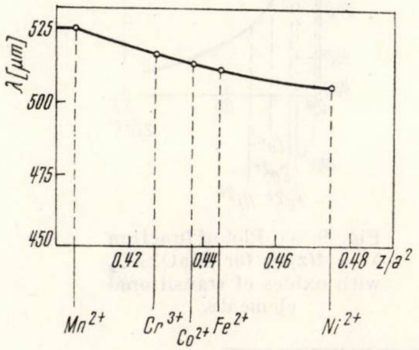

Fig. 13. — Plot of function $\lambda = f(z/a^2)$ for $3CaO.Al_2O_3$ with oxides of transitional elements.

4. THE INFLUENCE OF THE OXIDES OF TRANSITIONAL ELEMENTS ON THE BINDING PROPERTIES OF CALCIUM SILICATES AND ALUMINATES

The introduction of the extraneous ions liable to replace silicium and with a weaker polarization capacity leads to the weakening of the Si-O bond which results in the increase of the solubility of silicate.[1,11,13]

Butt, Timasev, Ceausanschi [14,18] show that the structure of the tricalcium silicate lattice is one of the major factors which determine its hydraulic properties. The solid solutions of substitution have different hydraulic properties as a function of the size of the substitute ion.

The replacement of Ca^{2+} by a smaller ion increases the hydraulic property of the solid solution whereas by replacing the Ca^{22} ion by a bigger substitute ion, a decrease of hydraulic properties takes place.

The interstitial solid solution has more reduced hydraulic properties. The binding properties of calcium silicates and alminates with and without

additions of oxides of transitional metals were examined by mechanical resistance determinations (on Kühl microprobes) and by roentgen and electromicroscopic analyses, in a more detailed work.

It has been found that in the samples synthesized with Fe_2O_3, MnO_2 and $Co_2\%O_3$ up to a certain value of their proportion, the mechanical resistances are higher having in general a maximum at the limit of the solid solution and starting to decrease thereafter. Even if the solubility limit of the ion of the transitional metal in C_3S, β C_2S, C_3A and CA is exceeded, compounds are formed including the oxide of the transitional metal with superior hydraulic properties compared to pure mineralogic compounds.

5. WHITE AND COLOURED CEMENTS

Our own investigations[1-10] are centered around the study of white Portland clinkers with high modules (with a content high in tricalcium silicate) in view of obtaining white cements with high initial resistances (300 – 400 daN/cm²) and high final resistances (500–600 daN/cm²) and also a high-grade white, over 80 %. Studies were carried out in parallel on the properties of white aluminous cements, proceeding thereafter to the study of the properties of coloured cements obtained from coloured clinkers.

The composition of the green, yellow and black Portland clinkers will include only tricalcium silicate, dicalcium silicate and tricalcium aluminate, compounds which from solid solutions with the added colouring oxides and whose structural particularities and quantitative ratio in the clinker will determine its colour. The quality of the coloured clinkers depends on the mineralogical composition, on the clinkerization conditions and on the cooling approach and to a large extent, on the percentage of the added colouring oxide. It was experimentally confirmed that the colour saturation increases with the approach of the solubility limit of the colouring oxide. Our own investigations[1] have indicated that some oxides have a more intense colouring action on alitic clinkers. By grinding the alitic Portland clinkers (green, yellow and black) we obtained cements with high initial resistances 300 – 400 daN/cm² and high final resistances 500 – 600 daN/cm², as well as a good colour stability at 80 hours UV radiation 30 gelinity cycles, artificial rain.

Based on the laboratory research it was possible to achieve green yellow and black cements at a semiindustrial level with a good reproducibility of the characteristics of the chemical-mineralogical composition, mechanical resistance and colour. Some results formed the subject of some invention patents[19,22].

6. CONCLUSIONS

The performed investigations led to the conclusion that the used transitional metal oxides form with calcium silicates interstitial solid solutions as well as substitution solid solutions, the probability on the last mentioned being greater.

By means of the performed investigations it was possible to determine the approximate values of the solubilisation limits of some colouring oxides in calcium silicates and in calcium aluminates. The solubilisation degree of the chromophore ions, the manner after which these are included in the base lattice, their bonding energy with oxygen, their coordination, clear up, in correlation with the silicates and calcium aluminates basicity, the colouring of these last mentioned.

Thus were established the ways by which hard cements, mortars and concretes with high mechanical resistance and high colour stability are obtained. In laboratory as well as in factory, Portland clinker cement and coloured aluminous cements were obtained starting from selected raw materials as well as from usual raw materials, clinkers with superior characteristics, thus contributing to the substantiation of the producing of this cement class. Very important results were obtained towards the direction of producing Portland cement with a high degree of white.

Revue Roumaine de Chimie, **19**, 9, 1503–1506 (1974)

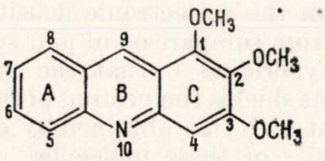
PROTON MAGNETIC RESONANCE SPECTRA OF SOME 1,2,3-TRIMETHOXYACRIDINES

M. VLASSA
Institute of Chemistry, str. Donath 65–103, Cluj, Romania

Received October 8, 1973

The proton magnetic resonance spectra of some 1, 2, 3-trimethoxyacridines and 1, 2, 3-trimethoxyacridine-N-oxides are analysed. The influence of various substituents on the chemical shift of the acridine ring protons is discussed.

MO-calculations of physico-chemical properties of the 1,2,3-trimethoxyacridine (I) molecule[1] showed that the presence of the electron-releasing methoxy groups on the acridine ring increases the π-electronic density, especially in rings C and B, the + E effect being transmitted weakly to the ring A (see I). These calculations pointed out also that π-electronic densities at the methoxy groups are not equal.



I

Although the π-electronic density gives only a rough approximation of the chemical shift, the above results suggest that in the proton magnetic resonance spectrum of 1, 2, 3-trimethoxycridine I, the resonance signals of the methoxy groups will be distinct, the most shielded among heteroaromatic protons will be H_4, the most deshielded H_9, and the ABCD type multiplet of $H_5 - H_8$ protons will appear between them. Because the + E effect is weakly transmitted in ring A, the position and shape of the $H_5 - H_8$ multiplet in acridine and in 1, 2, 3-trimethoxyacridine (I) pmr spectra are nearly the same. This fact allowed to analyse this multiplet by comparison with the acridine pmr spectrum recorded and analysed by Kokko and Goldstein.[2]

---

[2] J. P. Kokko and J. H. Goldstein, *Spectrochim. Acta*, **19**, 1119 (1963).

Comparison of experimental values of the chemical shifts of the 1,2,3,-trimethoxyacridine (I) protons with the previously calculated π-electronic density values[1] and with the chemical shift of acridine protons shows that the above assumption is correct (see table 1).

Table 1

The chemical shifts of acridine and of 1, 2, 3-trimethoxyacridine protons δ_H

Proton	$\pi-$electronic density of I[1]	δ_H of I	δ^+_H of acridine recorded by us	δ^{++}_H lit.[2]	$\Delta\delta_H = \delta^+_H - \delta_H$
H_4	1.095	7.33	8.22	8.25	0.89
H_5	1.008	8.18	8.22	8.25	0.04
H_6	0.986	7.76	7.81	7.80	0.05
H_7	1.015	7.42	7.55	7.55	0.13
H_8	0.996	8.00	8.06	8.06	0.06
H_9	0.928	8.91	8.71	8.71	−0.20
OCH_3	1.927	4.16	—	—	—
OCH_3	1.939	4.03	—	—	—
OCH_3	1.929	4.06	—	—	—

In spite of the rough correlation between chemical shifts and π-electronic densities, the two parameters show a parallel evolution, with the only exception of $H_5 - H_8$ protons (see table 1).

However, it is difficult to make an assignment of chemical shifts of the methoxy groups from the π-electronic densities values only.

We may conclude from comparison of pmr spectra of the acridine and of the 1, 2, 3-trimethoxyacridine I, that the presence of the methoxy groups in vicinal positions shields the protons of the acridine molecule. This conclusion is in agreement with that obtained by comparison of the calculated π-electronic densities of these molecules.

Studying the influence of various groups from position 9 of the 1, 2, 3-trimethoxyacridine I on the chemical shift of the protons, we note :

a) A deshielding effect for chlorine atom and a shielding one for SCH_3, OCH_3 and OC_6H_5 groups on $H_5 - H_7$ multiplet (see table 2), in good agreement with the order of magnitude of the Hammett substituent constants of the above groups (the shielding effect increases in the order $Cl < SCH_3 < OCH_3 < OC_6H_5$ and the values of the Hammett constants are $\sigma_{Cl} = +0.277$; $\sigma_{SCH_3} = -0.01$; $\sigma_{OCH_3} = -0.286$; $\sigma_{OC_6H_5} = -0.280$).[3,4] This shows that the shielding effect is mostly due to the electron-releasing strength of these groups.

b) A deshielding effect on the H_8 proton for all these groups (see table 2). This effect, well known in organic magnetic resonance as *peri* effect, is produced by various substituents[5] and was explained by Dudek[6]

-9-phenoxy-	s 7.32	m centre at $\longleftarrow$ 7.54 $\longrightarrow$			m 8.05	s 4.07	s 3.76	s 4.94	m 6.89

* $\delta_{H_5-H_8}$ centre of multiplet of 1,2,3- trimethoxyacridine = 7.77.

**s = singlet

*** m = multiplet

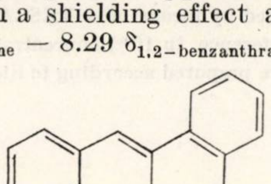
as a space interaction. The distance between the *peri* hydrogen and the substituent, e.g. the oxygen atom from the methoxy group, is 2.4 Å, that is smaller than the one encountered in a strong hydrogen bonding (2.7 Å).

This fact explains why the deshielding effect is greater for SCH_3 and chlorine than for the methoxy and phenoxy groups, through space the overlapping of the substituent and hydrogen orbitals being greater in the first two cases. The deshielding effect is greater for the SCH_3 group than for the chlorine atom because the sulfur atom is more basic due to the inductive effect of the methyl group.

Courtauld atomic model of the 1,2,3-trimethoxy-9-phenoxyacridine shows that, due to the steric hindrance of the benzene nucleus by the methoxy group from C_1 position, the H_8 proton lies above the benzene ring plane. It explains why methoxy group from C_9 has a stronger deshielding effect than the phenoxy group (see table 2).

The *peri* effect is exerted also by the methoxy group from C_1 position on the H_9 proton (see tables 1 and 3).

This explanation is also supported by the fact that in the case when a space interaction becomes impossible, the *peri* effect does not appear. For instance, the methyl group from C_4 position of the benzanthracene II produces on the H_{10} proton a shielding effect and not a deshielding one ($8.45\delta_{4-\text{methyl}-1,2\text{ benzanthracene}} - 8.29\ \delta_{1,2-\text{benzanthracene}} = 0.16$ ppm).[7]



II

---

[7] P. DURAND, J. PARELLO and N. P. BUN-HOI, *Bull. Soc. chim. France*, **1963**, 2438.

Due to the interaction of these groups with the methoxy groups from 1, 2 and 3 positions, the influence of these substituents on the chemical shifts of the H_4 proton and of the vicinal methoxy groups has a rather complex character.

The effect of the N-oxide group on the chemical shifts of the 1, 2, 3-trimethoxyacridine protons consists in a deshielding effect on the H_4 and H_5 protons (see table 3).

Table 3

Chemical shifts of acridine-N-oxide derivatives δ_H

Compound	H_4	H_5	H_6	H_7	H_8	H_9	OCH_3	OCH_3	OCH_3
acridine-N-oxide	8.84	8.84	7.71	7.50	7.88	8.13	—	—	—
1,2,3-trimethoxyacridine-N-oxide	s 8.05	m 8.84	m. centre at ←7.75→			s 8.55	s 4.15	s 4.03	s 4.16
1,2,3-trimethoxy-9-chloro-acridine-N-oxide	s 8.07	m 8.69	m. centre at ←7.66→		m 8.05	—	s 4.05	s 3.96	s 3.96

The comparison of the chemical shifts of the acridine-N-oxide with those of the 1,2,3-trimethoxyacridine-N-oxide shows that the methoxy groups have the same effect as in the acridine case. The presence of the chlorine atom in position 9 is reflected in pmr spectrum by the deshielding effect on the H_8 proton (*peri* effect) and on the $H_5 - H_7$ multiplet (see table 3).

From comparison of δ_H values of the H_9 proton from 1,2,3-trimethoxy-acridine-N-oxide and from 1, 2,3-trimethoxyacridine, one can see that the electronic density is increased in the case of the N-oxide derivative (0.36 ppm). This suggests that it is at the C_9 position of the 1,2,3-trimethoxyacridine-N-oxide, as in the case of the acridine-N-oxide[8], that electrophilic substitution reaction may take place.

EXPERIMENTAL

The pmr spectra were recorded by means of a TESLA BS 487 C instrument, in $CDCl_3$ solutions, with TMS as internal reference, in 10% concentration.

The substances recorded were prepared according to literature data. [9,10]

o-DIAZABICYCLIC DERIVATIVES OF BENZO [*c*] CINNOLINE. IV

ADDITION REACTIONS OF 3,8-DIMETHYLBENZO [*c*] CINNOLINE, VIA YLIDIC INTERMEDIATES, LEADING TO NEW *o*-DIAZABICYCLIC SYSTEMS

EUGENIA CARP, MARIA DORNEANU and ION ZUGRĂVESCU
Department of Organic Chemistry "Al.I. Cuza" University, Iassy

Received February 16, 1974

The reaction of 3,8-dimethylbenzo [*c*] cinnoline with dimethyl acetylenedicarboxylate in dimethylformamide affords a stable cycloadduct. The synthesis and structure of the stable benzocinnolinium dicyano-methylides is discussed. Possible synthetic routes to obtain the dimethylbenzo [*c*] pyrazolo- and tetrazolo [1.2a] cinnolines, *via* unstable ylidic intermediate from N-phenacyl-benzocinnolinium salt, have also been investigated.

In the previous papers[1–3] an attempt was made to verify the possible dienophilic activity of the "azo" system of benzo [*c*] cinnoline. It was also shown that the ylids, derived from benzocinnolinium salts, can undergo 1,3-dipolar cycloaddition reactions towards some dipolarophiles to give new *o*-diazabicyclic systems.

Our interest in the chemistry of benzo [*c*] cinnoline led us to investigate the behaviour of this weak heterocyclic base and their substituted derivatives in the reaction with dimethyl acetylenedicarboxylate and the formation, starting from benzocinnolinium salts, of azomethine ylids which, acting as 1,3-dipoles, react with various dipolarophiles to give the corresponding *o*-diazabicyclic heterocyclic systems.

In order to achieve these we have studied the reaction of 3,8-dimethylbenzocinnoline with dimethyl acetylenedicarboxylate (DMAD) in several solvents and we have established that the reaction occurs in the best yield in dimethylformamide (DMFA) at 0°C, to give 1 : 2 molar

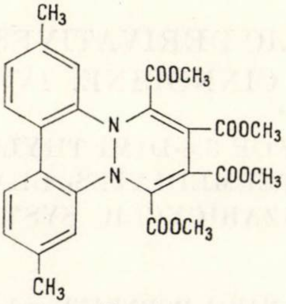
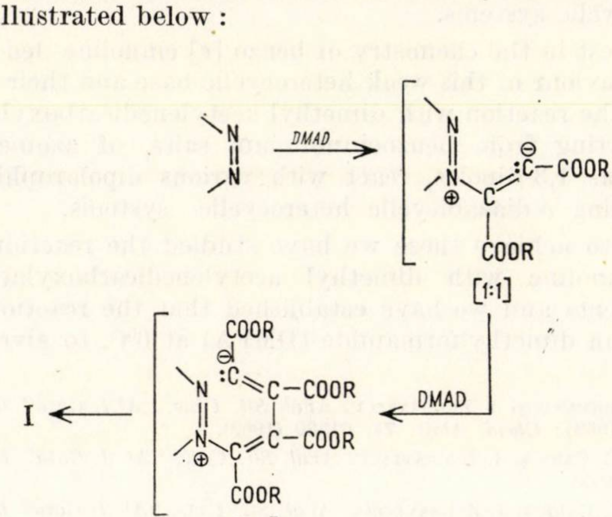
cycloadduct (I):



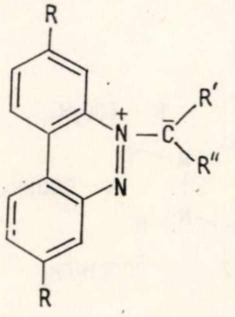
I

The cyclic structure assigned to this product is compatible with its elemental analysis and spectral data, as well as with its stability relative to other electrophilic reagents. In our experiments it is clear that the polarity of the solvent (DMFA) plays an important role and determines readily the cycloadduct formation, by (2 + 4) addition reaction. In this unusual type of Diels-Alder reaction, a possible open adduct system with charge separation is eluded because such a zwitterionic structure could allow the establishment of a new covalent bond between the carbanion and the neighbouring ring nitrogen, ultimately resulting the stable nonpolar cycloadduct. This zwitterionic structure probably appears rather as an intermediate in a stepwise mechanism for the addition reaction (2 + 4). The formation of the cycloadduct (I) by adding two molecules of DMAD across the "azo" system of dimethylbenzocinnoline can be accounted for on the assumption that an initial Michael-type reaction leads to the (1 : 1) molar zwitterionic intermediate, which attacks another molecule of the DMAD to afford the (1 : 2) zwitterion and this can then cyclise to the stable cycloadduct, as illustrated below:



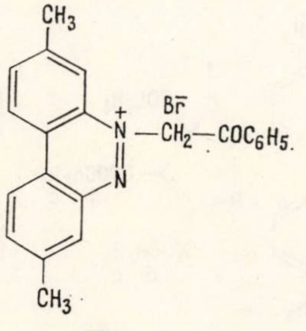
A similar mechanism has been postulated by other workers[4,5] in connection with the reaction of acetylenecarboxylate with conjugated systems containing heteroatomic bases. In the same manner we have already reported[1] the yielding of the 1 : 2 cycloadduct from benzocinnoline and DMAD in a better yield than it was described by another way in the literature.[6]

Further we have prepared the azomethine ylids, derived from the corresponding benzocinnolinium salts, such as benzocinnolinium and 3,8-dimethylbenzocinnolinium dicyano-methylides (II_a and II_b) and 3,8-dimethylbenzocinnolinium-N-phenacylide (II_c) :



II

a. $R = H$; $R' = R'' = CN$
b. $R = CH_3$; $R' = R'' = CN$
c. $R = CH_3$; $R' = H$; $R'' = COC_6H_5$



III

The dicyanomethylides, II_a and II_b, have been obtained by three different ways : a) by salt method from the corresponding heterocyclic bases and bromomalononitrile in acetonitrile solution, followed by the treatment with aqueous potassium carbonate ; b) by the reaction of benzocinnoline with tetracyanoethylene oxide, according to the Linn method[7] ; c) from benzocinnoline-N-oxide and malonodinitrile in the presence of thionyl chloride, an application of the Middleton procedure[8] for obtaining the analogous S-ylids. All these methods afford the corresponding stable nicely red-violet coloured ylids. The most interesting feature of these ylids is their stability relative to other benzocinnolinium ylids which possess only one electronwithdrawing substituent on the carbanion. They do not undergo 1,3-dipolar cycloaddition reactions and are unaffected by weak acids or bases. This chemical stability is due to the stabilizing effect of the two cyano groups on the carbanion charge, which would cause a pronounced decrease in the nucleophilic activity of the ylids.

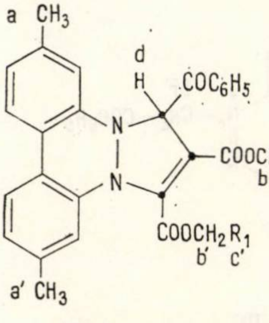
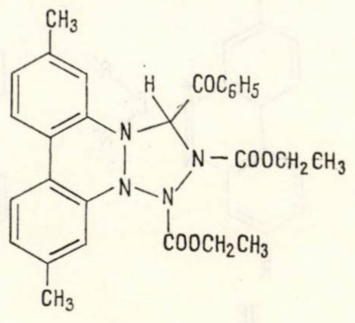
3,8-Dimethylbenzocinnoline by the reaction with ω-bromoacetophenone has been converted in N-(phenacyl)-3,8-dimethylbenzocinnolinium bromide (III). On treatment with triethylamine of the N-phenacyl salt an unstable ylid (II_c) is produced, which can be trapped *in situ* by 1,3-dipolarophiles; otherwise it gives formal dimers. The formation of the ylid can be easily intercepted by the change of the colour in aprotic solvents from yellow to deep red.

The 1,3-dipolar contributory structure to the resonance hybrid is responsible for the 1,3-dipolar cycloaddition reactions of the ylid. We have thus obtained the expected cycloadducts (IV), (V) and (VI):



IV $R_1 = H$ (b,b')
V $R_1 = CH_3$ (c,c')



VI

by reaction of the ylid, generated *in situ* from the salt, with dimethyl and diethyl acetylenedicarboxylate and also with diethyl azodicarboxylate.

Thus, the application of the 1,3-dipolar additions is a successful route for the synthesis of some new *o*-diazabicyclic systems. Only few members belonging to this group are known in the literature.[9,10]

The i.r. and n.m.r. spectral data are in satisfactory agreement with the attributed structures for the cycloadducts.

EXPERIMENTAL

3,8-Dimethylbenzo[*c*]*cinnoline*. This compound was prepared by a similar procedure to that described by Badger[11] from 4,4'-dimethyl-2,2'-dinitrobiphenyl which was reduced with lithium aluminium hydride in refluxing anhydrous ether; needles from methanol, m.p. 187^0.

6,7,8,9-Tetracarbomethoxy-3,12,-dimethylbenzo [*c*] *pyridazino* [*1.2a*] *cinnoline* (*I*). A solution of 3,8-dimethylbenzocinnoline (1.04 g, 0.005 mole) and DMAD (1.42 g, 0.01 mole) in 35 ml DMFA was allowed to stand at 0°C for 5 days, and then at room temperature for 24 hrs. A red colour appeared and a precipitate was formed. The solvent was removed *in vacuo* and the red-dark residue was dissolved in methylene chloride and precipitated with petroleum ether. After recrystallization from benzene (by chromatography over alumina) and petroleum ether the crude product gave 1.2 g of a crystalline light-red adduct, m.p. 169°.

CHROMATOGRAPHIC STUDY OF ACETYLENE AND ETHYLENE ADSORPTION AND OF PALLADIUM DISPERSION FROM Pd/Al_2O_3 CATALYSTS

I.V. NICOLESCU* and I. SUCIU**
***Faculty of Chemistry. Department of Chemical Technology and Catalysis, Splaiul Independenţei nr. 89, Bucharest**
****Industrial Central for Refineries and Petrochemistry, Brazi.**

Received October 13, 1973

By using the pulse microreactor technique, acetylene and ethylene adsorption on Pd/Al_2O_3 catalysts at the temperature of 150° was studied in relation with the properties of the support, which resulted after applying various thermal treatments (600°–900°). It was found that the thermal treatment to which the support was subject, influences the adsorption properties of the catalysts. The studied catalysts : PdA_6, PdA_7, PdA_8 and PdA_9 (1 % palladium content) show different adsorbing capacities, both at first injection and at equilibrium. Palladium dispersion on the alumina support was calculated by using chemisorption data of acetylene. The size of the Pd particles is dependent on the textural properties of the support, treated thermally at 600°, 700°, 800° and 900°. The size of the Pd particles varies from 32.2 Å to 60.7 Å.

INTRODUCTION

Important progress in the study of the phenomena taking place at the interface reactant-catalyst was made by investigating the chemisorption of some gaseous components, with the help of various working techniques : infrared spectroscopy,[1,2] pulse microreactor combined with gaschromatography[3] or radiochromatography[4]. Our research work had the purpose to evidence the influence of the thermal treatment of alumina on the chemisorbing properties of C_2H_2 and C_2H_4 on Pd/Al_2O_3 catalysts. Also, considering that the chemisorption of acetylene on Pd is achieved on two active centres, the chemisorption data were used to determine palladium dispersion on the support. For this purpose, the pulse microreactor method was used.

Research work concerning the correlation of the chemisorbing capacity of a metal laid down on a support with its dispersion was carried out

by Boreskov and Karnaukhov.[5] In subsequent studies,[6-10] research work was carried out concerning chemisorption of hydrogen on platinum laid down on a support and the dispersion degree of platinum. Palladium catalysts were less studied from this point of view.[11-16]

EXPERIMENTAL

The apparatus (fig. 1) used in the present study included : a chromatograph, a device directing the gas-flow to the microreactor and to the chromatographic column, a pipette dosing the injection of the reactant, a microreactor and a chromatographic column.

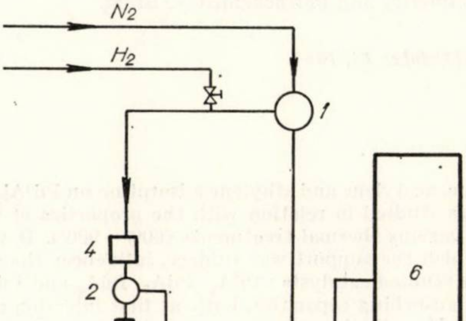

Fig. 1. — Scheme of the apparatus used in the study of acetylene and ethylene adsorption.
(N_2); *2.3* switch valve for bypassing the microreactor; *4*, device for sample injection; *5*, microreactor; *6*, chromatograph.

The catalysts were prepared by impregnating η-Al_2O_3 with palladium nitrate solution, for the concentration of 1 % Pd/support. After impregnation and drying, the catalysts were calcined under a dry air current. The general textural properties of the support are shown in table 1. The four catalysts, differing only by the calcinating temperature of the alumina-support, which is respectively 600°, 700°, 800° and 900° were marked with the indexes : PdA_6, PdA_7, PdA_8 and PdA_9.

A quantity of 1 g of catalyst was introduced into the microreactor and activated with hydrogen at the temperature of 300° with a flow-rate of 50 ml/minute, for 30 minutes. After having activated the catalyst, the microreactor was switched on nitrogen circuit and the catalyst was flushed for 30 minutes with the same flow-rate of 50 ml/minute.

Table 1

Some general properties of the support-aluminas used for the preparation of the PdA_6-PdA_9 catalysts

Alumina	Calcination temperature of the alumina °C	Specific area (A)m^2/g	Total volume of pores (V_t) cm^3/g	Volume of micropores <75Å %	Volume of macropores > 75 Å %
$Al_2O_3-T_6$	600	220	0.546	55.0	45.0
$Al_2O_3-T_7$	700	200	0.486	54.0	45.8
$Al_2O_3-T_8$	800	186	0.543	53.7	46.3
$Al_2O_3-T_9$	900	160	0.452	42.1	57.9

After carrying out this work, the microreactor was cooled down to the working temperature (150°). To the catalyst treated in this way, successive samples of acetylene or ethylene of 0.3 ml content were introduced at equal time intervals, under nitrogen stream (which was at the same time the carrier gas for the chromatographic analysis of the injected C_2H_2 and C_2H_4 samples) via the capillary pipette, set up on a 8 way-valve.

The calibration of the acetylene and ethylene injection was carried out by introducing the sample directly into the chromatographic column and by bypassing the microreactor. The amount of adsorption, respectively the quantity of retained substance was determined by introducing into the microreactor containing the catalyst, which is connected with the chromatographic column (25% squalan on chromosorb W, 60–80 mesh, 1 = 10 m, Øi = 4 mm) the same volume of substance as for calibration, i.e. 0.3 ml.

From the difference of the chromatographic peak areas determined for the two cases related to the volume of the introduced sample, the quantity of substance retained by the catalyst results, according to the following equation :

$$V_r = V_i \ (S_1 - S_2)/S_1, \tag{1}$$

where :

V_r = volume of retained gas (cm^3).

V_i = volume of gas introduced into the microreactor by one injection (cm^3).

S_1 = area of the chromatographic peak, corresponding to V_1 at the calibration (cm^2).

S_2 = area of the chromatographic peak, corresponding to the substance introduced into the microreactor by one injection and not retained by the catalyst (cm^2).

The sample injections were carried out until the complete saturation of the catalyst was reached. The saturation moment was marked by the equality of areas S_1 and S_2.

RESULTS AND DISCUSSION

In order to have a more complete picture of the phenomenon studied, the retention at each newly added substance injection was measured, i.e. from the first injection to the equilibrium. The results obtained are shown in figures 2–5.

Adsorption at first injection. It was found that the retention capacity of the four catalysts studied was different. At first injection, only a higher or a smaller fraction of the sample was retained on the catalyst, depending on the thermal treatment of the support. In each case, the adsorption at first injection was smaller than its value at equilibrium (fig. 2). The thermal treatment temperature of the support is shown on the abscissa and the adsorbed quantity of C_2H_2 and C_2H_4, on the ordinate.

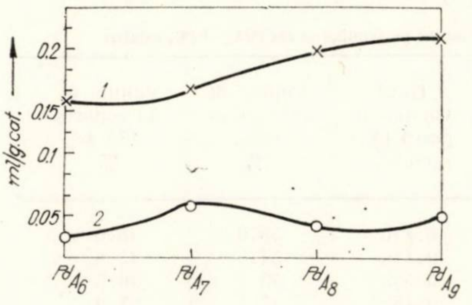

Fig. 2. — Acetylene and ethylene adsorption at first injection on PdA_6 — PdA_9 catalysts. 1 — C_2H_2; 2 — C_2H_4.

For acetylene, the maximum adsorption capacity at first injection is shown by catalyst PdA_9 and the minimum adsorption capacity by PdA_6, whereas catalysts, PdA_7 and PdA_8 are placed in intermediate positions.

Under identical conditions, the retained quantity of ethylene is by far smaller than the quantity of acetylene. But it was noticed that the two curves representing adsorption of acetylene and ethylene at first injection on the four catalysts have not the same aspect. For ethylene, maximum adsorption capacity is shown by catalyst PdA_7. Catalyst PdA_9 which for acetylene shows maximum adsorption capacity, shows for ethylene an intermediate value.

The decreasing order of acetylene and ethylene adsorption at first injection, depending on the thermal treatment of the support shows the following sequence :

— C_2H_2 adsorption : $PdA_9 > PdA_8 > PdA_7 > PdA_6$

— C_2H_4 adsorption : $PdA_7 > PdA_9 > PdA_8 > PdA_6$

Retention at equilibrium. Several injections (between 3 and 7) of reactant were necessary to reach an equilibrium.

Examining the evolution of the adsorption (figures 3, 4 and 5), it has been observed that if for acetylene the sequence of adsorption capacities at first injection is similar to that at equilibrium, for ethylene there are inversions (PdA_8 and PdA_9) and the catalysts which at first injection showed a maximum adsorption capacity for ethylene, at equilibrium have an intermediary position.

The curves representing the amount of acetylene and ethylene adsorbed at equilibrium (fig. 5) on the four catalysts depending on the calcinating temperature of the support show higher values, but in general, they keep the same aspect as in the case of retention at first injection, particularly for acetylene.

The decreasing sequence of acetylene adsorption at equilibrium is identical with that at first injection and varies in the same sense with the calcinating temperature of the support.

The ethylene adsorption at equilibrium is little influenced by the characteristics of the support. A minimum can be observed for the PdA_8 catalyst.

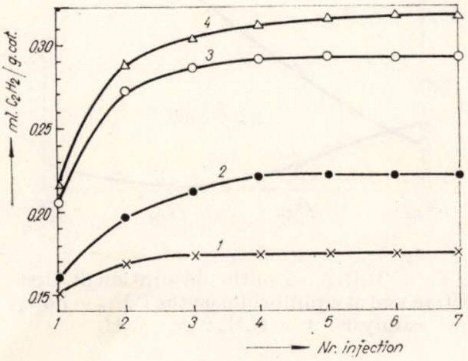

Fig. 3. — Acetylene adsorption on PdA_6—PdA_9 catalysts.

1 – PdA_6; *2* – ; PdA_7; *3* – PdA_8; 4 – PdA_9.

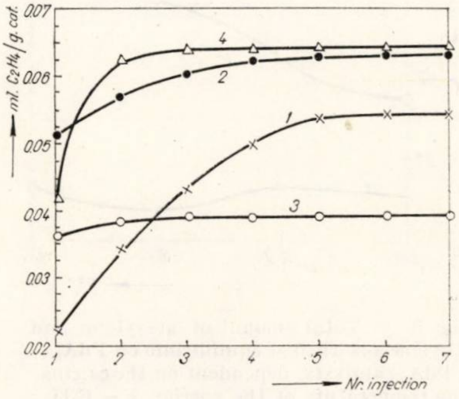

Fig. 4. — Ethylene adsorption on PdA_6—PdA_9 catalysts.

1 – PdA_6; *2* – PdA_7; *3*;PdA_8 – *4* – PdA_9.

By plotting the difference between the quantity of adsorbed gas at first injection and at equilibrium, diagrams shown in figure 6 were obtained. Catalyst PdA_8 (support calcinated at 800°) showing a minimum of ethylene adsorption and a value near to that of saturation for C_2H_2 is revealed. This fact could possibly be correlated with the selectivity of the catalyst in the selective hydrogenation reaction of acetylene to ethylene.

The differentiated adsorption which was noticed, could probably be interpreted in the sense of the strength of the π bond, which takes place at the interaction reactant-catalyst.

Determination of palladium particle size. In the present work, the relation between acetylene chemisorption and palladium dispersion on the support in connection with the thermal treatment of the support, respectively its capacity to disperse palladium was also studied.

For this purpose, the dispersion of the palladium granules on the support was determined from the gaschromatographic data, obtained according to the previously described method, taking into consideration acetylene adsorption.

Considering that palladium covers various zones of the support area with a bidimensional layer[16,17] and taking into account that the radius of the palladium is 1.37Å, the area of one gram of palladium is 424 m^2.

This result assumes that palladium laid down on the support has the shape of a continuous monoatomic film, without any interference with the support alumina.

The following relation was used[16,17] to determine the diameter of palladium particles :

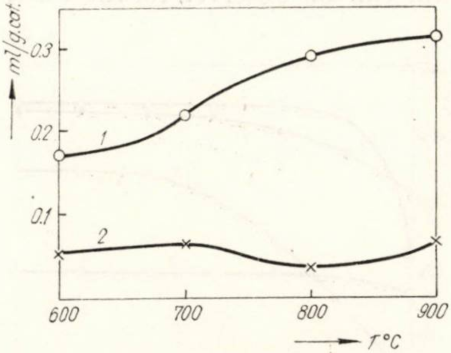

Fig. 5. — Total amount of acetylene and ethylene adsorbed at equilibrium on PdA_6—PdA_9 catalysts, dependent on the calcinating temperature of the carrier. 1 — C_2H_2 ; 2 — C_2H_4.

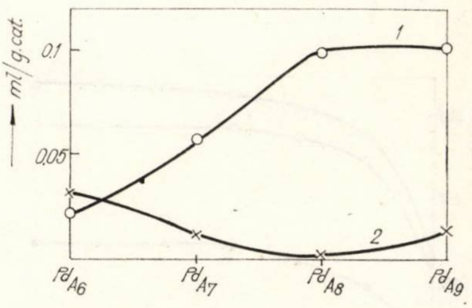

Fig. 6. — Difference of the adsorption at first injection and at equilibrium on the PdA_6 — PdA_9 catalysis. 1 — C_2H_2 ; 2 — C_2H_4

$$d_A = \frac{5 \times 10^4}{A \rho \theta}, \qquad (2)$$

where :

A = specific area of palladium (424 m^2/g).

ρ = specific gravity of palladium (g/cm^3).

θ = coverage degree of palladium with acetylene molecules.

In the present calculations concerning the size of palladium particles, it was assumed that acetylene adsorption on palladium takes place through π electrons, on two centres[18]. The size of palladium particles laid down on alumina by impregnation, differs from one catalyst to another.

The maximum particle size is shown by the PdA_6 catalyst (fig. 7).

In the case of C_2H_2 adsorption, the coverage degree θ, varies inversely with the particle size of palladium. Palladium dispersion in the catalysts prepared with an Al_2O_3 support, treated thermally at high temperatures of 600°—900°, increases with the rise of this temperature. It is an interesting conclusion for the manufacturing technology of this catalyst at industrial level.

[18] G.C. BOND and P.B. WEISZ, *J. Catalysis*, **4**, 211 (1965).

In order to find out if there is any connection between palladium dispersion and activity, respectively between chemisorption and activity in the selective hydrogenation reaction of acetylene, this reaction was carried out and the results will be reported in another paper.

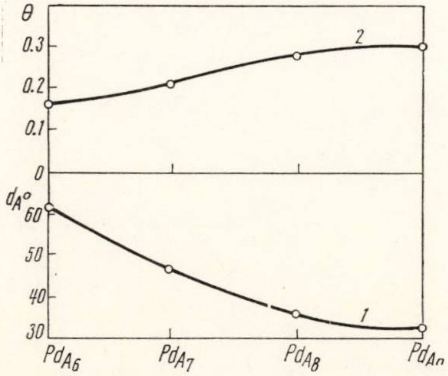

Fig. 7. — 1) Diameter of the palladium particles. 2) Coverage degree.

CONCLUSIONS

The results obtained show that the character of the support determines a specific structure of the palladium catalyst with different behaviour in acetylene and ethylene adsorption. The fact that the adsorption value for C_2H_2 and C_2H_4 both at first injection and at equilibrium differs according to the calcinating temperature of the influence of the support alumina, points to the influence of the support on the adsorption properties of the catalyst, particularly in the case of acetylene. In other words, the textural and structural characteristics of the support, resulting as a consequence of differential thermal treatment it has undergone, confer different adsorbing characteristics to the Pd/Al_2O_3 catalysts, probably as a consequence of the different distribution of palladium crystals on the support and of the orientation in various proportion, of the surfaces (100) and (110), towards the exterior or as a consequence of the differentiated dispersion of the palladium.

The particle size determined by us ranges within the values given by other authors in literature [19,20] and determined by other methods.

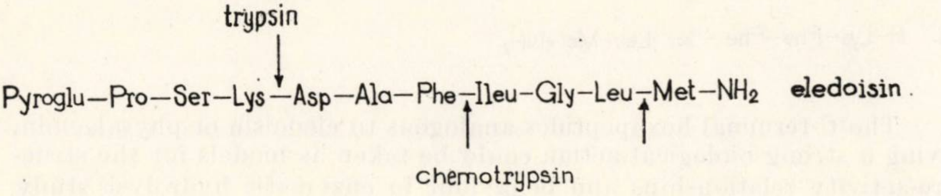
THE SYNTHESIS OF SOME *C*-TERMINAL ANALOGUES OF THE PEPTIDES : ELEDOISIN AND PHYSALAEMIN

F. CUIBAN*, STELIANA CILIANU and VERONICA BADEA
Institute for Chemical-Pharmaceutical Researches, Bucharest, Sos. Vitan 112

Received February 25, 1974

Several hexapeptides, *C*-terminal analogues of eledoisin and physalaemin were synthesized, in which modifications of the peptide chain could influence enzymatic hydrolysis. Some peptides are highly biologically active but of short duration.

Among the numerous peptides intensely studied with regard to amino acid composition-biological activity relationships, eledoisin and physalaemin are listed. They produce a strong vasodilator, hypotensive effect, stimulating also the smooth muscles, but the effect is of short duration. Being constituted of amino acids proper to animal and human organisms, the products are exposed to usual enzymatic degradation within the framework of proteic metabolism. Although they have related structures, physalaemin is several times more active than eledoisin, but the duration of activity is much shorter. Both peptides are inactivated by the enzymatic equipment of blood serum. Their cleavage may be undertaken also with purified enzymes as shown in scheme 1.



trypsin
Pyroglu–Pro–Ser–Lys–Asp–Ala–Phe–Ileu–Gly–Leu–Met–NH2
eledoisin
chemotrypsin
Pyroglu–Ala–Asp–Pro–Asp–Lys–Phe–Tyr–Gly–Leu–Met–NH2
NH2
physalaemin
trypsin

Scheme 1. Enzymatic cleavage of eledoisin and physalaemin.

A great number of analogous peptides were synthesized and especially fragments with *C*-terminal approached amino acid sequences and it was found that they produce even a stronger biological effect than the natural products. Among the biologically active fragments, there are also hexapeptides with related structure to the *C*-terminal part of eledoisin and physalaemin, but their action is also of short duration[1].

---

* Present address : Polytechnic Institute Timişoara, POB 103, Romania

In order to prolong the duration of the peptide activity, conditioning techniques were used, e.g. administration of the peptide suspensions in solvents[2] but which did not provide satisfactory results. One tried also to prepare some aliphatic or aromatic acyl-derivatives but in most cases the biological effect diminished[3] while the prolongation of the activity was unsignificant[4]. Starting from the observation that the loss of activity of oxytocin is due to the cleavage of the *N*-terminal residue by the action of oxytocinase, the substitution of the implied amino acids in the peptide bond (cysteine and tyrosine) by their N-methylated correspondents[5] was checked. An important decrease in biological action was observed with these products. The substitution of glycine by sarcosine in biologically active peptides resulted generally either in a variable or in the total loss of activity[1]. Investigating the hydrolysis of simple peptides, it was found that the enzymatic action was much more reduced than in the case of usual peptides. Some peptides with N-methylated amino acids can display a protease inhibitory function[6].

Scheme 2. The structure of the *C*-terminal sequence of eledoisin hexapeptide analogues.

The *C*-terminal hexapeptides analogous to eledoisin or physalaemin, having a strong biological action could be taken as models for the structure-activity relationships and behaviour in enzymatic hydrolysis study by the methylation of *N*- and *C* -terminal fragments or by the substitution of natural amino acids with N-methyl-amino acids. For this purpose, we synthesized some analogous hexapeptides to the *C*-terminal residue of eledoisin with modifications in the chain which could influence the enzymatic hydrolysis[7]. The structure of these peptides is presented in scheme 2*.

The general synthesis scheme was approached experimentally by the condensation of peptide fragments. In most cases the *C*-terminal dipeptide was condensed with the tetrapeptide, obtained *via* stepwise synthesis or by the condensation of fragments. We adopted a slightly different way of synthesis for the dipeptide BOC-Leu-Met-NH_2 from that described in literature[8] in order to avoid the difficulties connected with the separation of H-Met-NH_2[9] and the use of the *o*-nitrophenylsulphenyl group in the protection of leucine[10]. By coupling BOC-leucine[11] with methionine methyl ester hydrochloride in the presence of DCC we obtained the methyl ester of the dipeptide in good yield. The ammonolysis of the ester by ammonia or by methylamine allowed to obtain the corresponding amines of high optical purity in practically quantitative yield.

Scheme 3. Synthesis of peptides I and II.

The synthesis of hexapeptides (I) and (II) was realized for both compounds after the same scheme (scheme 3) which differs from that described in the literature.[12–15] Tetrapeptide (I_c) was synthesized by stepwise increasing the *C*-terminal end growth. For the preparation of dipeptide (I_e) the use of DCC proved to be more advantageous than activating the carboxyl function *via* its reactive ester$_8$. The use of DCC in the tetrapeptide (I_j) condensation with dipeptide (I_d) led to a strongly impurified compound by dicyclohexylurea derivatives from which the hexapeptide can be isolated with great losses. The use of activated ester (I_k) proved much more convenient for the same synthesis. Although some part of the ester remains unreacted, the isolation and purification of the end-product can be accomplished easily. If an excess of dipeptide (I_d) is employed with the purpose of a more complete conversion of the tetrapeptide ester (I_k), the purification losses will be much greater.

---

* The abbreviations according to the recommandations of I.U.P.A.C. – I.U.B. Commission on Biochemical Nomenclature (I.U.P.A.C. Information Bulletin Nrs. 26 and 27). All amino acids were L-amino acids. In addition: DCC = N,N′–dicyclohexylcarbodiimide; DCCU = = N,N′ -dicyclohexylurea; DMF = dimethylformamide.

The hexapeptide III was previously synthesized *via* coupling the *N*- and *C*-terminal tripeptides, and it was found it possessed only 15% of the hypotensive effect of eledoisin[9]. In order to check whether the decrease of biological action is due to racemization during the synthesis, we prepared this hexapeptide according to the general scheme i.e. by coupling the *N*-terminal tetrapeptide to the dipeptide. In this case, the glycine residue participates in the reaction, when no racemization possibility exists. The *N*-terminal tetrapeptide was synthesized stepwise,

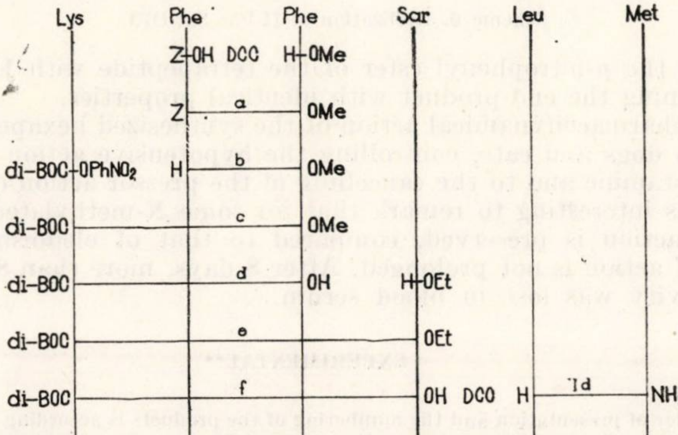
comparing the activation by DCC, mixed anhydride and *p*-nitrophenyl-ester. Almost in every case, better yields were obtained in the condensation by the *p*-nitrophenyl-esters. The details are given in the experimental part.

By preparing peptides (IV) and (V) the general synthesis route was followed using the common *C*-terminal dipeptides for compounds (I) and (II). The *N*-terminal protected tetrapeptide (IV_a) was synthesized by coupling the common tripeptide (III_c) of compound (III) to the *p*-nitrophenyl ester of di-BOC-N,N′-lysine. After the ester was hydrolysed, the tetrapeptide-COOH (IV_f) was coupled to the *C*-terminal dipeptide and the protecting groups were removed from the peptide (IV_c) *via* routine procedure. The synthesis of product (V) was effected similarly to the hexapeptide (IV).



Scheme 5. Synthesis of peptide VI.

For the synthesis of peptide (VI) the adopted scheme was in principle the same, mentioning special difficulties encountered in the stepwise synthesis of the *C*-terminal tetrapeptide. Difficulties occurred even in the preparation of H-Phe-Sar-OEt. The *p*-nitrophenyl ester of carbobenzoxyphenylalanine does not react with ethyl sarcosinate. If carbobenzoxyphenylalanine is coupled with ethyl sarcosinate in the presence of DCC, the compound cannot be obtained in crystalline form. On removal of the amine protecting group, only the corresponding 2,5-diketopiperazine was isolated and characterized instead of the dipeptide ester, according to the reaction shown in scheme 6.

The obtaining of diketopiperazines in the case of dipeptide esters of glycine was evidenced earlier[16] but it appears that this cyclization tendency is much greater for sarcosine ester dipeptides. Following several experiments, the synthesis of peptide (VI) was achieved after a modified scheme (Scheme 5), when the tripeptide di-BOC-Lys-Phe-Phe-OH was first obtained then condensed with sarcosine and thereafter with the *C*-terminal dipeptide. The hexapeptide (VI) could also be prepared by condensing the *p*-nitrophenyl ester of the tetrapeptide with H-Leu-Met-NH_2, obtaining the end-product with identical properties.

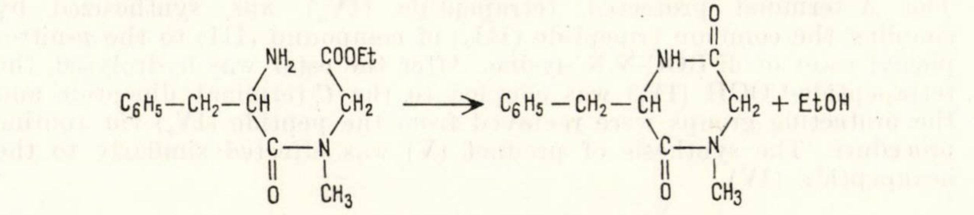

Scheme 6. Cyclization of H-Phe-Sar-OEt.

The pharmacodynamical action of the synthesized hexapeptides was checked on dogs and cats, controlling the hypotensive action in comparison to histamine and to the cancelling of the pressor action of noradrenaline. It is interesting to remark that for some N-methylated peptides, biological action is preserved, compared to that of eledoisin[*] but the duration of action is not prolonged. After 8 days, more than 80% of the initial activity was lost in blood serum.

EXPERIMENTAL[**]

The order of presentation and the numbering of the products is according to the indications in schemes 2—5. All melting points are uncorrected. Vacuum evaporation was effected by a rotatory evaporator. The purity of the compounds was checked by TLC on silica G plates or on Whatman paper nr. 1, colouring with iodine vapours and/or with ninhydrine. The R_f values are referring to the following solvent systems, in V/V : $R_f^0 = CHCl_3 - MeOH$ (20 :1) ; $R_f^a = CHCl_3 - MeOH$ (10 :1) ; $R_f^b = CHCl_3 - MeOH$(5 :1) ; $R_f^c = CHCl_3 - MeOH$ (2 :1) ; $R_f^d = CH_3COC_2H_5 : CH_3CH_2COOH : H_2O$ (6 :2 :3,5) ; $R_f^e = nBuOH - CH_3COOH - H_2O$ (4 :1 :5) ; R_f^j = nPrOH-ammonia 25% sol. (7 :1) ; R_f^k = nPrOH-ammonia 25% sol. (7 :3).

BOC-Leu-Met-OMe (I_a)

To the solution of 2.49 g (10mM) BOC-Leu-OH and 2.59 g (13mM) HMet-OMe.HCl, in 70 ml chloroform, cooled to 0°, 1.8 ml (13 mM) triethylamine was added under stirring. After some min a solution of 2.26 g (11mM) DCC in 10 ml chloroform was added dropwise stirring at 0° for further 5 hours. The mixture was allowed to stand at room temperature for 2 days. After cooling to $-10°$, the resulting DCCU was filtered, while the filtrate washed successively in a separatory funnel with 2 × 35 ml 2N HCl, 2 × 35 ml Na_2CO_3 10% solution and water. The solution was dried over anhydrous Na_2SO_4 and the solvent removed in vacuum. The oil-like residue solved in 30 ml methanol, ice-cooled, 30 ml water was added dropwise. The precipitate was dried at 60° after filtering, recrystallized from 120 ml n-heptane, yielding 2.9g (78%) BOC-Leu-Met-OMe, m.p. 103—104° ; $(\alpha)_D^{25} = -43.4$ (c = 1, MeOH) ; $R_f^0 = 0.5$. Calcd. : $C_{17}H_{32}N_2O_5S$, C : 54.2 ; H : 8.52 ; N : 7.44 ; S : 8.51 ; Found : C : 54.5 ; H :8.70 ; N : 7.50 ; S : 8.30%.

BOC-Leu-Met-NH$_2$ (I_b)

The solution of 2.2 g (5.8 mM) ester (I_a) in 40 anh. methanol, saturated with ammonia at −5° was allowed to stand for 2 days at 0−5°. After the solvent removal in vacuum, BOC-Leu-Met-NH$_2$ resulted in a quantitative yield, presenting a TLC a single spot. $R_f^c = 0.15$; m.p. 158−160°; $(\alpha)_D^{25} = -42.6$ (c=1, MeOH). Lit.[8] m.p. 158−159°; $(\alpha)_D^{25} = -42$.

H-Leu-Met-NH$_2$ (I_d) was prepared *via* literature[8] by removing the amino-protecting group with saturated solution of HCl in acetic acid, then neutralized with K_2CO_3 50 % solution, in 63 % yield; m.p. 124−126°.

Z-Phe-Gly-OEt (I_e)

To the solution of 8.97 g (30 mM) Z-Phe-OH and 5.2 g (37.5 mM) glycine methyl ester chlorohydrate in 60 ml DMF, cooled to 0°, 4.6 ml (37.5 mM) triethylamine was added dropwise, under stirring. After 10 min, a solution of 6.77 g (33 mM) DCC in 10 ml DMF was added drop-. wise. The mixture stirred for 5 hours at 0° was allowed to stand over night in the refrigerator. To the cooled solution 150 ml ethyl acetate was added and the resulting DCCU filtered. The filtrate was washed twice with 2N HCl (100 ml and 50 ml), then successively washed with 2 × 50 ml Na_2CO_3 10 % solution and water to neutral reaction. The solution was dried over anh. Na_2SO_4 and the solvent removed in vacuum. The crystalline residue was several times triturated with anh. ether, dried, achieving 7.2 g (I_e) (Yield- 62 %), m.p. 110−112°, identical to the product described in literature[8], chromatographically pure; $R_f^b = 0.77$.

Z-Phe-Phe-Gly-OEt (I_g), *di-BOC-Lys-Phe-Phe-Gly-OEt* (I_i) and *di-BOC-Lys-Phe-Phe-Gly-OH* (I_j) were prepared according to the procedure described in the literature [8], obtaining products with identical properties.

di-BOC-Lys-Phe-Phe-Gly-OPhNO$_2$ (I_k)

In a mixture of 100 ml dioxane and 66 ml ethyl acetate, 2.3 g (3 mM) tetrapeptide-COOH (I_j) and 0.66 g (4.9 mM) *p*-nitrophenol were solved. To the solution, 0.68 g (3.3 mM) DCC dissolved in 5 ml ethyl acetate was added dropwise under stirring and was kept for 2 days at room temperature. The mixture was cooled to −10° and the resulting DCCU from the reaction, filtered. After the solvent removal in vacuum the residue mixed with Et_2O and solved with 110 ml ethanol, under reflux. After cooling to 20° water was added until a slight opalescence, then cooled to −15°. After filtering and drying, 2 g of product (I_k) were obtained, m.p. 136−140° (yield−74 %). Calcd.: $C_{42}H_{54}N_6O_{11}$, C :61.58 ; H :6.64 ; N :10.26 ; Found : C :61.70 ; H :6.60 ; N :10.37 %.

di-BOC-Lys-Phe-Phe-Gly-Leu-Met-NH$_2$ (I_l)

1.42 g (1.68 mM) *p*-nitrophenyl ester of tetrapeptide (I_k) and 0.44 g (1.68 mM) leucylmethionine-amide (I_d) were solved in 32 ml DMF and stirred for 10 days at room temperature. After advanced solvent removal in vacuum, the oil-like residue was triturated with 20 ml water, filtered and washed with Et_2O, dried, achieving 1.4 g crude product (I_l). For purification, the crude product was solved in 6 ml DMF, ice-cooled and precipitated in 60 ml Et_2O, under stirring. After filtering, it was washed with 10 ml cooled Et_2O, dried, obtaining 0.5 g hexapeptide, m.p. 234−235° (yield −31 %) with identical properties to the product described in literature[8], chromatographically unitary, $R_f^b = 0.65$.

H-Lys-Phe-Gly-Leu-Met-NH$_2$*.2HCl* (I)

To 0.33 g (0.35 mM) of protected peptide (I_l), 27 ml glacial acetic acid with HCl 2 % were added. After 5 min, [88 ml anhydrous Et_2O was added to the filtered solution, cooling to −15°. After filtering and washing with absolute Et_2O, dried over P_2O_5 and NaOH, 0.255 g peptide (I) (yield-86 %) were achieved, m.p. 160−165°. The product is chromatographically unitary on silica G plates, $R_f^d = 0.66$, and on paper $R_f^e = 0.59$; Calcd. : $C_{37}H_{56}O_6N_8S.2HCl.2H_2O$, C :52.20 ; H :7,37 ; N :13.18 ; Found : C :52.10 ; H :7.40 ; N :13.00 %.

BOC-Leu-Met-NHCH$_3$ (II$_b$)

To the solution of 0.75 g (2 mM) ester (I_a) in 4 ml absolute ethanol, 5 ml methylamine 33 % alcoholic solution were added and allowed to stand for 3 days at room temperature. Adding 16 ml water the product was precipitated and filtered. For purification, it was dissolved in 10 ml EtOH by heating and 10 ml water was added, achieving 0.5 g BOC-Leu-Met-$NHCH_3$ (yield-66 %), m.p. 133−135° ; $(\alpha)_D^{25} = -45$ (c = 1, MeOH) ; $R_f^a = 0.37$; Calcd. : $C_{17}H_{33}O_4N_3S$, C : 57.37 ; H :8.80 ; N :11.32 ; S :8.53 ; Found : C :54.70 ; H : 9.00 ; N :11.27 ; S :8.30 %.

H-Leu-Met-NHCH$_3$*.HCl* (II$_c$)

1 g (2.66 mM) amide (II_b) was treated at room temperature with a solution of HCl 7 % in glacial acetic acid and allowed to stand for 1 hour. After adding 100 ml absolute Et_2O and cooling, it was filtered, avoiding the contact with atmospheric humidity, because the compound is hygroscopic. Dried in vacuum over P_2O_5 0.7 g H-Leu-Met-$NHCH_3$.HCl was obtained (yield-−87 %), displaying a single chromatographical spot, $R_f^c = 0.45$; Calcd. : $C_{12}H_{26}SO_2Cl$, Cl :11.38 ; S : 10.31 ; Found : Cl :11.60 ; S :10.00 %.

di-BOC-Lys-Phe-Phe-Gly-Leu-Met-NHCH$_3$ (II$_1$)

To the solution of 0.32 g (1 mM) leucyl-methionine-methyl amide chlorohydrate (II_c) in 10 ml DMF, cooled to 0° 0.1 g (1 mM) triethylamine was added and after 10 min, the triethylamine chlorohydrate was filtered. To the filtrate, 0.82 g (1 mM) *p*-nitrophenyl ester peptide (I_k) was added, stirring for 6 days at room temperature. After DMF removal in vacuum, the *sicc* residue was solved in 25 ml Et_2O, cooled to −10°, filtered, achieving 0.8 g impure peptide (II_1). For purification the product was dissolved under reflux in 15 ml methanol, hot filtered, ice-cooled and filtered after adding 4 ml water. When purification was repeated, 0.34 g pure hexapeptide (II_1) was obtained (yield-35 %), m.p. 235−237°, chromatographically pure, $R_f^a = 0.25$; Calcd. : $C_{40}H_{74}O_{10}N_8S$, C :60.35 ; H :7.80 ; N :11.73 ; Found : C :60.40 ; H :8.00 ;N :11.78 %.

H-Lys-Phe-Phe-Gly-Leu-Met-NHCH$_3$*.2HCl* (II)

0.25 g protected peptide (II_1) was treated at room temperature with 19 ml of HCl 9 % solution in glacial acetic acid and after 7 min vacuum filtered, through a porous crucible. The solution diluted with 200 ml absolute Et_2O was let to crystallize in the cold. The filtered product was dried over NaOH in an exicator, thereafter in a drying pistol over P_2O_5 at 35°, yielding 0.19 g (II) as dichlorohydrate, m.p. 152−153° ; $(\alpha)_D^{22} = -16.7$ (c = 0.43, MeOH :H_2O, 1 : 1). The product is chromatographically pure, $R_f^d = 0.7$ on silica G plates and $R_f^e = 0.76$ on paper. Calcd. : $C_{38}H_{58}O_6N_8S.2HCl.1\ 1/2\ H_2O$, C :53 :38 ; H :7.44 ; N :13.10 ; Found : C :53.30 ; H : 7.30 ; N :13.00 %.

Z-Val-OPhNO$_2$

In a magnetically stirred Erlenmeyer flask, 2.8 g (11 mM) carbobenzoxy-valine[11] and 1.56 g (11 mM) *p*-nitrophenol were dissolved in 10 ml ethyl acetate. Cooled to 0°, 2.3 g (11 mM) DCC dissolved in 3 ml ethyl acetate under stirring was added and kept at room temperature for 3 hours. Washed successively with $NaHCO_3$ saturated solution, 1N HCl and water. Thereafter dried over anhydrous Na_2SO_4, it was concentrated to *sicc* in vacuum. The residue was treated with 10 ml. absolute EtOH, and after filtering, precipitated with 5 ml petroleum ether. After filtering and washing with a solution consisting of equal volume absolute EtOH and petroleum ether, dried in vacuum, 2.54 g Z-Val-OPhNO$_2$ was obtained (yield-60 %), m.p. 63–65°, chromatographically pure, $R_f^a = 0.7$. Calcd. : N :7.32 ; Found : N :7.70 %.

BOC-Ala-OPhNO$_2$. To a solution of 3 g (16 mM) BOC-Ala-OH[11] and 2.24 g (16 mM) *p*-nitrophenol in 17 ml DMF, 3.3 g (16 mM) DCC dissolved in the same solvent, was added at 0°. After 2 hours stirring at 0° and 4 hours at room temperature, it was allowed to stand over night. After diluting the reaction media in 50 ml water and 5 ml ethanol, the yellow oil-like product crystallized in time. After filtering and washing with petroleum ether, 4.4 g BOC-Ala-OPhNO$_2$ were achieved (yield –90%), m. p. 225–227°, chromatographically unitary on silica G plates, $R_f^c=0.6$. Dioxane may be used also condensation solvent achieving very good yields. The removal of DCCU in this case is accomplished by filtering.

Z-Val-Gly-OMe (III$_a$)

(i) *Via p*-nitrophenyl ester : To a solution of 2.7 g (7 mM) Z-Val-OPhNO$_2$ and 0.9 g (7 mM) glycine methyl ester chlorohydrate in 15 ml DMF, an equivalent of triethylamine was added under stirring ; after stirring for 5 hours at room temperature, it was allowed to stand over night, then diluted in 30 ml water and filtered. The precipitate, dissolved in 3 ml EtOH, was again precipitated with 20 ml water. After filtering and drying in vacuum over P_2O_5, 2 g of product (III$_a$) were achieved (yield-86 %), m.p. 160–162°, chromatographically pure, $R^a{}_f=$ $=0.68$. Calcd. : $C_{16}H_{22}N_2O_5$, C :59.62 ; H :6.88 ; N :8.69 ; Found : C :59.50 ; H :6.54 ; N :8.80 % ·

(*ii*) Synthesis *via* DCC method. To a suspension of 1.2 g (9mM) methyl-glycinate chlorohydrate in 15 ml $CHCl_3$, 1.35 ml (9 mM) triethylamine then 2 g (8 mM) Z-Val-OH dissolved in $CHCl_3$ were added. After cooling to 0–5°, a solution of 1.64 g (8 mM) DCC in 2 ml $CHCl_3$ was added dropwise, the reaction media stirred for 2 hours at the same temperature, was let to stand thereafter, over night at room temperature. DCCU was filtered, the chloroformic solution successively washed with 3 × 15 ml 1N HCl, 3 × 15 ml $NaHCO_3$ saturated solution and 2 × 20 ml NaCl saturated solution. The organic solvent layer was dried over anh. $MgSO_4$ and evaporated to *sicc*. After solving the residue in 80 ml ethyl acetate and precipitation with petroleum ether, 0.9 g (III$_a$) were obtained (yield-35 %) with identical characteristics to the product resulted *via p*-nitrophenyl ester method (*i*).

Z-Phe-Val-Gly-OMe (III$_c$)

The equimolal mixtures (7 mM) of carbobenzoxyphenyl-alanine *p*-nitrophenyl ester[17] with dipeptide bromohydrate (III$_b$) obtained by deprotecting peptide (III$_a$) *via* routine techniques and triethylamine were dissolved in 17 ml DMF. After keeping for 5 days at room temperature, the mixture was diluted in 30 ml water and the precipitate washed with Et_2O, then dried in vacuum, achieving 2.94 g (III$_c$), m.p. 195–197°, (yield-88 %), chromatographically pure, $R_f^a=0.62$. Calcd. : N :8.94 ; Found : N :9.20 %. If condensation is made *via* mixed anhydride of Z-Phe-OH with isovaleric acid, the reaction yield diminishes to 20 %, while performing with DCC it is only 10 %, on account of the difficulties encountered at purification ; m.p. in the last scheme was somehow lower, 192–193°.

BOC-Ala-Phe-Phe-Val-Gly-OMe (III$_e$)

After deprotecting tripeptide (III$_c$) under usual conditions with HBr 33 % solution in glacial acetic acid and obtaining bromohydrate (VI$_d$), (7 mM) thereof was solved in 30 ml mixture of equal volume DMF : ethyl acetate (or the necessary amount of dioxane), equimolal amounts of triethylamine and BOC-Ala-OPhNO$_2$ were added. Kept at room temperature for 4 days the solvents were eliminated in vacuum. The *sicc* residue was purified by repeated precipitations with petroleum ether from ethyl acetate, chloroform or absolute ethanol and was used for the next operation. Reaction yield, 75.5% versus the tripeptide (III$_c$).

---

[17] V. Du Vigneaud and M. Bodanszki, *J. Amer. Chem. Soc.*, **81**, 6072 (1959).

BOC-Ala-Phe-Val-Gly-OH (III$_f$)

To the solution of 0.3 g (0.6 mM) tetrapeptide ester (III$_e$) in 36 ml absolute ethanol, prepared at 55–60°, 3 ml water was added. After cooling to room temperature, 1.5 ml 1N NaOH was added, stirring for 1 hour. The alcoholic solution was diluted with 70 ml water and acidulated to pH=2 with 2N HCl solution. After extraction with 100 ml Et_2O and drying over $MgSO_4$, the ether was removed in vacuum, achieving 0.3 g (in quantitative yield) product (III$_f$) chromatographically pure, m.p. 180–182°.

BOC-Ala-Phe-Val-Gly-Leu-Met-NH$_2$ (III$_g$)

To the solution of 0.24 g (0.485mM) tetrapeptide–COOH (III$_f$) and 0.15 g (0.575 mM) H-Leu-Met-NH$_2$ (I$_d$) in 12 ml anh. pyridine, cooled to 0°, 0.12 g (0.585 mM) DCC was added, maintaining the same temperature for 2 hours. After stirring for 2 days at room temperature, the solvent was removed in vacuum and the residue washed successively with 6 × 5 ml 1N HCl, 5 × 5 ml $NaHCO_3$ 5% solution and Et_2O. The precipitate was dissolved in 6 ml DMF, DCCU removed by filtering and the solution diluted with 28 ml ethyl acetate. After filtering and washing at 40–50° with ethyl acetate and chloroform, 0.043 g product (III$_g$) (yield–17.2%) were obtained, chromatographically pure, m.p. 248–249°.

H-Ala-Phe-Val-Gly-Leu-Met-NH$_2$.HCl (III)

To 2 ml HCl 7% solution in glacial acetic acid, 0.043 g (0.084 mM) protected hexapeptide (III$_g$) was added, allowed to stand for 25 min at room temperature, then filtering over a G$_3$ crucible in order to remove the very small amounts of insoluble products. To the filtrate, 10 ml anh. Et_2O was added, cooled to 0°, kept for 1–2 hours at this temperature, the precipitate was filtered and washed with anh. Et_2O avoiding contact with atmospheric humidity. After drying in vacuum over P_2O_5, 0.036 g hexapeptide chlorohydrate (yield-96%) were achieved, m.p. 288–290°, chromatograpphically pure, $R_f^d=0.68$ on silica plates and $R_f^e=0.65$ on paper. Calcd. : Cl^- :5.27 ; Found : 5.20%.

di-BOC-Lys-Phe-Val-Gly-OMe (IV$_a$)

3.5 g (7.4 mM) Z-Phe-Val-Gly-OMe (III$_c$) was treated at room temperature with 35 ml HBr 25% solution in anh acetic acid. After standing for 1 hour, 200 ml anh. EtOH were added and then cooled to –10° for 2 hours. The filtered product was dried in vacuum over P_2O_5 and NaOH. The achieved crystals were dissolved in 200 ml DMF, the solution cooled to –5° and treated with 0.85 g (7.4 mM) triethylamine. After filtering, 3.5 g (7.4 mM) N,N′-di-BOC-lysine *p*-nitrophenyl ester[13] were added to the solution, stirring for 6 days at room temperature. The reaction mixture was diluted with 100 ml water, ice-cooled, and after filtering, the precipitate was washed with Et_2O ; 3.5 g tetrapeptide (IV$_a$) were obtained (yield-70%), m.p. 190–192°, chromatographically pure on silica plates ; R_f^a =0.6. Calcd. : N :10.56 ; Found : 10.70%.

di-BOC-Lys-Phe-Val-Gly-OH (IV$_b$)

Into a mixture of 120 ml EtOH and 3 ml 1N NaOH solution, 2.4 g (3.6 mM) ester (IV$_a$) were solved and allowed to stand over night. The alcohol was removed in vacuum, 25 ml water

---

[18] E. Sandrin and R.A. Boissonnas, *Helv. Chim. Acta*, **46**, 1637 (1963).

was added after ice-cooled, it was acidulated to pH=3 with HCl 10 % solution. After filtering and drying in vacuum, 2 g peptide (IV_b) was obtained in 85 % yield, chromatographically pure on silica plates ; $R_f^o=0.1$, m. p, 154–156°. Calcd. : $C_{32}H_{51}N_5O_9$, C : 59.15 ; H : 7.91 ; N : 10.78 ; Found : C :59.00 ; H :7.90 ; N :10.80 %.

di-BOC-Lys-Phe-Val-Gly-Leu-Met-NH_2 (IV_c)

In a solution of 10 ml DMF and 5 ml acetonitrile, 0.85 g (1.3 mM) tetrapeptide (IV_b) and 0.33 g (1.5 ml) leucyl-methionine amide (I_d) were dissolved ; after cooling to −5°, 0.27 g (1.3 mM) DCC was added. It was kept over night at 0°, thereafter for 3 days at room temperature. The reaction mixture was slowly poured into 50 ml water and ice-cooled. The gel-like precipitate was filtered, dried in vacuum and 1.2 g crude product (IV_b) was achieved. The product was solved in 50 ml $CHCl_3$, filtered and the solution successively washed with 2 × 20 ml 1N HCl, 2×20 ml $NaHCO_3$ saturated solution and water. The solution was dried over anh. Na_2SO_4, the solvent removed in vacuum, the residue solved in 15ml DMF and diluted with 50ml water. After filtering and drying in vacuum over P_2O_5, the chromatographically pure product was obtained ; $R_f^a=0.7$ on silica plates, m. p. 220–225° (decomposition).

H-Lys-Phe-Val-Gly-Leu-Met-NH_2*.2HCl* (IV)

The protecting groups of the hexapeptide (IV_c) were removed *via* procedure described for the other peptides i.e. by means of the HCl 5 % solution in glacial acetic acid. Purification was effected by solving in DMF and allowing to precipitate in anh. Et_2O. The product was chromatographically pure, $R_f^d=0.7$ on silica plates. Calcd. : Cl^- :9.28 ; Found : 9.50 %.

di-BOC-Lys-Phe-Val-Gly-Leu-Met-$NHCH_3$ (V_a)

The synthesis was approached in a similar way to that applied in the synthesis of protected hexapeptide (IV_c), using for coupling dipeptide (II_d). At purification, identical techniques were performed, yielding a product (V_a), m.p. 235–240° (decomposition), $R_f^a=0.7$.

H-Lys-Phe-Val-Gly-Leu-Met-$NHCH_3$*.2HCl* (V)

Removal of the protecting groups was effected similarly to that for peptide (IV). $R_f^d=0.7$ on silica plates. Calcd. : Cl^- :9.12 ; Found : 9.40 %.

Z-Phe-Phe-OMe (VI_a)

To 2.15 g (10 mM) phenyl-alanine methyl ester chlorohydrate, prepared *via* literature references[19], solved in 15 ml DMF, cooled to −10°, 1.01 g (10 mM) triethylamine was added. After 15 min the triethylamine chlorohydrate was filtered, 2.29 g (10 mM) carbobenzoxy-phenylalanine added, allowing the temperature to increase to 0–2°. The same temperature was maintained while a solution of 2.20 g (11 mM) DCC in 10 ml ethyl acetate was dropwise added to the mixture, stirring for 2 hours. The solution was allowed to stand over night at 5°, then cooled to

---

[19] R.A. BOISSONNAS, *Helv. Chim. Acta*, **39**, 1421 (1956).

$-10°$ for 30 min for the complete precipitation of DCCU. After filtering, 100 ml ethyl acetate were added to the filtrate. The solution was washed successively with 2 × 20 ml 2 N HCl, 2 × × 20 ml Na_2CO_3 10 % and with water to neutral reaction. After drying over anhydrous Na_2SO_4, the solvent was removed in vacuum and residue recrystallized from 40 ml methanol, 3.5 g of (VI_a) (yield-76 %) were obtained, m.p. 148–150° ; $(\alpha)_D^{22} = -21.8$ (c=0.5, MeOH), chromatographically pure on silica plates, $R_f^o = 0.67$; Calcd. : $C_{27}H_{28}O_5N_2$, C : 70.41 ; H : 6.12 ; N : 6.08 ; Found : C :70.60 ; H :5.80 ; N :6.18 %.

di-BOC-Lys-Phe-Phe-OMe (VI_c)

4,6 g (10 mM) dipeptide ester (VI_a) was treated with a solution of 14 ml HBr 25 % in anh. acetic acid and allowed to stand for 1 hour ; 200 ml anh. Et_2O were added to the solution, cooled to $-10°$ for 1.5 hours, separating after filtering and drying in vacuum over NaOH and P_2O_5, the peptide ester bromohydrate (VI_b). This was dissolved in 30 ml DMF, cooled to $-10°$ and reacted with 1.01 g (10 mM) triethylamine when triethylaminebromohydrate precipitated. After filtering and washing with DMF, 4.67 g (10 mM) di-BOC-lysine *p*-nitrophenyl ester[3] was added to the solution of peptide (VI_b), keeping the mixture stirred at room temperature for 4 days. After cooling to $-10°$, 40 ml water were added and the precipitated product, separated by filtering, was dried at ambiant temperature. After careful washing by trituration with Et_2O, 4.7 g ester (VI_c) were achieved, m.p. 150–152°, $(\alpha)_D^{22} = -31.2$ (c = 0.5, MeOH), chromatographically pure on silica plates, $R_f^a = 0.53$. Calcd. : $C_{35}H_{50}N_4O_8$, C :64.20 ; H :7.70 ; N :8.56 ; Found : C :64.00 ; H :7.50 ; N :8.66 %.

di-BOC-Lys-Phe-Phe-OH (VI_d)

To 3 g (4.58 mM) peptide ester (VI_c) solved by refluxing 450 ml EtOH, 120 ml water was added and after cooling to 40°, 12 ml 1N NaOH solution was added dropwise, keeping at room temperature over night. The solution acidulated to pH=3–4 with HCl 10 % when EtOH was removed in vacuum. After cooling and filtering 2.8 g peptide (VI_d) were separated in 95 % yield, m.p. 186–189°, chromatographically pure on silica plates ; $R_f^i = 0.7$.

di-BOC-Lys-Phe-Phe-Sar-OEt (VI_e)

In 60 ml pyridine, 4.5 g (7 mM) peptide (VI_d) and 1.35 g (8.8 mM) sarcosine ethyl ester chlorohydrate were dissolved. After cooling to 2°, 1.65 g (8 mM) DCC was added and allowed to stand at room temperature for 2 days. Pyridine was removed in vacuum, the oil-like residue was washed several times with water after decanting and thereafter treated with 50 ml dioxane. Cooled to 10°, DCCU was separated by filtering and the filtrate concentrated in vacuum to *sicc.* The residue solved in 150 ml ethyl acetate and the solution washed successively with 3 × 35 ml 2N HCl, 35 ml Na_2CO_3 10 % solution, 2 × 35 ml $NaHCO_3$ 5 % solution and water. After drying the organic layer over anydrous Na_2SO_4, the solvent was removed in vacuum and the crystalline residue purified by triturating with 15 ml Et_2O cooled to $-10°$. After filtering and washing with Et_2O, 2.8 g ester (VI_e) were obtained (yield-55 %), m.p. 85–89°, $(\alpha)_D^{22} = -18.2$ (c=0.5, MeOH), chromatographically pure on silica plates ; $R_f^a = 0.47$. Calcd. : $C_{39}H_{57}N_5O_9$, C :63.30 ; H :7.77 ; N :9.46 ; Found : C :63.50 ; H :7.80 ; N :9.30 %.

di-BOC-Lys-Phe-Phe-Sar-Leu-Met-NH$_2$ (VI_g)

(*i*) Synthesis of acid tetrapeptide (VI_f). To the solution of 1 g (1.3 mM) ester (VI_e) in 50 ml ethanol and 10 ml water, 3 ml 1N NaOH were added, keeping under stirring at room temperature for 30 min. After acidulating with HCl 10 % to pH=3–4, the alcohol was removed in vacuum, the solution ice-cooled and filtered, achieving 0.9g tetrapeptide acid (VI_f) (yield–90 %), m.p. 122°, chromatographically pure on silica plates, $R_f^k = 0.77$.

(*ii*) Synthesis *via* *p*-nitrophenyl ester of tetrapeptide (VI_f). To the solution of 0.5 g (0.7 mM) peptide (VI_f) and 0.13 g (1 mM) *p*-nitrophenol in 30 ml anhydrous ethyl acetate cooled to 0°, 0.16 g (0.7 mM) DCC solved in 4 ml ethyl acetate were added. After stirring for 6 hours at room temperature and cooling to $-10°$, DCCU was filtered. After solvent elimination in vacuum, the residue consisting of peptide *p*-nitrophenyl ester (VI_f) was dissolved in 10 ml DMF together with 0.2 g (0.74 mM) leucyl-methionine amide (I_d) and stirred at room temperature for a week. After removing DMF in vacuum, the resulted oil-like residue was treated with 5 ml water, ice-cooled in order to promote crystallization and after filtering, was dried in vacuum over P_2O_5. The precipitate was solved in 100ml ethyl acetate and the solution successively washed with 5 × 20 ml 2N HCl, 8 × 20 ml Na_2CO_3 10% and water to neutral reaction. After drying the estereal solution over anhydrous Na_2SO_4, the residue was triturated in the cold with 8 ml Et_2O, then filtered and dried, the protected hexapeptide (VI_g) was obtained, chromatographically unitary on silica plates, $R_f^a=0.5$, m.p. 161–164°. Calcd. : $C_{48}H_{74}O_{10}N_8S$, C :60.35 ; H :7.81 ; N :11.73 ; Found : C :60.00 ; H :7.50 ; N :11.77%.

(*iii*) Synthesis *via* DCC method. To a solution of 0.5 g (0.7 mM) peptide (VI_f) and 0.36 g (1.4 mM) leucyl-methionine amide (I_d) in 7.5 ml pyridine cooled to 0°, 0.43 g (2.1 mM) DCC was added. After stirring for 1 week at ambiant temperature, pyridine was removed in vacuum, the *sicc* residue dissolved in 10 ml dioxane, thereafter cooled to 5–10° and DCCU removed by filtering. After concentrating to *sicc*, the precipitate was dissolved in 50 ml ethyl acetate and successively washed with 4 × 20 ml 2 N HCl, 4 × 20 ml Na_2CO_3 10% solution, then with water and dried over anh. Na_2SO_4. The residue achieved after solvent removal was solved in 4 ml methanol, the solution cooled to $-5°$ and small amounts of DCCU eliminated by filtering. After the solvent removal, the residue was triturated with Et_2O ; hexapeptide (VI_g) was yielded with identical properties to that described at (*ii*).

H-Lys-Phe-Phe-Sar-Leu-Met-NH$_2$.2HCl (VI)

The protected amide (VI_g) — 0.35 g — was treated at room temperature with 27 ml HCl 9% solution in glacial acetic acid. Filtered after 5 min, it was precipitated with 120 ml anh. Et_2O, obtaining after separation and drying over NaOH and P_2O_5 at 35°, 0.26 g (VI), m.p. 142–146° ; $(\alpha)_D^{22} = -13.8$ (c=0.62, MeOH :H_2O, 1 :1). The product was chromatographically unitary on silica plates and paper ; $R_f^d=0.75$, respectively $R_f^e=0.76$. Calcd. : $C_{38}H_{58}O_6N_8S.2HCl.2H_2O$, C :52.82 ; H :7.46 ; N :12.96 ; Found : C : 52.50 ; H :7.30 ; N :13.00%.

COPOLYMERS OF CONJUGATED DIENES WITH MALEIC ACID MONOESTERS. VIII[1]

BULK COPOLYMERIZATION OF ISOPRENE WITH MONOBUTYL MALEATE

C. ANDREI* and I. NANU**

* Research Laboratory, Ploieşti Petrochemical Industrial Group Brazi, Romania
** Chair of Macromolecular Chemistry, Polytechnic Institute, str. Karl Marx 3, Timişoara, Romania.

Received October 22, 1973

A study is carried out on bulk copolymerization of isoprene with monobutyl maleate in presence of free radicals (A.I.B.N.), in comparison with the concurrent Diels-Alder reaction between the two monomers. The appearance of the "Trommsdorf" effect is remarked in the bulk copolymerization reaction. On the basis of the studied kinetic aspects of the structure and microstructure of the coopolymers, a mechanism is admitted for the copolymerization reaction involving the participation of a *cisoid* donor-acceptor complex and which, at the same time, can be common to the Diels-Alder reaction. Some considerations are also presented on the donor-acceptor complex.

INTRODUCTION

The main kinetic aspects of the solution copolymerization reaction (homogeneous medium) of isoprene with different monoesters of maleic acid were presented in previous works.[2-5]

The values of the copolymerization constants, as well as the Q and e values showed a marked alternating tendency in copolymerization.

The study on bulk copolymerization of isoprene with monobutylmaleate is intended to provide additional information on the kinetics and mechanism of the copolymerization reaction in presence of free radicals and at the same time to give answers to the questions raised before.

This reaction takes place in a heterogeneous medium as the copolymers formed are insoluble in unreacted monomers (copolymerization with precipitation).

EXPERIMENTAL

MATERIALS

The isoprene used (Schuchardt) of $> 99\,\%$ mol. concentration was separated from the polymerization inhibitor by simple distillation.

Monobutyl maleate was prepared in the laboratory by esterification of maleic anhydride with butyl alcohol in molar ratio of 1 : 1 at 80° temperature. The monoester thus obtained had the following characteristics : colourless liquid, $d_{20}^{20} = 1.4570$ and acidity index (A.I.) = 326.7 – – 327.2.

The polymerization initiator, α,α'-azobisisobutyronitrile, was recrystallized twice from acetone or ethyl ether.

METHOD OF WORK

The process of mass copolymerization of isoprene with monobutyl maleate was carried out in closed Pyrex-phials blown beforehand with nitrogen.

The stirring of the reaction mixture was achieved by rotating of the phials in an oil bath maintained at an established working temperature.

After the reaction was carried out, the phials were cooled suddenly under 0° temperature, in order to break off the reaction.

In order to separate the copolymer from the reaction mixture, the latter was dissolved in ethyl ether and precipitated with petroleum ether.

Quantitative purification was achieved by repeated dissolution and precipitation of the copolymer, whereas drying was carried out at a temperature of 40°.

The composition of the copolymer was analyzed by elementary microanalysis.

RESULTS AND DISCUSSIONS

THE GEL EFFECT OR THE "TROMMSDORF EFFECT" IN BULK COPOLYMERIZATION

Unlike the solution copolymerization,[1] where it was established that the gel effect can be eliminated by dilution of monomers, in the case of bulk copolymerization the appearance of this effect is evident.

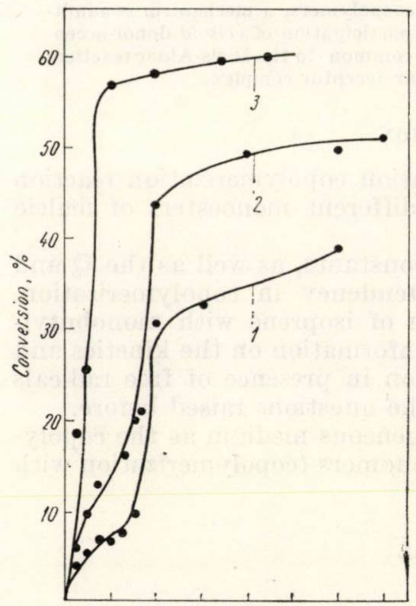

Fig. 1. — Conversion variation depending on bulk copolymerization time of isoprene with monobutylmaleate (1 :1 molar ratio). Reaction temperature :
1) 50°, 2) 60° and 3) 80° ; Initiator: (AIBN) × 10^2 = 4.30 moles/l.

In fig. 1 the conversion variation in time is represented for the bulk copolymerization of isoprene with monobutyl maleate (1 :1) (molar ratio) at different temperatures.

From this plotting it results that at a certain conversion the copolymerization process undergoes autoacceleration. This autoacceleration, found in the case of polymerization of other monomers too, was called the "gel effect" or the "Trommsdorf effect"[6-9] and is due to the increase of the medium's viscosity.

In these conditions the interruption reaction is controlled to a much greater extent by the diffusion process in comparison with the process carried out at small conversions.

Thus, due to the increase of the viscosity, a decrease in the diffusion rate of macroradicals takes place, the probability of interruption reaction (collision of macroradicals and their disappearance) becomes less and, as a result, an increase in the concentration of macroradicals takes place. The appearance

of "occluded" macroradicals in the reaction mass of the medium promotes the increase at high rate (autoacceleration).

The autoacceleration of the copolymerization process at temperature of 80°, from the very moment of initiation (fig. 1), is due to a higher concentration of free radicals, the period of halving the (A.I.B.N.) initiator being much shorter at this temperature.

FORMATION REACTION OF DIELS-ALDER ADDUCT CONCURRENT WITH COPOLYMERIZATION REACTION

From fig. 1 it also results that the value of conversion becomes constant after a period of time, but does not reach the maximum value (total copolymerization reaction). Supplementary addition of initiator to the copolymerization medium in this stage of reaction (constant conversion) did not lead to an increase of conversion. Naturally it was presumed that under these conditions a part of the reactants transform themselves into another product by other means and namely the formation of a Diels-Alder adduct.

Surprisingly no literature data were found on the Diels-Alder reaction of isoprene with maleic acid monoesters. Thus it was also necessary to investigate the evolution of this reaction.

In order to obtain a Diels-Alder adduct of isoprene with monobutylmaleate of high purity with the wiev of establishing its characteristics, we started with the Diels-Alder adduct of isoprene with maleic anhydride, well known in literature.[10,11]

The isoprene-maleic anhydride adduct (crystalline substance with melting point = 62−64°) was esterrified with *n*-butyl alcohol in equimolecular ratio at a temperature of 90° for 150 minutes, the method used also to obtain monoesters of maleic acid.[12] Thus isoprene-monobutyl maleate adduct was obtained, a very viscous liquid at room temperature, with acidity index (A.I.) = 232.9.

On the basis of the great difference between the acidity indexes of monobutyl maleate and isoprene-monobutyl maleate adduct, it was possible to establish a simple method of analysis of these from a mixture by simple or potentiometric titration.[12]

In order to observe the formation reaction of the Diels-Alder adduct, concurrent with the copolymerization reaction, the above indicated method of separation of the copolymers was used.

On termination of the bulk reaction of the two monomers (1 : 1 ratio) in presence or absence of free radicals and separation of the copolymer, the mixture between the unreacted monobutyl maleate and the Diels-Alder adduct (distinguished by I.R. spectrophotometry) was separated from isoprene, petroleum ether and ethyl ether by vacuum distillation and analysed by titration.

[11] N.G. Gaylord, Pat. U.S.A. 3.491.068, 1970.

[12] I. Nanu and C. Andrei, *Bul. St. Tehnic I.P.T.* **17** (31), Fasc. 1,7 (1972)

In fig. 2 the variation of the conversion is shown in Diels-Alder adduct and in copolymer of the isoprene-butyl maleate system depending on the duration of the reaction at a temperature of 70° and in the absence of free radicals.

From this plotting the ease is remarked with which the Diels-Alder reaction of isoprene with monoesters of maleic acid takes place, as well as the fact that in the absence of free radicals the conversion in copolymer is very reduced.

The same variation of conversion in adduct and in copolymer of isoprene-monobutyl maleate system, but in the presence of (A.I.B.N.) free radicals is shown in fig. 3.

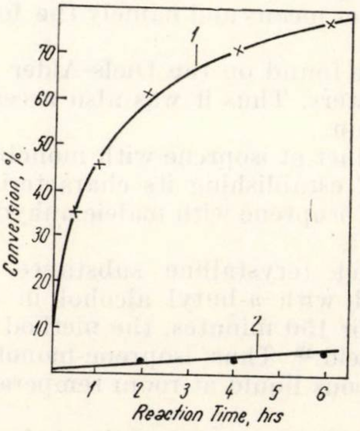

Fig. 2. — Conversion variation in Diels-Alder adduct and copolymer depending on reaction time of isoprene with monobutyl maleate (1 : 1 molar ratio) at a temperature of 70° and in absence of radicalic initiators.
1) conversion in Diels-Alder adduct, 2) conversion in copolymer.

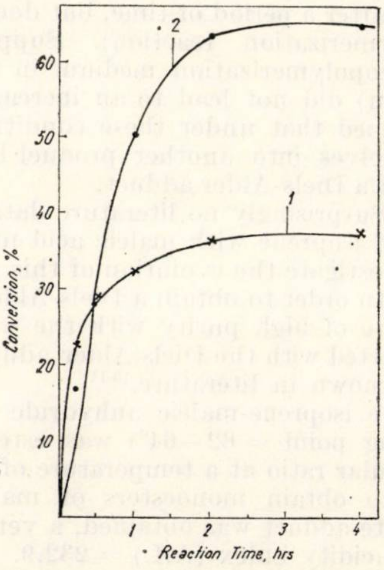

Fig. 3. — Conversion in Diels-Alder adduct and copolymer depending on reaction time of isoprene with monobutyl maleate (1 : 1 molar ratio) at a temperature of 70° and in presence of free radicals (AIBN).
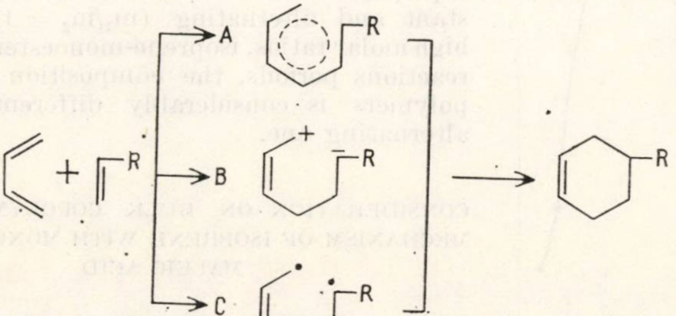
1) conversion in Diels-Alder adduct, 2) conversion in copolymer; Initiator: (AIBN) × 10^2 = = 4.30 moles/l.

From this figure the competition between the two reactions reveals itself. After two hours of reaction, the conversion in copolymer reaches 63.5% and the conversion in adduct 36.5 %. Now it can be explained why the conversion did not increase further on, even by addition of supplementary initiator. A part of the monomers were reacting with the formation of copolymer and a part with the formation of Diels-Alder adduct, the consumption of monomers being total after a period of time.

It is also remarked that in the case of running the reaction at a temperature of 70°, the acceleration of the process takes place at the very moment of initiating.

In the period of over forty years since the discovery of the Diels-Alder reaction a great volume of experimental results was accumulated, however the interpretation of the mechanism of this reaction has remained somewhat behind the accumulation of these results. It is unlikely whether the formation of the two new bonds in the adduct is formed simultaneously by a one step mechanism (A = multicentres) or by a mechanism in two successive steps (B and C).[13]



In an earlier work Woodward[14] suggested the fact that the Diels-Alder reaction is preceded by the formation of a complex with charge-transfer (transfer of electron form diene to dienophile), whereas later on to affirm that this reaction should take place through a two step mechanism, in which the bonds between the components are formed successively but without involving the transition states of the B and C type.[15]

Although the mechanism by which the Diels-Alder reaction takes place has not yet been accepted definitely, stereochemical considerations as well as the latest research work on transition state,[16–18] admit that the reaction takes place through a transition complex whose nature will require further investigations and in continuation new facts are being accumulated both in favour of one step and two step mechanism.

We consider that a parallel study of the Diels-Alder reaction and of the copolymerization reaction of the diene-dienophile systems will bring new elements on the mechanisms of both reactions.

THE INFLUENCE OF THE RATIO BETWEEN MONOMERS ON THE CONVERSION AND COMPOSITION OF COPOLYMERS

The variation of conversion depending on the ratio of the two monomers in the feed composition is shown in fig. 4 for copolymerization of isoprene with monobutyl maleate.

[18] M.J.S. DEWAR and R.S. PYRON, *J. Amer. Chem. Soc.*, **92**, 3098 (1970)

The highest value of conversion is obtained in case of molar ratio of 1 : 1 between isoprene and monobutyl maleate.

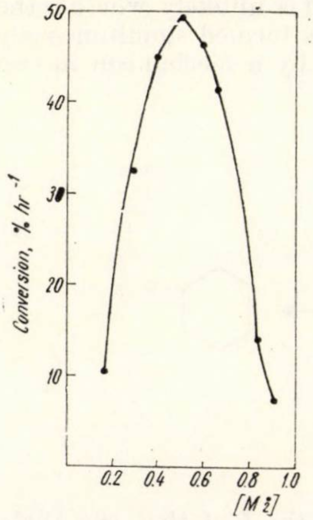

Fig. 4. — Ratio influence between monomers on conversion in bulk copolymerization reaction of isoprene with monobutylmaleate. Reaction temperature 70°, reaction time, 1 hour; Initiator : (AIBN) × 10^2 = 4.30 moles/l.

In table 1 is shown the composition of the copolymers obtained at different ratios of monomers in the feed composition.

It can be observed that the variation between monomers in the feed composition of the copolymers, the latter remaining relatively constant and alternating ($m_1/m_2 = 1$). Only at high molar ratios, isoprene-monoester and longer reactions periods, the composition of the copolymers is considerably different from the alternating one.

CONSIDERATION ON BULK COPOLYMERIZATION MECHANISM OF ISOPRENE WITH MONOESTERS OF MALEIC ACID

In a former work [5] it was shown that the strongly alternating tendency in solution copolymerization of isoprene with monoesters of maleic acid can be explained by the polarity difference of comonomers, as a result of a coulomb attraction between two dipoles, according to Alfrey and Price's theory of polar factors,[19] as well as by adopting Walling and Mayo's point of view,[20] consisting of an explanation of transition stability by dipolar structures of resonance, the transition state being the result of electron transfer between the radical and the monomer.

Table 1

Composition of isoprene-monobutyl maleate copolymers depending on monomer ratio of feed composition

Test n°	Feed composition (moles)			Copolymer composition		
	$[M_1^0]$	$[M_2^0]$	$[M_1^0]/[M_2^0]$	C, %	H, %	m_1/m_2

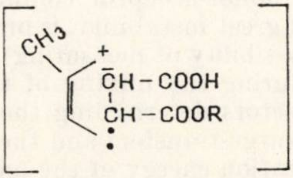
[19] T. Alfrey and C.C. Price, *J. Polymer Sci.*, **2**, 101 (1947).
[20] C. Walling and F.R. Mayo, *J. Polymer Sci.*, **3**, 895 (1948).

These points of view do not exclude however the participation in copolymerization reaction of a donor-acceptor complex, formed between the monomers.

The results of the kinetic study on bulk copolymerization reaction of isoprene with monobutyl maleate (copolymers with high alternation, indifferent of the ratio between the monomers of the feed composition and the maximum reaction rate at equivalent concentrations of monomers) can be explained convincingly on the basis of the mechanism involving the formation of a donor-acceptor complex between monomers of the type :



and its participation in the reaction in presence of free radicals :

$$D + A \rightarrow C$$

$$R^{\cdot} + C \rightarrow R - C^{\bullet}$$

$$R - C^{\cdot} + C \rightarrow R - (C)_x^{\cdot}$$

$$2R - (C)_x^{\cdot} \rightarrow \text{copolymer}$$

in which :

D — donor monomer (isoprene)

A — acceptor monomer (monoester) and

C — donor-acceptor complex

The enrichment of the copolymer in isoprene at high donor-acceptor ratios and at long reaction periods is due to the conventional addition of this monomer to the increasing chain,

$$R - (C)_x^{\cdot} + D \rightarrow R(C)_x D.$$

As an argument for the support of the proposed mechanism, the dilution effect on the conversion and composition of copolymers can be considered, as well as the influence of the solvent's nature on the copolymerization reaction presented in a former work.[1]

A similar mechanism but which implies homopolymerization only of the donor-acceptor complex, was proposed by Gaylord[21,22] for copolymerization of conjugated dienes with maleic anhydride. It is appreciated that the Diels-Alder reaction which develops easily in conditions of copolymerization, recognized as one of the most characteristic examples of donor-acceptor interaction, cannot proceed through a transition complex different to the one participating in the copolymerization reaction.

Gaylord[21] postulated that the Diels-Alder adduct, diene maleic anhydride, results from a complex in ground state and the copolymer from a complex in excited state.

The formation of a donor-acceptor complex between isoprene and monobutyl maleate, but of great instability, is proved by the instantaneous disappearance (without possibility of measuring) of the faint yellow-brown colour which is formed during the mixing of the two components. The fact is known that the factors determining the formation of the donor-acceptor complex (with charge-transfer) and the strength of its bond are, on the one hand, the ionization energy of the molecule which gave up the electron and, on the other hand, the affinity for the electron of the acceptor molecule, the complete transition of the electron taking place between very strong donors and acceptors only.

In the systems studied, isoprene is not a very strog donor. If stronger donors are added to monobutyl maleate, such as conjugated diene 1,4-diphenyl-1,3-butadiene or naphthalene, a yellow colouring appears whose intensity reaches a maximum at 1 :1 molar ratio. This colouring whose disappearance was not observed even after a long time is characteristic for the complex with stable charge transfer.

Taking the above into consideration, it can be admitted that associations of the "weak complexes" type are formed between isoprene and maleic acid monoesters, which are also called charge-transfer "contacts" by Mulliken and coworkers.[23,24] In case of formation of these weak complexes, the spectrum of the donor or acceptor is more or less modified by association and can or cannot contribute to the absorption of the charge-transfer.[25,26] For these weak complexes, which have not got independent bands of component molecules, the U.V. measurements are difficult and especially the determination of the equilibrium constant.

Dewar and Thompson,[25] as well as Matsuo and Higuchi,[27] referring to the concept of "weak complexes" showed that the interaction charge-transfer is not always the main force in formation of these complexes. In this sense they emphasized the essential part of the van der Waals forces in the ground state of these associations whose effects are stabilized in addition by the charge-transfer forces.

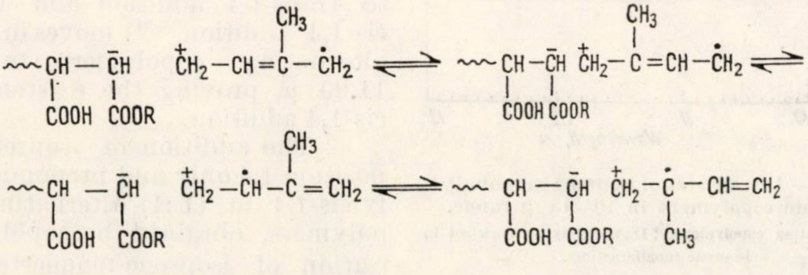
The formation of a weak complex with charge-transfer between isoprene and butyl maleate is also in agreement with the rule established by Nimoura and Suruki.[28,29]

On the basis of copolymerization results of several α,β-disubstituted olefines, the latter established a relation between the "e" values of monomers (obtained according to Alfrey and Price[19]) and the reaction mechanism followed. As "Δ e" increases, the preferred mechanism is the following : mechanism according to Alfrey and Price ($\Delta e > 2.5$) → mechanism according to Mayo and Walling ($2.5 < \Delta e < 3$) → mechanism with participation of donor-acceptor complexes ($\Delta e > 3$).

The value of $\Delta e = 3.04$ for isoprene-monobutyl maleate,[5] although it is situated in the range of complex formation, is nevertheless near the demarcation limit of the last two mechanisms and therefore the idea of a Mayo and Walling mechanism is not eliminated entirely.

From what was presented, it clearly results that the determination of the reaction mechanism or the choosing of the most correct explanation for alternating copolymerization cannot be done by kinetic measurements only.

On analysing Mayo and Walling's point of view according to which the transition states are the result of the transfer of electron between the increasing macroradical and monomer,



It can be noticed that according to this mechanism in the radicalic reaction of copolymerization, isoprene can be added in all positions, trans-1,4, addition —1,2, addition —3,4 and less cis —1,4 (as it is known from radicalic polymerization of isoprene), whereas the copolymers resulting from the reaction involving the participation of a cisoid complex should have a structure enriched in cis—1,4 addition of isoprene and at the same time the 1,2 and 3,4 addition is excluded.

Thus the study of the structure and microstructure of copolymers of different compositions will contribute to a great extent in eliminating the dualism of these reaction mechanisms.

In fig. 5 the I.R. spectra in 10–13μ range are shown, for two isoprene-monobutyl maleate copolymers with different ratios between the monomers in the chain.

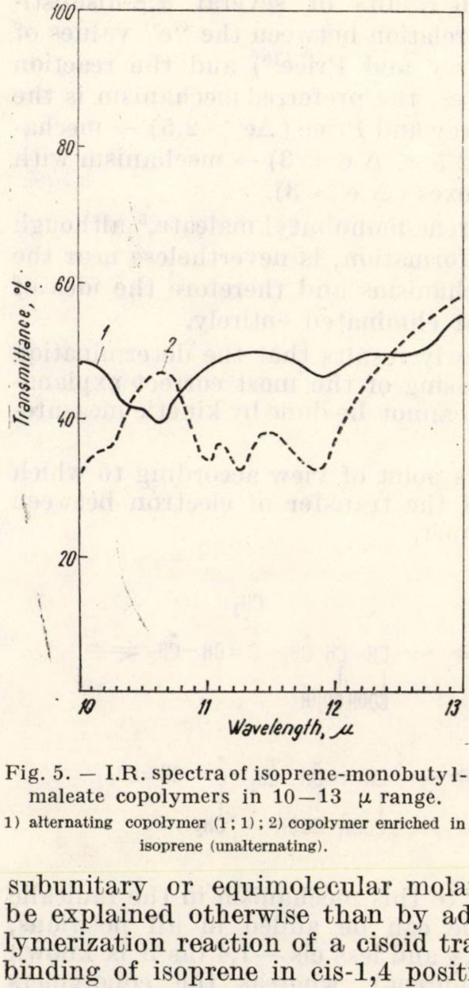

Fig. 5. — I.R. spectra of isoprene-monobutyl-maleate copolymers in 10–13 μ range.
1) alternating copolymer (1 ; 1) ; 2) copolymer enriched in isoprene (unalternating).

From investigation of the spectra of two copolymers differences are observed in the 10.5–12μ range owing to the manner of addition of isoprene.

In the copolymers spectrum enriched in isoprene (unalternating), bands characteristic to 1,2 addition (11μ) and 3,4 addition (11.28μ) of isoprene in the copolymer chain are distinguished. These bands are absent in the copolymer whose molar ratio between monomers is 1 :1, the addition of isoprene taking place in 1,4 (cis or trans) position only characterized by band from 11.87μ. At the same time the band from 11.87 μ specific to both cis-1,4 and trans-1,4 addition in unalternating copolymers (resulting from superpositioning of two bands : 11.83 μ attributed to trans-1,4 addition and 11.90μ cis-1,4 addition [30,31]) moves in (1 : 1) alternating copolymers towards 11.90 μ, proving the existence of cis-1,4 addition.

The addition of isoprene in position 1,4 only and preponderently cis-1,4 in (1 :1) alternating copolymers, obtained by copolymerization of isoprene-monoester at subunitary or equimolecular molar ratios in feed composition, cannot be explained otherwise than by admitting the participation in the copolymerization reaction of a cisoid transition complex which constrains the binding of isoprene in cis-1,4 position (stereodirected reaction through the cisoid donor-acceptor complex).

In unalternating copolymers obtained at superunitary isoprene-monoester molar ratios in feed composition and at lengthy periods of reaction, the uncomplexed isoprene is added by the conventional mechanism, the whole range of structures (cis-1,4, trans-1,4, addition -1,2 and 3,4) being obtained as in polymerization of isoprene in presence of free radicals.

Thus in this last case the structure of the copolymer is the result of the competition between the copolymerization reaction by the complex and the conventional addition.

HYDROPEROXIDATION OF ORGANIC COMPOUNDS AT THE LIQUID/GAS INTERFACE. VII[1]

CONTRIBUTIONS TO THE PHYSICO-MATHEMATICAL CHARACTERIZATION OF THE APPARATUS

J. VODNÁR and R. DEUTSCH

"Babeş-Bolyai" University, Department of Organization and Technology
Piaţa Ştefan cel Mare 4, Cluj, Romania

Received October 31, 1973

The paper presents some contributions to the physico-mathematical characterization of the apparatus equipped with an outside spiral curved tube, used for the hydroperoxidation of organic compounds at the liquid/gas interface, patented by the author. The contributions are referring to the cases when the reaction rate between liquid and gas in tube II is so high, that more than 1 % (1 – 10 %) of the amount of gas passing through tube II reacts and the gas is not completely carrying off the liquid from tube II.

In a previous paper [1] some relations were described for the characterization of the apparatus equipped with an outside spiral curved tube, used for the hydroperoxidation of organic compounds at the liquid/gas interface, invented by the author. [2] In order to obtain mathematical relations which could underlie the design of such apparatus, we made use of a model with all the characteristics of the experimental installation (fig. 1).

The gas current (gaseous reactant), after penetration through a porous layer, moves upwards through tube II, carrying off the liquid of this tube, too. After the liquid in tube II has reached the upper part of the partition wall between tube I and II, the liquid passes into tube I and flows downwards. A permanent convection is thus occurring. The liquid with gas bubbles climbs in tube II and descends in tube I, without carrying off the bubbles.

We assumed that in tube II the liquid and the gas are mixing to such an extent that the mixture which is formed may be characterized by a mean density, $\bar{\rho}$, while the reaction rate between liquid and gas in tube II is so slow as not to react with more than 1% of the amount of gas passing through tube II. Under such conditions the mixture in the recycling tube I may be characterized by the approximately constant density ρ.

[1] J. Vodnár and R. Deutsch, "The IInd Conference on the Applied Physical Chemistry", vol. 2/2 1971, p. 601, Veszprem, Hungary.

[2] J. Vodnár, Patent of the Socialist Republic of Romania N⁰ 51928 (1969).

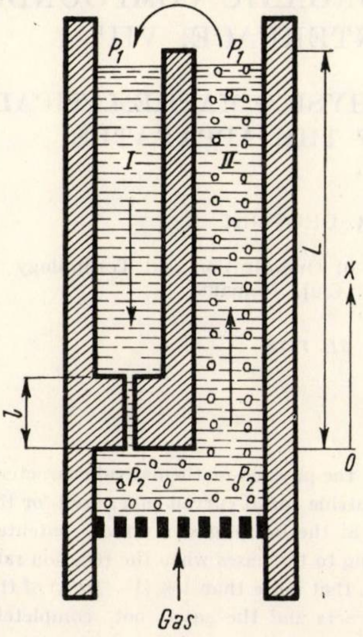

Fig. 1. — The model of the apparatus.

Using the Bernoulli equation:

$$p + \rho \cdot g \cdot h + 1/2 \rho \, v^2 = p_0 \text{ const.} \tag{1}$$

and considering that the expression $1/2 \rho \, v^2$ is negligible both in the rising current in tube II and in the descending current in the recycling tube, the following relation holds:

$$p + \rho \cdot g \cdot x = \text{const.} \tag{2}$$

and the difference in pressure at both ends of the capillary will be:

$$p_1 - p_2 = \rho \cdot g \cdot L \left[1 - \frac{l}{L} - K \right] \tag{3}$$

where K is a constant value, characterizing the apparatus used.

If we denote by Q_l the volumetric flow of the liquid, then, according to Poiseuille equation, we may write:

$$p_1 - p_2 = \frac{8 \mu \cdot l}{r^4 \cdot \pi} \cdot Q_l \tag{4}$$

If the gas is completely carrying off the liquid, then the rate of the liquid becomes equal in tube II with the gas rate; the volumetric flows of the liquid and gas are directly proportional to the partial volumes of the liquid and of the gas:

$$\frac{Q_l}{Q_g} = \frac{V_l}{V_g} \tag{5}$$

Using the definition:

$$K = \frac{V_l}{V_l + V_g} \tag{6}$$

one may write:

$$\frac{Q_l}{Q_g} = \frac{K}{1 - K} \tag{7}$$

By replacing this mathematical expression in (4) we get:

$$Q_g = \frac{r^4 \cdot \pi \cdot \rho \cdot g}{8\mu \cdot l \cdot K} (1 - K) \left[(1 - K)\, L - l\right] \tag{8}$$

In the cases when the reaction rate between liquid and gas in tube II is so high, that more than 1% (1 − 10%) of the amount of gas passing through tube II reacts, the mixture in tube II may be characterized by the mean density $\overline{\rho}(x)$, dependent on the x values. By approximation, for $\overline{\rho}(x)$ we can write:

$$\overline{\rho}(x) = \overline{\rho}(0) + \alpha \cdot x \tag{9}$$

The difference in pressure at height x will be:

$$p(0) - p(x) = \int_0^x \overline{\rho}(x) \cdot g \cdot dx = \overline{\rho}(0) \cdot g \cdot x + 1/2\, \alpha \cdot g \cdot x^2 \tag{10}$$

At height $x = 0$

$$p(0) = p(x) + \overline{\rho}(0) \cdot g \cdot x \cdot + 1/2\alpha \cdot g \cdot x^2 = p(L) + \overline{\rho}(0) \cdot g \cdot L + 1/2\alpha \cdot g \cdot L^2 \tag{11}$$

If we divide this expression with $\rho \cdot g \cdot L$, we obtain:

$$\frac{p(0)}{\rho \cdot g \cdot L} = \frac{p(L)}{\rho \cdot g \cdot L} + \frac{\overline{\rho}(0)}{\rho(0)} + \frac{1}{2}\, \frac{\alpha \cdot L}{\overline{\rho} \cdot (0)} \cdot \frac{\overline{\rho}(0)}{\rho(0)} \tag{12}$$

Because $\bar{\rho}/\rho = K$ and $\alpha \cdot L$ can be expressed as:

$$\frac{\alpha \cdot L}{\bar{\rho}(0)} = \frac{\Delta \rho}{\bar{\rho}(0)} = \gamma \tag{13}$$

where γ is the part of the bubble reacted in the process, we can write:

$$\frac{p(0)}{\rho \cdot g \cdot L} = \frac{p(L)}{\rho\, g \cdot L} + K + 1/2\ \gamma K \tag{14}$$

In the case when $K = 1/2$ and about 10% of the bubbles react, $\gamma = 0.1$ and the pressure variation caused by the chemical reaction will be about 0.025 (2.5%).

By introducing relation (14) into (4), we get:

$$Q_g = \frac{\mathrm{r}^4 \cdot \pi \cdot \rho \cdot g}{8\,\mu \cdot l \cdot x}(1 - K)\left[\left(1 - K - \frac{\gamma K}{2}\right)L - l\right] \tag{15}$$

This relation stands for the dependence between the gas flow (Q_g), the geometrical characteristics of the apparatus and the physical characteristics of the liquid in the case when more than 1% of the amount of gas passing through tube II reacts.

When the gas is not completely carrying off the liquid from tube II, one must make a correction.

Let us denote the liquid passing through the capillary tube under the above-mentioned conditions with:

$$Q_l - \Delta Q_l \tag{16}$$

and the part of the liquid not being carried off from tube II, with:

$$\beta = \frac{\Delta Q_l}{Q_l} \tag{17}$$

Thus,

$$Q_l - \Delta Q_l = Q_l(1 - \beta) \tag{18}$$

and instead of relation (4) one must introduce another one:

$$p_1 - p_2 = \frac{8 \cdot \mu \cdot l}{r^4 \cdot \pi}\, Q_l(1 - \beta) \tag{19}$$

By replacing Q_l from (7) in (19) and the difference of pressure corresponding to (19) in (15), we will get the final mathematical expression for Q_g :

$$Q_g = \frac{r^4 \cdot \pi \cdot \rho \cdot g}{8\mu \cdot l \cdot K} : \frac{1 - K}{1 - \beta} \left[\left(1 - K - \frac{\gamma K}{2} \right) L - l \right] \tag{20}$$

This final relation stands for the dependence between the gas flow, the geometrical characteristics of the apparatus and the physical properties of the liquid, in the case when more than 1%(1 – 10%) of the amount of gas passing through tube II reacts, and the gas is not completely carrying off the liquid from tube II.

Revue Roumaine de Chimie, 19, 9, 1551–1553 (1974)

SEPARATION OF SMALL AMOUNTS OF AMINO ACIDS AND THEIR IDENTIFICATION IN COMPLEX MIXTURES WITH UREA IN EXCESS

A. CONSTANTINESCU and C. LITEANU
Babeş-Bolyai University, Cluj, Str. Arany Janos, 11

Received November 9, 1973

By associating the electrophoretical method with the zonal melting technique it has become possible to reveal the presence of histidine and of arginine in a complex mixture of amino acids with urea in excess, obtained by a plasmochemical approach.

Chromatographic separation, effective in general, is hindered in the case of amino acids by the presence of urea in the solution under analysis. When urea is in excess, chromatography is no longer applied as a method for the separation and identification of amino acids, since by dislocation, amino acids identification according to R_f values becomes impossible.[1]

For this reason we have undertaken to develop a method which would enable the separation and identification of amino acids which are not revealed by chromatographic approach due to the presence of urea in excess.

WORKING PROCEDURE

The analysed solutions were supplied by the Laboratory of Physical Chemistry of the Faculty of Pharmacy in Bucharest where they had been obtained under plasmochemical conditions through high frequency electrical discharges over three gaseous mixtures each of them containing ammonia, water and one of the following hydrocarbonate components : methane, butane, petroleum ether, in an installation fitted with exterior electrodes, designed and achieved by Prof. D. Ştefănescu.

These solutions contain, among numerous compounds[2,3] small concentrations of various amino acids in addition to urea.[4]

0.02 ml of these solutions were chromatographed according to Mathias' technique, using the *n*-butanol + acetic acid + water (4 :1 :5 v/v) solvent system. After repeated irrigations, the chromatograms were dried. In order to reveal the plasmochemically formed amino acids, a few chromatograms were sprayed with a 0.2 % ninhydrin solution in acetone.

---

[3] D. Ştefănescu, D. Moraru, L. Necula, I. Predescu and T. Stanciu, Communication presented at the Symposium of Biophysics, Iaşi, September, 1965.

[4] A. Constantinescu, Dissertation, Faculty of Chemistry, Cluj, 1971.

The identification of the separated amino acids was made by using Aji-No-Moto—Tokio pure reference amino acids which were chromatographed under similar conditions.

In order to identify the urea, a few other chromatograms were sprayed, this time with a 3.3 % *p*-dimethylaminobenzaldehyde acidic solution in ethanol. One single very large spot was obtained which we have attributed to urea, as it had the same R_f as the reference urea.

Further on, urea was separated from amino acids by using paper electrophoresis, the vertical technique. A 2 n formic acid solution was used as an electrolyte, the intensity of the electric current was 6 mA, the voltage was 420 V, the migration time was 6 h, and the paper bands were 24 cm long and 3 cm broad. Urea remains close to the starting line and turns yellow as the electrophoregram is sprayed with *p*-dimethylaminobenzaldehyde in ethanol.

By cutting out the zones corresponding to amino acids in a number of at least 50 electrophoregrams, after their fragmentation into small portions, the amino acids were extracted in aqueous solution. This solution was then evaporated and the residue was dissolved into one ml water, and this urea-free solution was then chromatographed according Mathias technique.

Arginine and histidine were absent, though their presence might have been possible since the UV absorption spectrum of these solutions indicated some absorption maxima seen in the UV spectra of arginine and histidine aqueous solutions and also in aqueous solutions of the mixture of these two amino acids.[5]

This shows that arginine and histidine could have been included during the separation of the urea macrocomponent. To verify this assumption, the electrophoretic zones corresponding to urea, resulting froma number of 50 electrophoregrams, were subjected to an aqueous extraction. After evaporation of the solution, the melting point of the resulted crystalline product was checked by means of a Boëtius apparatus.

A rather large range of melting temperature was obtained, between 111° – 125° which proved that the electrophoretically separated urea was not pure. The method of zonal melting was applied to investigate the impurities contained by urea. The device used reaches zonal melting with the simultaneous run of several zones, impressing an ascending motion to the substance bar. After a number of 17 runs, each taking two hours, the glass capillary tube was sectioned into 1 cm portions, the melting point of the substance being recorded for each of them on a Boëtius apparatus.

In order to reveal possible impurities, — amino acids, UV absorption spectra were taken for the portions of the zonal melting bar.

The first portion obtained by sectioning the zonal melting bar with the melting point at 132.7° contains high purity urea, in agreement with the data obtained from the literature.[6]

The UV absorption spectrum of the solution obtained when dissolving this first portion of the substance bar in water presents the same absorption maxima as pure urea.

The UV absorption spectrum of the aqueous solution obtained on dissolving the last portion indicates the additional presence of some absorption maxima characteristic of arginine and histidine amino acids in aqueous solution (fig. 1), which proves that these two amino acids, too, are plasmochemically obtained.

COMPTES RENDUS

DIETER ZIESSOW, "On-line Rechner in der Chemie" W. de Gruyter, Berlin, New York, 1973, 376p.

The use of modern computers in chemistry, is developing in two main directions, namely : the use of big computers in processing numerical data regarding different chemical subjects and the use of "on-line" computers in which analogic data (physical, usually electrical signals) are processed.

The literature is sufficiently rich in papers regarding the first type of utilizations and a book has been already published on the subject in Romanian.

As far as the second type ot utilisation is concerned, in spite of the fact that it is more and more widely used, bibliographical materials are not so abundent. They are limited to manufacturer's literature and to a few papers published in scientific journals.

Dieter Ziessow's book fills on important gap regarding the problem of utilization of "on-line" computers. Although the book is not a synthesis of all the materials published in the domaine, (dealing especially with problems of Fourier spectroscopy) it presents the main problems regarding the use of "on-line" computers.

Thus, after a general introduction, the principal methods of analogic data transformation, the conversion of analogic data in numerical data, the problem of signal to noise ratio, the problem of mean values, etć, are presented in the book.

Also, the most used procedure of data processing such as differentiating or integrating, etc., are described.

After these general problems, some methods regarding the curve adjustment, simulation or line identification are presented.

The last part of the book deals with the general problems of Fourier spectroscopy and of Optical Fourier spectroscopy.

The whole book contains a great number of examples for the utilisation of " on-line" computers in chemistry and gives a number of programs in ASSEMBLER or in FORTRAN language.

An extensive bibliography is also given.

Şerban Moldoveanu

KARL HAUFFE und S. ROY MORRISON, Adsorption "Eine Einführung in die Probleme der Adsorption. Walter de Gruyter, Berlin, New York, 1974, 19p.

The basic problem in understanding the solid-fluid boundary processes is to find out the dependence of the process parameters on the solid surface properties. The adsorption studies aim at solving this problem.

A large number of very different fields like : heterogeneous catalysis, corrosion, flotation, substances'purification, chromatographic analysis, electronic tube engineering, profit from the results of adsorption studies. It seems that adsorption is also playing an important part in some biological processes like membrane equilibria, enzime action and even in the smell and taste sensations.

The book issued by Prof. Karl Hauffe and Dr. S. Roy Morrison is not that much of a monography as it is an introduction to the problematics of this phenomenon. The book is the result of a long and remarkable activity of the authors in this field. It is divided in 6 chapters.

The first chapter presents the general features of adsorption emphasizing the energetics of the process. Then the main isotherms are deduced and their principal uses shown ; e.g. the specific area measurements (chap. 2).

Chapter 3 refers to the adsorption involving the electron exchange both on metallic and semiconductor surfaces. Electrochemical thermodynamics is given a special attention in explaining chemisorption on semiconductors in contrast with physical adsorption on the same surface in which chemical thermodynamics is used. Plenty of space is assigned to photosorption and photodesorption as well as to the role of surface states in adsorption.

The metal-support catalytic systems are described in chapter 4 and the methods of evaluating the dispersion of the active component are indicated.

The fifth chapter is devoted to the impact of adsorption on the surface reactions, heterogeneous catalysis, chromatography, flotation, corrosion and oxidation of metals.

The last chapter is a critical review of some experimental techniques used in adsorption studies. The information one can get by this methods are also reviewed.

The references are given on chapters and the book concludes with subjects and authors indexes.

Some of the problems presented — such as the kinetics of the gas adsorption on oxide type semiconductors—are exhaustively presented and form an up-to-date critical synthesis of the results in the field.

Published in excellent graphical conditions, the book is intended by the authors for the use of large number of specialists from industry, research and universities as well as of students in related fields.

31 Galaţi str., Bucharest 13

D. COSTACHE, "*Analiza chimică prin metoda cinetică*" (Chemical analysis through the kinetic method), Editura Academiei, Bucharest, 1974, 270 p.

The progress recorded by the chemical industry and other related branches has raised the necessity to determine some elements or substances in very small amounts. In addition to the microanalytical methods which use the same arsenal of substances for identification and dozing, the recent years have witnessed the appearance of new methods of analysis based on new principles. One of the procedures used for this purpose is that to determine the concentration of some substances which may influence the reaction rate (catalytic method of analysis). The kinetic methods used in analytical chemestry have won the unanimous recognition of specialists due to their sensitivity, selectivity, simplicity in execution as well as to the automation prospects.

The book has 14 chapters, based on a comprehensive bibliography which also includes author's works. It presents two large types of reactions used in the kinetic analysis, namely the oxido-reduction reactions and the enzyme reactions. There are also presented theoretical problems pertaining to the kinetic analysis as well as applicative problems. Thus, the first two chapters explain the general notions used in the kinetic analysis and the action of catalysts on which the kinetic methods are based, and Chapter 3 reviews the catalytic reactions. The following chapters discuss the obtaining and processing of the experimental data and the equipment employed for this purpose. Particular stress is laid on the application of the kinetic method to the determination of the concentration of inorganic compounds, some particularities being shown. Special chapters are devoted to the determination of pollutants (in which the characteristics of such types of analyses are shown) and to other determinations. It is found that the kinetic methods led not only to the determinations of concentrations, but can be also used for the examination of some complex combinations or for the calculation of some constants of importance in the analytical chemistry. An important place is given to the enzyme analysis and to the automation of the kinetic methods of analysis. The precautions to be taken in the kinetic analysis are shown, each factor contributing to the alteration of the results estimated. All reactions used are given in tables. The practical aspects are exemplified by several significant methods.

The book emphasizes the possibility of applying the kinetic methods in industry, control of water and air pollution, elucidation of some problems of the reaction mechanism, characterization of the solubility of some hardly soluble compounds, investigation of some complex equilibria on which new analysis methods or even procedures are based.

The book is intended to chemists working in universitary research, or plant laboratories, to biochemists, candidates for a doctor's degree and analytic chemists who wish to improve their post-graduation training.

NOTE POUR LES AUTEURS

La *Revue Roumaine de Chimie* publie des articles en anglais, français, russe, allemand ou espagnol. Les auteurs sont priés d'envoyer des articles, notes, communications et comptes rendus inédits.

Les manuscrits seront dactylographiés à deux intervalles. Les tableaux seront dactylographiés sur feuilles séparées, de même que la légende des figures. Les diagrammes seront tracés à l'encre de Chine sur papier calque. Les tableaux et les figures seront numérotés par des chiffres arabes, en nombre strictement nécessaire. Prière de ne pas inscrire les mêmes données dans les tableaux et les figures. Les formules chimiques seront incluses dans le texte ; en outre, elles seront transcrites sur des feuilles séparées. Les auteurs sont priés d'indiquer les caractères italiques (en soulignant les lettres au crayon), ainsi que tout autre caractère spécial. L'ordre des références bibliographiques sera celui de leur mention dans le texte ; le nom de l'auteur sera précédé de l'initiale du prénom ; les publications périodiques seront présentées suivant les prescriptions internationales. Les références seront ajoutées à la fin de l'article ; elles paraîtront comme des notes, au bas de la page. Le texte sera précédé d'un résumé comprenant 15 lignes au maximum.

L'entière responsabilité du contenu des articles appartient aux auteurs. On publie des articles dus aux collaborateurs roumains ou étrangers.

PRINTED IN ROMANIA

KINETICS AND MECHANISM OF AZIBENZYL RADIOLYSIS IN BENZENE SOLUTION

TATIANA ONCESCU and M. CONTINEANU

Department of Physical Chemistry, University of Bucharest, Bd. Republicii 13

Received December 12, 1973

The radiolysis of benzene solutions of azibenzyl was studied in the concentration range $3 \times 10^{-1} - 3 \times 10^{3}$ mole/l and a first-order kinetics was found. A reaction mechanism was suggested which involves the energy transfer processes from irradiated-excited benzene molecules to dissolved azibenzyl molecules.

INTRODUCTION

The kinetics of diazocompounds radiolysis is not described in the literature. The only reference is our previous paper regarding the radiolysis of diphenyldiazomethane.[1] The present paper deals with the azibenzyl radiolysis in benzene solution performed as in the case of diphenyldiazomethane to confirm the decomposition mechanism proposed; it involves the excited benzene molecules as energy carriers.

At the same conclusion lead also the results obtained on irradiation of polycrystalline azibenzyl.[2]

EXPERIMENTAL

The benzene solutions of azibenzyl were irradiated with Cs^{137} radiations. The installation is a "Gammator" type fitted with three total activity sources 1600 Ci. Irradiations were simultaneously performed on four samples included in phials of identical geometry, symmetrically placed on a rack which was continually revolving in the irradiation chamber so that all the samples received the same dose. The absorbance of irradiated solution was measured on a Pye Unicam SP 1800 spectrophotometer.

The azibenzyl was prepared by oxidizing the benzylmonohydrazone with HgO according to the indications from literature.[3,4]

The E.P.R. measurements were carried out on an ART 5 apparatus which operates in an X band having a high frequency field modulation.

Benzene solutions of azibenzyl of a 3×10^{-3}; 1.65×10^{-3}; 3×10^{-2} and 3×10^{-1} moles/l concentration were irradiated as described above.

[3] Th. Curtius, *Ber. dtsch. Chem. Ges.*, **22**, 2162 (1889).

[4] Th. Curtius and H. Lang, *J. prakt. Chem.*, **44**, 544 (1891).

The dosimetry was performed through chemical approach using a Fricke [5] dosimeter. The radiochemical decomposition of azibenzyl G was calculated from the relation :

$$G = \frac{n}{D} x\, 100,$$

where

n – number of decomposed azibenzyl molecules

D – absorbed dose, expressed in eV/cm^3, necessary for the decomposition of n molecules of azibenzyl.

The absorbed dose D in the dosimeter was calculated according to the formula below[6]

$$D = 1.75\text{c}10^{18} \frac{\varepsilon_i - \varepsilon_0}{l} \text{ eV/cm}^3,$$

where

ε_i – absorbance of the irradiated dosimetric solutions

ε_0 – absorbance of the non-irradiated dosimetric solution

l – thickness of absorbant solution in the spectrophotometric cell.

The energies obtained as a function of concentration are given in table 1.

Table 1

The dose calculation by the Fricke dosimeter method

Initial concentration of the solution in mole/l	3×10^{-3}	1.65×10^{-2}	3×10^{-2}	3×10^{-1}
Dose 10^{16} eV/cm^3.min.	8.52	8.4	9.3	8.92

Since the thermal decomposition of azibenzyl in a benzene solution occurred also at room temperature at which irradiations took place, a correction was necessary for this decomposition. To this purpose the sample was irradiated keeping at the same time another sample of the same solution at room temperature to serve as reference.

The absorbance of both irradiated and reference samples was measured at $\lambda = 320$ nm and $\lambda = 425$ nm where azibenzyl presents absorption maxima.

RESULTS AND DISCUSSION

The values for the absorbance of solution (ε_i) at various irradiated times (t) permitted the calculation of rate constants which verify the equation of the first-order reactions :

$$k = \frac{2{,}303}{t} \lg \frac{\varepsilon_0}{\varepsilon_i},$$

where ε_0 is the absorbance of the non-irradiated (reference) solution.

---

For illustration, Table 2 lists the values of rate constants for one of the studied concentrations.

Table 2

The rate constants and radiochemical yield determined by the radiolysis of a solution having an azibenzyl concentration of 1.62 × 10^{-2} mole/l

	λ = 320 nm			λ = 425 nm		
t (hours)	$\frac{\varepsilon_0}{\varepsilon}$	k × 10^6 s^{-1}	*G*	$\frac{\varepsilon_0}{\varepsilon}$	k × 10^6 s^{-1}	*G*
8	1.201	6.36	3.12	1.286	8.70	2.38
10	1.234	5.20	2.26	1.2859	7.21	1.42
13	1.369	6.71	2.83	1.414	7.34	1.64
16	1.481	6.80	2.90	1.516	6.81	1.71
18.5	1.494	6.01	2.82	1.571	6.76	1.80
23	1.667	6.13	2.74	1.79	7.02	1.75
27	1.818	6.10	2.64	1.973	6.89	1.63
32	2.118	6.48	2.45	2.36	7.42	1.54
41	2.500	6.20	2.00	2.795	6.95	1.14
52	2.941	5.76	1.51	3.857	7.21	0.91
55	3.030	5.62	1.44	4.153	7.22	0.88

k_m = 6.13 ± 0.14 k_m = 7.23 ± 0.16

Table 3 shows the average values of the rate constants determined for the four concentrations involved in this study.

Table 3

The rate constants for the radiolysis of azibenzyl solutions

Concentration	3 × 10^{-3}		1.65 × 10^{-2}		3 × 10^{-2}		3×10^{-1}	
λ (nm)	320	425	320	425	320	425	320	425
k × 10^6 s^{-1}	8.54	9.4	6.13	7.23	5.54	6.22	4	4.2

The following aspects have been observed from the above data :

1. The values of rate constants at the two wavelengths are close, slightly higher at λ = 425 nm, because in this region there is an overlapping of azibenzyl and diphenylketene absorption. The last one disappears more quickly from the system due to the reaction with the atmospheric oxygen, as our experimental data show.

2. The rate constant has been observed to decrease only twice with a concentration increase of hundred times (from $3 \cdot 10^{-3}$ to $3 \cdot 10^{-1}$) ; this can be explained by the radiolysis mechanism suggested below.

3. The radiochemical yield increases with the rise in the concentration of the irradiated solution, as it was expected.

It is of interest to compare the results from this radiolysis with those obtained in the thermal decomposition of azibenzyl.

It has been observed that in the case of radiochemical decomposition both absorption maxima decrease (λ = 425 nm and λ = 320 nm) whereas at the thermal[7] decomposition the absorption at λ = 425 nm increases and shifts towards 406 nm due to the absorption of diphenylketene occurring in the system.

Finally, a comparison between the radiochemical decomposition of diphenyldiazomethane and that of azibenzyl shows the azibenzyl to be more stable. This can be observed both from the values of the rate constants and from the value of the radiochemical yield which are lower in the case of azibenzyl.

In order to define the nature of radiolysis products, the following experiment was carried out.

An azibenzyl benzene solution having a 3×10^{-3} mole/l concentration, was irradiated after previously bubbling oxygen therein and its absorption spectrum was compared to that of a sample through which argon had been bubbled, irradiating under identical conditions. The UV absorbance values of the two samples (oxygen and argon) were practically similar. On the contrary, the visible absorbance decreases in samples through which oxygen had been bubbled (fig. 1) and this has been observed with all samples irradiated without degasing precautions.

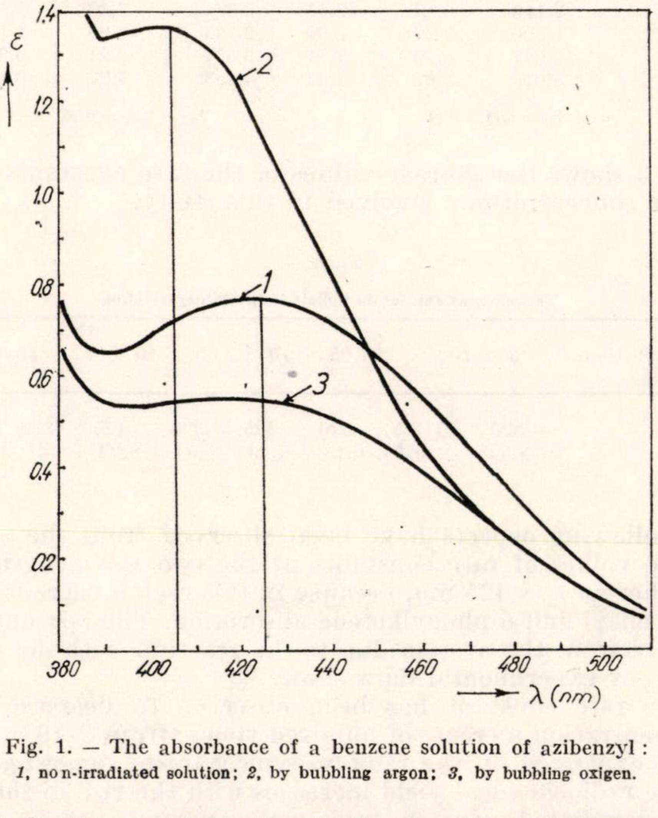

Fig. 1. — The absorbance of a benzene solution of azibenzyl : *1*, non-irradiated solution; *2*, by bubbling argon; *3*, by bubbling oxigen.

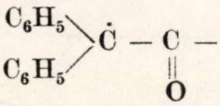
---

[7] M. Contineanu, T. Oncescu and R. N. Schindler, *Rev. Roumaine Chim.*, **18**, 549 (1973).

In contrast, an absorption increase in visible was found in the sample irradiated in an argon atmosphere, with a maximum at 406 nm, characteristic of diphenylketene. The oxygen was subsequently bubbled through this latter sample which was then kept in cold for a few hours, and the absorption spectrum was thereafter recorded as shows figure 1. The sudden absorbance decrease in the visible which is due to the reaction on diphenylketene with oxygen,[8] provides another evidence of its existence in the system as assumed by the mechanism proposed by us.

Considering these results, it is possible to explain the reason for the absorption decrease to 320 nm and to 425 nm. Observed in the air-irradiated samples, the diphenylketene occurring by irradiation of azybenzyl, reacts with oxygen[8] from the air dissolved into the solution forming an unstable peroxide under irradiation which is then converted into benzophenone and CO_2. The formation of benzophenone as a final reaction product was revealed by irradiating a concentrated azybenzyl solution in benzene for a long time, by filtering and recording the UV absorption spectrum.

In the case in which the irradiations take place *in vacuo* or in an inert atmosphere, the diphenylketene accumulates in the system and it may be revealed by its characteristic absorption at $\lambda = 406$ nm. Yet, diphenylketene is not stable at γ irradiation, either. An indirect experiment performed by us may be taken as an argument in support of this statement. In a previous study[9] we found that the diphenylketene obtained by thermal decomposition *in vacuo* of an azibenzyl benzene solution, regardless of the working temperature, presents an EPR signal due to a species which we ascribed to be :



dentically with those found for the first time by Singer and Lewis.[10] Watching the kinetics of this radical species, it disappears through irradiation according to a first-order kinetics.

Figure 2 presents the plot of lg *I* as function of the irradiation time, where *I* represents the intensity of the EPR signal.

A rate constant of 4.1×10^{-4} s^{-1} was calculated from the slope of the straight line.

The solid azibenzyl samples irradiates[2] with the same dose as benzene solution do not reveal a significant change. This proves that the solvent molecules (benzene) play an important role in the radiolysis process, i.e. the decomposition occurs through the means of benzene-excited molecules[11] which disappear through a monomolecular process.

---

[9] T. Oncescu, O. Constantinescu and M. Contineanu, to be published.

[10] L. S. Singer and I. C. Lewis, *J. Amer. Chem. Soc.*, **90**, 4212 (1968).

[11] R. Cooper and K. J. Thomas, *J. Chem. Phys.*, **48**, 5097 (1962).

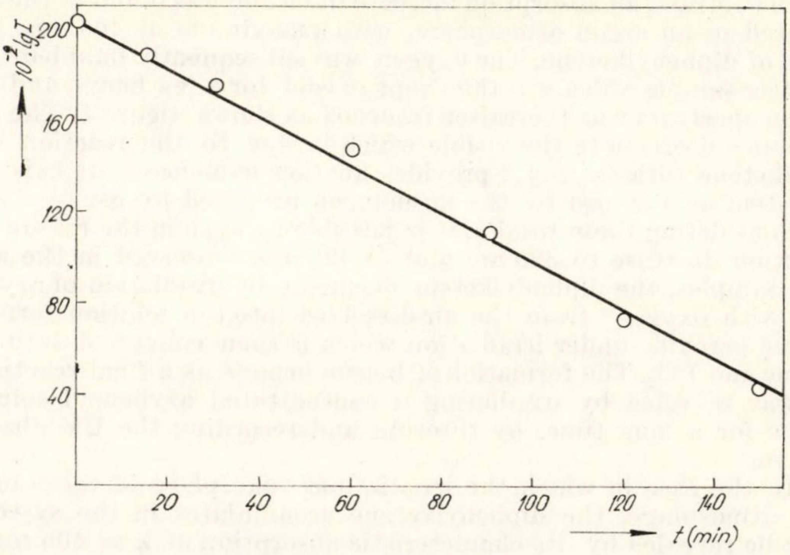

Fig. 2. — The plotting of lg *I* as a function of time for an irradiated diphenylketene benzene solution.

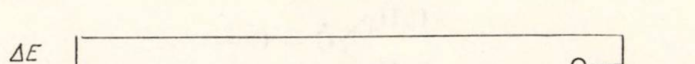

Fig. 3. — The absorption variation ($\Delta\varepsilon$) of an irradiated azibenzyl benzene solution with anthracene concentration.

In view of establishing the radiolysis mechanism we proceeded to the iradiation of azibenzyl benzene solutions in the presence of anthracene which is known from pulse radiolysis studies [12-14] to be a good energy trapping factor for benzene-excited molecules.

The results obtained are presented in figure 3 where $\Delta\varepsilon$ represents the difference between the absorption of the irradiated solution in the presence of anthracene and that of the anthracene-free irradiated one, as a function of anthracene concentration.

The plotting shows that the reaction rate decreases with the increase in the anthracene concentration, reaching a constant value.

Considering this behaviour, the following processes are highly probable:

$$4B \xrightarrow{k_0 I} 4B^* \tag{a}$$

$$B^* \xrightarrow{k_1} B \tag{b}$$

$$B^* + B \xrightarrow{k_2} 2B \tag{c}$$

$$2B^* + 2A \xrightarrow{k_3} 2B + 2A^* \tag{d}$$

$$A^* + B \xrightarrow{k_4} A + B \tag{e}$$

$$A^* \xrightarrow{k_5} Dc + N_2 \tag{f}$$

$$Dc + O_2 \xrightarrow{k_6} DcO_2 \tag{g}$$

$$DcO_2 \xrightarrow{k_7} Bz \tag{h}$$

where B, A, Dc, Bz represent benzene, azibenzyl, diphenylketene and benzophenine molecules and DcO_2 is the diphenylketene peroxide respectively.

The reaction rate for the azibenzyl molecules is:

$$\frac{dC_A}{dt} = -4k_3\, C_{B*}\, C_A + k_4\, C_{A*}\, C_B \tag{1}$$

---

[12] J. M. Nosworthy and J. P. Keene, *Proc. Chem. Soc.*, **5**, 114 (1964).
[13] J. W. Hunt and J. K. Thomas, *J. Chem. Phys.*, **46**, 2954 (1967).
[14] F. S. Dainton, *Pure Appl. Chem.*, **10**, 395 (1965).

By applying the principle of stationarity to intermediates A*, B*, DcO_2 one obtains:

$$\frac{dC_{A^*}}{dt} = 4k_3 C_{B^*} C_A - k_4 C_{A^*} C_B - k_5 C_{A^*} = 0 \tag{2}$$

$$\frac{dC_{B^*}}{dt} = 4k_0 I C_B - k_1 C_{B^*} C_B - 4k_3 C_{B^*} C_A = 0 \tag{3}$$

$$\frac{dC_{DcO_2}}{dt} = k_6 C_{DcO_2} C_{O_2} - k_7 C_{DcO_2} = 0 \tag{4}$$

From (2) and (3) one obtains:

$$C_{B^*} = \frac{4k_0 I C_B}{k_1 + k_2 C_B + 4k_3 C_A} \tag{5}$$

$$C_{A^*} = \frac{16\, k_0\, k_3 I C_B C_A}{(k_1 + k_2 C_B + 4k_3 C_A)(k_4 C_B + k_5)} \tag{6}$$

which introduced into (1), give:

$$\begin{aligned} \frac{dC_A}{dt} = &- 4\, k_3\, C_A \frac{4k_0 I C_B}{k_1 + k_2 C_B + 4k_3 C_A} + \\ &+ k_4 C_B \frac{16 k_0 k_3 I C_B C_A}{(k_4 C_B + k_5)(k_1 + k_2 C_B + 4k_3 C_A)} \end{aligned} \tag{7}$$

Since the irradiated solutions are relatively diluted, one may assume that:

$$4k_3 C_A << k_1 + k_2 C_B.$$

Under such conditions:

$$\frac{dC_A}{dt} = \left(- \frac{16k_0\, k_3\, I C_B}{k_1 + k_2 C_B} + \frac{16 k_0\, k_3\, k_4\, C_B^2}{(k_1 + k_2 C_B)\,(k_4 C_B + k_5)} \right) C_A = kC_A, \tag{8}$$

that is, the differential equation of a first-order reaction as it is verified by our experimental data.

This equation also accounts for the variation of the rate constant, with the solution concentration (see table 3).

The experimentally determined total rate constant k actually contains the rate constant k_1, k_2, k_3 and k_4 which characterize the proposed processes. The number of azibenzyl-excited molecules (process d) would be expected to increase with the increase of the concentration of azibenzyl irradiated solution. At the same time, the deactivation of the excited molecules (process e) clustered along the trajectory of secondary electrons is favoured and it competes with the process (f) since the solvent molecules are always in excess even for the most concentrated solution.

As has been seen in the case of the irradiations performed in the presence of anthracene (A_n), the reaction rate decreases significantly due to the process (i) with energy transfer.

$$B^* + An \xrightarrow{k_8} B + An \qquad \text{(i)}$$

which competes with the process (d) reducing the number of benzene-excited molecules in the system.

In conclusion, the radiolysis of benzene solutions of azibenzyl and also that of diphenyldiazomethane occurs by an indirect mechanism mediated by γ irradiation-excited benzene molecules.

This conclusion is in good agreement with our results obtained at the radiolysis of policrystalline azibenzyl,[2] which shows a much higher stability on γ irradiation in comparison to the benzene solution of azibenzyl.

Revue Roumaine de Chimie, **19**, *10*, 1569–1572 (1974)

THERMODYNAMIC DATA ON VAPORIZATION OF FUSED RUBIDIUM AND CESIUM FLUORIDES

LETIȚIA TOPOR

Institute of Physical Chemistry, str. Galați 31, Bucharest 13, Romania

Received February 6, 1974

The vapour pressures of molten RbF and CsF have been measured by the Rodebush-Dixon method on the temperature range 1189 K–1387 K and 1108 K–1288 K, respectively. The heats and entropies of vaporization, the heats of sublimation at 298 K and the boiling points have been calculated. The ΔH_{298} values allowing for the presence of dimers in the vapour phase are not essentially different from those calculated without any corrections.

The thermodynamic data on fused alkali fluoride vaporization as measured by the vapour pressure experiments have made the subject of publications to a much smaller extent than the data on other alkali halides. This can be explained by the experimental difficulty due to their great reactivity and higher melting point.

The vapour pressures of the molten RbF and CsF have been determined long ago by the boiling point method.[1,2] More recent measurements have been carried out on solid RbF and CsF by the torsion-effusion[3] and the molecular-beam velocity-selector[4] methods. The vapour pressure of the solid CsF has also been determined by the Knudsen effusion method in which case the beam intensities were measured by the method of surface ionization.[5] The alkali fluoride vapours in equilibrium with the condensed phase have been analysed by the mass spectrometric method.[6]

The purpose of the present work is to determine the thermodynamic data of vaporization in molten RbF and CsF from vapour pressure measurements.

EXPERIMENTAL

The vapour pressures of molten RbF and CsF have been determined by the quasi-static Rodebush-Dixon method. Tha apparatus and the required procedures have been previously described.[7] Because of the great reactivity of the molten fluorides we have used a platinum cell similar

to the quartz ones previously utilized.[7-9] The body of the cell (30 mm outer diameter, 25 mm height) has attached to it two arms of 4 mm inner diameter. The values of the vapour pressure were measured with a mercury manometer using a cathetometer to within ±0.1 mm. The temperature was measured with a Pt—PtRh thermocouple and regulated to ±1° by a thermosetting device.

RbF and CsF Merck superpure grade were dried directly in the cell as follows: RbF was dried for 10 hours at 500 K and for 7 hours at 600 K under vacuum; CsF was dried for 16 hours at 450 K and for 5 hours at 600 K under vacuum. Tha salts were melted in dry argon.

RESULTS AND DISCUSSION

A number of 46 measurements of vapour pressures were carried out on RbF within the temperature range 1189K—1387K and 50 on CsF between 1108K and 1288K.

If the difference between the heat capacities of the gas and the liquid ΔC_p is assumed[10] -7 cal. mol^{-1} deg^{-1}, the variation of the vapour pressure *versus* temperature is expressed by the equation:

$$\log\ p = -\ \Delta H_0/4.576\ \mathrm{T} + \Delta C_p \log\ T/1.986 + I \qquad (1)$$

or if ΔC_p is zero or negligible eq. (1) becomes:

$$\log\ p = -\ \Delta H/4.576\ \mathrm{T} + C \qquad (2)$$

where ΔH_0 is the heat of vapcrization at OK, ΔH the heat of vaporization at the midtemperature of the experimental range, I and C are two constants. To obtain (1) type equation the experimental pressures were fitted by the Σ -plot method.[10] The calculations have been made by the least-square method on an IBM computer. The heat of vaporization ΔH_T and the constants I for RbF and CsF obtained from eq. (1) are given in table 1 together with those reported by Kelley [10] and determined by Wartenberg and Schulz [1] and Ruff, Schmidt and Mugdan.[2]

The following (2) type equations have been obtained: RbF (1189K —1387K)

$$\log p\,(\mathrm{mm}) = -\,(9589.5 \pm 68.5)/T + (8.625 \pm 0.053) \qquad (3)$$

CsF (1108 K — 1288 K)

$$\log p\,(\mathrm{mm}) = -\,(7725.6 \pm 25.8)/T + (7.907 \pm 0.021) \qquad (4)$$

The standard per cent deviations of the vapour pressure values for RbF and CsF are 3.55 and 1.33, respectively.

From equations (3) and (4) the heats of vaporization at the midtemperature are for RbF $\Delta H_{1300} = 43.88 \pm 0.3$ kcal. mol^{-1} and for CsF $\Delta H_{1200} =$

$= 35.35$ kcal.mol^{-1}. From the boiling point method the heats of vaporization are 40.0 kcal. mol^{-1} and 40.4 kcal. mol^{-1} for RbF[1,2] and 34.7 kcal.mol^{-1} and 33.6 kcal.mol^{-1} for CsF.[1,2]

Table 1

Heats of vaporization at temperature T and the constants I for RbF and CsF

Substance	ΔH_T kcal.mol^{-1}	I	References
RbF	$(52.84 - 7 \times 10^{-3}\ T) \pm 0.3$	21.109 ± 0.057	present data
	$51.280 - 7 \times 10^{-3}\ T$	—	10
CsF	$(43.65 - 7 \times 10^{-3}\ T) \pm 0.1$	20.275 ± 0.025	present data
	$54.00 - 7 \times 10^{-3}\ T$	—	10

The second-law values of ΔH_{298} for RbF and CsF have been deduced from the heats of vaporization at the melting point $\Delta H_{v,T_m}$ (calculated from table 1), the heats of sublimation at the melting point $\Delta H_{s,T_m}$ and the heat capacities of the solid and gas. The following values have been used for RbF : the melting point[11] $T_m = 1068$ K, the heat of fusion $\Delta H_m = 5.82$ kcal.mol^{-1}, the heat capacity for the solid and gas [3] $C_p(s) = 11.94 + + 2.37 \times 10^{-3}$ T and $C_p(g) = 8.88 - 4.42 \times 10^4 T^{-2}$, and for CsF : the melting point [11] $T_m = 976$ K, the heat of fusion [11] $\Delta H_m = 5.19$ kcal.mol^{-1}, the heat capacity for the solid [3] $C_p(s) = 11.315 + 2.71 \times 10^{-3}\ T$ and the heat capacity for the gas [10] $C_p(g) = 8.94 - 0.23 \times 10^5\ T^{-2}$.

For third-law values of ΔH_{298}, the differences between the free energy functions of rubidium fluoride [11] and cesium fluoride [12] in liquid and gaseous phase and the vapour pressures from the equations (3) and (4) have been used. These values of ΔH_{298} are shown in table 2. All the values have been obtained from vapour pressure measurements of molten fluorides except those of Pugh and Barrow[3] which are for the solid phase.

The agreement between our ΔH_{298} values calculated by the two methods is satisfactory. The discrepancies may be due to the heat capacity values; since the heat capacity of molten fluorides are not known we have assumed the difference between the heat capacities of the gas and liquid phase [10] to be -7 cal.mol^{-1} deg^{-1}.

Table 2

ΔH_{298} values for RbF and CsF from the second and third-law methods

Mass spectrometric [6] and molecular-beam velocity-selector[4] studies have shown that the vapour in equilibrium with condensed alkali fluoride is complex and contains monomeric, dimeric and in some cases trimeric molecules. To calculate the thermodynamic data of gaseous alkali halides, Brewer and Brackett[11] take into account the molecular composition of these vapours. They have used the ratio of partial pressures of dimer to the monomer equal to 0.14 for RbF and 0.12 for CsF. Chao[12] has also calculated the thermodynamic data of alkali fluorides vaporization considering the presence of the associated species in gaseous phase. Scheer and Fine[5] have measured the vapour pressure of solid cesium halides. To obtain the CsF monomer vapour pressures they have corrected the experimental results for the presence of 7 per cent dimers in the gaseous phase. In table 3 ΔH_{298} are presented when associated species are considered. These values are in good agreement with those calculated from a third-law method without corrections for the associated species (table 2).

THERMODYNAMIC TREATMENT OF BINARY AND TERNARY SALT SYSTEMS WITH SINGLE CHARGE IONS

Z. MOSER and K. FITZNER

Institute for Metal Research, Polish Academy of Sciences, Kraków, Reymonta 25, Poland

Received December 10, 1973

Krupkowski's formalism applied so far to solutions of metals was used for binary and ternary salt systems of single charge ions. Using chiefly experimental emf data of reversible formation cells of binaries : AgCl–RbCl, AgCl–KCl, NaCl–RbCl, NaCl–KCl, AgCl–NaCl and AgCl–LiCl the Eqs. for activity coefficients of both components were determined. Next, based on those relations, the values of molar enthalpy were calculated and compared with the calorimetric data. With the exception of the KCl–LiCl system which has been accepted as regular, the other binaries were classified as semiregular solutions when the $\omega(T)$ function in Krupkowski's formalism takes the form $\frac{\alpha}{T} - \beta$ or $-\frac{\alpha}{T} + \beta$, and the asymmetry coefficient m is close to 2. In the case of $m = 2$ the thermodynamic functions are symmetrical.

Next, the thermodynamic analysis of the ternary AgCl–RbCl–NaCl, AgCl – NaCl – – KCl and AgCl – KCl – LiCl systems was carried out in which the activity coefficients and the integral molar function, namely, the enthalpy and the excess free energy, were considered. Those functions calculated on the basis of binaries are in good agreement with the experimental data. In the case of the AgCl – LiCl – KCl system, the analysis of ln γ_{AgCl} when $X_{AgCl} = 0$ was performed and it was shown that as in the case of the solutions of metals, the deviation from linear dependence at the plot $(\ln\gamma_{AgCl})_{X_{AgCl}} \rightarrow 0$ *vs.* X_{KCl} is determined by the term

$$- \omega_{(Li,KCl)} (1 - XKCl)^{m(Li,K)Cl-2} X_{KCl} X_{LiCl}$$

connected with the KCl–LiCl system.

INTRODUCTION

Krupkowski's method,[1] which together with Darken's [2] and Wagner's [3] procedures is one of the possible solutions of the Gibbs-Duhem equation, is applied to the interpretation of the experimental results of binary and multicomponent systems. In a previous paper Krupkowski's formalism was used for liquid solutions of metals including also quaternary zinc systems. [4,5] This method was also applied to dilute solutions where the activity coefficients equations obtained over the entire range of concentrations[6,7] were used.

It was shown that Krupkowski's and Darken's methods consisting in graphical integration when applied to ternary systems[8] result in very similar data of partial and integral thermodynamic functions. The fact that Krupkowski's method is frequently used in binary and multicomponent solutions of metals leads us to attempt its application to liquid salt solutions. First some simple binary and ternary systems with single charge ions were considered. In the previous attempts to interpret the experimental data in liquid salts for instance of the AgCl—RbCl—NaCl system, use was made of an analytical solution of the Gibbs-Duhem equation.[9] The application of this procedure requires the experimental data for the ternary system.

Markov[10] was also concerned with the calculation of the integral thermodynamic functions in ternary salt systems assuming them to be regular. Those considerations enabled the presentation of 5 models of integral excess free energy in ternary systems. On the one hand, the application of Krupkowski's formalism through the $\omega(T)$ function and exponent m takes into consideration the type of solution (not only regular) and its asymmetry, and on the other hand, makes it possible to base the results only on the thermodynamic properties of the binary systems. The further application of this method to the salt systems would enable the calculation of thermodynamic data even in the multicomponent systems in which the experiments are very difficult and sometimes even impossible.

APPLICATION OF KRUPKOWSKI'S FORMALISM TO BINARY SALT SYSTEMS

For the interpretation of the experimental data by means of Krupkowski's method, its application first to binary systems will be discussed, as those equations for the activity coefficients of both components are the starting point for calculating the integral molar function and for further analysis of the multicomponent system.

According to Krupkowski's concept[1] the activity coefficient of component i in a multicomponent system takes the following form:

$$\ln \gamma_i = \sum_{\substack{j,k=1 \\ j \neq k}}^{n} [\ln \gamma_i]_{j,k} \tag{1}$$

where: $[\ln \gamma_i]_{jk}$ is the partial contribution of the binary solutions.

---

[6] Z. Moser, *Met. Trans.*, **2**, 2175 (1971).

[7] Z. Moser, *Arch. Hutn.*, **14**, 371 (1969).

[8] Z. Moser and K. Fitzner, *Met. Trans.*, **3**, 3109 (1972).

[9] A. D. Pelton and S. N. Flengas, *J. Electrochem. Soc.*, **118**, 1307 (1971).

[10] B. F. Markov, *Rev. Roumaine Chim.*, **17**, 203 (1972).

[11] Z. Moser, *Rev. Roumaine Chim.*, **16**, 327 (1971).

The general form of Krupkowski's Eqs. for binary solutions[11] is as follows:

$$\ln \gamma_j = \omega_{jk}(T)\left[(1 - X_k)^{m_{jk}} - \frac{m_{jk}}{m_{jk} - 1} (1 - X_k)^{m_{jk}-1} + \frac{1}{m_{jk} - 1}\right] \quad (2)$$

$$\ln \gamma_k = \omega_{jk}(T)\ (1 - X_k)^{m_{jk}} \quad (3)$$

where: γ_j, γ_k are the activity coefficients of the substance j and k, ω_{jk} is the function dependent on temperature, m_{jk} is the experimental coefficient independent of temperature. The exponent m, for the majority of solutions, takes the values $1 < m \leqslant 2$, and the closer m to unity the higher the asymmetry of such thermodynamic functions as integral molar enthalpy and excess free energy. When $m = 2$, Eqs. (2) and (3) take the symmetrical form of Margules[12] relations:

$$\ln \gamma_j = \omega_{jk}(T)\ (1 - \mathrm{X}_j)^2 \quad (4)$$

$$\ln \gamma_k = \omega_{jk}(T)\ (1 - \mathrm{X}_k)^2 \quad (5)$$

The value of $m > 2$ suggests the appearance of some additional components. This is the case for instance in metal solutions when intermetallic compounds exist.[13] In the salt systems it is probably connected with the tendency to complex formation.

For the determination of Eqs. (2), (3) or (4), (5) of respective binary salt solutions use was made chiefly of experimental emf values of reversible formation cells, then, on the basis of those relations, the values of integral molar enthalpy were calculated. They were next compared with $\Delta H'$ data from calorimetric measurements.

It may generally be assumed that in the salt systems, contrary to metal solutions, less precise $\Delta H'$ from calorimetric data are obtained in comparison with analogical values based on emf measurements interpreted by Krupkowski's or Darken's method.

The resulting values of $\omega(T)$ function and m for the binary systems are summarized in table 1. Making use of those data and Eqs. (2)—(5) it is a simple procedure to verify the respective relations for the activity of both components. For the determination of $\omega(T)$ and m we assume that Eq. (3) will be applied to the component for which the partial thermodynamic functions may be obtained. The values of m were next obtained from the plot $\log \ln \gamma_k$ *vs.* $\log (1 - \mathrm{X}_k)$. The calorimetric data were only included in analysis when these data were available for only one temperature. Next, having m and γ_k, the values of $\omega(T)$ and the relation of this function *versus* temperature were calculated. In the case of the LiCl—KCl system the phase diagram [18] was used instead of the emf data, and for this system a $\omega(T)$ function is characteristic of regular solutions. The

KCl — LiCl	$-\frac{1097}{T}$	1.76	[18]

remaining systems from table 1 are classified as semiregular and, with the exception of the AgCl—LiCl system, m takes values lower than 2 as in metal solutions. From Eqs. (2)—(5) the relation for integral molar enthalpy takes the following form :

$$\Delta H' = \frac{R\alpha_{jk}}{m_{jk}-1}\left[X_j - X_j^m\right] \tag{6}$$

Eq. (6) is independent of temperature and is characteristic of regular and semiregular solutions. From Eq. (6) the integral molar enthalpies for binary salt systems were calculated and were found to be in good agreement with the calorimetric data (References as in table 1). Figure 1 gives the plots of the $\Delta H'$ values of binaries which are nearly symmetrical, this being connected with m oscillating slightly round 2.

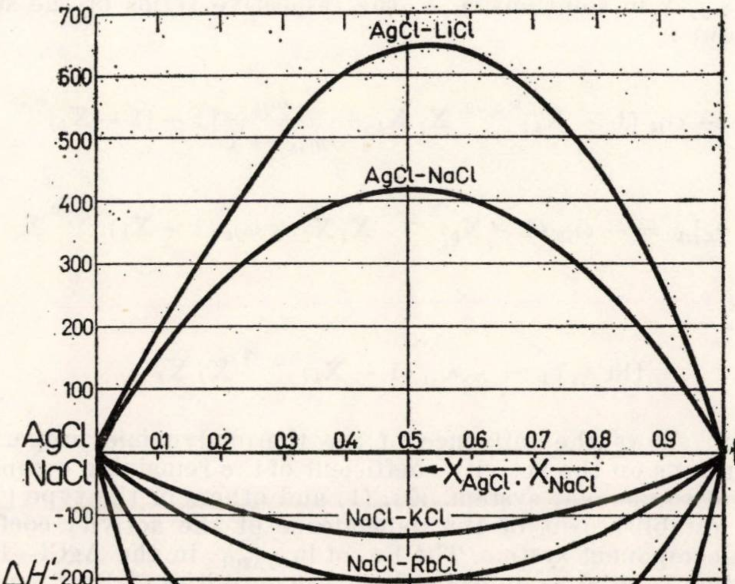

Fig. 1 — Integral molar enthalpies of mixing in binary systems calculated from Eq. (6) and table 1.

TERNARY SYSTEMS

From Eq. (1) relations in ternary solutions can be determined on the basis of the additivity of thermodynamic functions in the multicomponent system and the properties of binaries.

When the activity coefficients are given by Eqs. (2) and (3) for the components j, k in solutions, j, k, the respective terms of the sum (1), are as follows:

for $i = j$

$$[\ln \gamma_j]_{jk} = -\omega_{jk}(1 - X_k)^{m_{jk}-2} X_j X_k + \frac{\omega_{jk}}{m_{jk} - 1}\left[1 - (1 - X_k)^{m_{jk}-1}\right] \tag{7}$$

for $i = k$

$$[\ln \gamma_k]_{jk} = -\omega_{jk}(1 - X_k)^{m_{jk}-2} X_j X_k + \omega_{jk}(1 - X_k)^{m_{jk}-2} X_j \tag{8}$$

for $i \neq k$
$i \neq j$

$$[\ln \gamma_i]_{jk} = -\omega_{jk}(1 - X_k)^{m_{jk}-2} X_j X_k \tag{9}$$

Eq. (9) shows the influence of the thermodynamic properties of the j, k solutions on the activity coefficient of the remaining components i in the multicomponent system. Eq. (1) and others of the type (7)–(9) enable the establishment of the dependence of the activity coefficient in the multicomponent system. The Eq. of $\ln \gamma_{AgCl}$ in the AgCl–RbCl–NaCl system is cited as an example as the activities of RbCl and NaCl for this system were calculated, in the following part of this paper, and were used for isoactivity plots:

$$\begin{aligned}
\ln \gamma_{AgCl_{(Ag,Rb,Na)Cl}} &= -\omega_{(Ag,Na)Cl}(1 - X_{AgCl})^{m_{(Ag,Na)Cl}-2} X_{AgCl} \cdot X_{NaCl} + \\
&+ \omega_{(Ag,Na)Cl}(1 - X_{AgCl})^{m_{(Ag,Na)Cl}-2} X_{NaCl} - \omega_{(Ag,Rb)Cl} \\
&\cdot (1 - X_{AgCl})^{m_{(Ag,Rb)Cl}-2} X_{AgCl} X_{RbCl} + \omega_{(Ag,Rb)Cl}(1 - X_{AgCl})^{m_{(Ag,Rb)Cl}-2} X_{RbCl} - \\
&- \omega_{(Na,Rb)Cl}(1 - X_{NaCl})^{m_{(Na,Rb)Cl}-2} X_{NaCl} X_{RbCl} = \omega_{(Ag,Na)Cl} \cdot \\
&\cdot (1 - X_{AgCl})^{m_{(Ag,Na)Cl}-1} X_{NaCl} + \omega_{(Ag,Rb)Cl}(1 - X_{AgCl})^{m_{(Ag,Rb)}-1} X_{RbCl} - \\
&- \omega_{(Na,Rb)Cl}(1 - X_{NaCl})^{m_{(Na,Rb)Cl}-2} X_{NaCl} X_{RbCl}
\end{aligned} \tag{10}$$

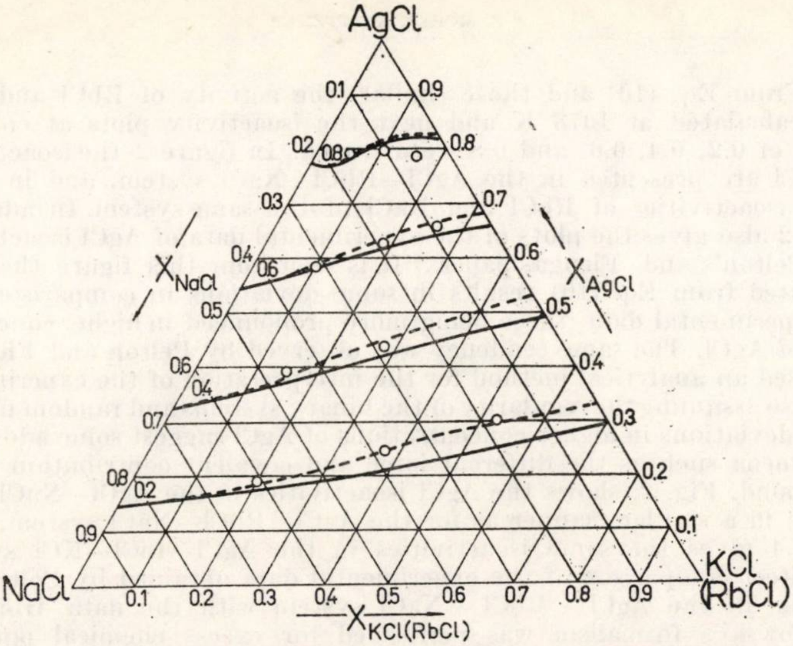

Fig. 2 — Isoactivities of AgCl in the AgCl—RbCl—NaCl system calculated from Eq. (10) (— — —), O — Ref.[9], (———) isoactivities of AgCl calculated in the AgCl—NaCl—KCl system.

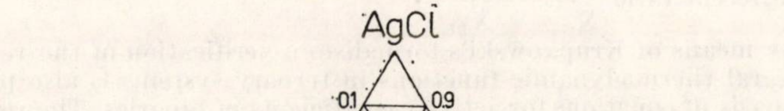

Fig. 3 — Isoactivities of RbCl (— — —) and NaCl (———) in the AgCl—RbCl—NaCl system.

From Eq. (10) and those similar, the activity of RbCl and NaCl were calculated at 1073 K and next the isoactivity plots at constant values of 0.2, 0.4, 0.6, and 0.8 were traced. In figure 2 the isoactivities of AgCl are presented in the AgCl—RbCl—NaCl system, and in figure 3 the isoactivities of RbCl and NaCl of the same system. In addition, figure 2 also gives the plots of the experimental data of AgCl isoactivities from Pelton's and Flengas'paper .[9] It is seen from this figure that a_{AgCl} calculated from Eq. (10) results in some deviations in comparison with the experimental data, these being more pronounced in higher concentrations of AgCl. The same tendency was observed by Pelton and Flengas [9] who used an analytical method for the interpretation of the experimental data also assuming the regularity of the binary systems and random mixing. Those deviations in higher concentrations of AgCl suggest some additional phenomena such as the different ionic and covalent contribution in the AgCl bond. Fig. 2. shows the AgCl isoactivities in the AgCl—NaCl—KCl system in a similar manner as for the AgCl—RbCl—NaCl system, while figure 4 gives the same isoactivities in the AgCl—LiCl—KCl system. The direct comparison of the experimental data obtained by Pelton and Flengas in the AgCl — RbCl — NaCl system with the data from the Krupkowski's formalism was performed for excess chemical potential of AgCl. For this purpose in fig. 5, $\Delta\bar{G}^{*}_{\mathrm{AgCl}}$ *vs.* X_{AgCl} at $T = 1073$ K was plotted. It is seen from this figure that a good agreement was obtained for a different ratio $\dfrac{X_{\mathrm{NaCl}}}{X_{\mathrm{NaCl}} + X_{\mathrm{RbCl}}}$.

By means of Krupkowski's formalism a verification of the relations for integral thermodynamic functions in ternary systems is also possible on the basis of equations for activity coefficients of binaries. The relations for integral excess free energy and molar enthalpy in the AgCl—RbCl—NaCl system will be discussed in this paper the more so that such thermodynamic functions are available for comparison with the results of Pelton and Flengas .[9] In the AgCl—RbCl—NaCl system, the equations for integral excess free energy and molar enthalpy are as follows :

$$\Delta G'^{*}_{(\mathrm{Ag,Rb,Na})\mathrm{Cl}} = \frac{R\,(\alpha + \beta T)_{(\mathrm{Ag,Na})\mathrm{Cl}}}{m_{(\mathrm{Ag,Na})\mathrm{Cl}}^{-1}} \left[1 - (1 - X_{\mathrm{AgCl}})^{m_{(\mathrm{Ag,Na})\mathrm{Cl}}^{-1}}\right] X_{\mathrm{NaCl}} +$$

$$+ \frac{R\,(\alpha + \beta T)_{(\mathrm{Ag,Rb})\mathrm{Cl}}}{m_{(\mathrm{Ag,Rb})\mathrm{Cl}}^{-1}} \left[1 - (1 - X_{\mathrm{AgCl}})^{m_{(\mathrm{Ag,Rb})\mathrm{Cl}}^{-1}}\right] X_{\mathrm{RbCl}} +$$

$$+ \frac{R\,(\alpha + \beta T)_{(\mathrm{Na,Rb})\mathrm{Cl}}}{m_{(\mathrm{Na,Rb})\mathrm{Cl}}^{-1}} \left[1 - (1 - X_{\mathrm{NaCl}})^{m_{(\mathrm{Na,Rb})\mathrm{Cl}}^{-1}}\right] X_{\mathrm{RbCl}} =$$

$$= (1667.1 - 0.622\ \mathrm{T})\, X_{\mathrm{AgCl}} X_{\mathrm{NaCl}} + (-3869.5 + 1.15\ T)\ [1 - (1 - X_{\mathrm{AgCl}})^{0.95}] \cdot$$

$$\cdot X_{\mathrm{RbCl}} + (-\ 890.9 + 0.336\ \mathrm{T})\ [1 - (1 - X_{\mathrm{NaCl}})^{0.87}] X_{\mathrm{RbCl}} \qquad (11)$$

$$+ \frac{R\alpha_{(\mathrm{Na,Rb})\mathrm{Cl}}}{m_{(\mathrm{Na,Rb})\mathrm{Cl}}^{-1}} \left[1 - (1 - \mathrm{X}_{\mathrm{NaCl}})^{m_{(\mathrm{Na,Rb})\mathrm{Cl}}^{-1}}\right] \mathrm{X}_{\mathrm{RbCl}} = 1667.1\, \mathrm{X}_{\mathrm{AgCl}}\, \mathrm{X}_{\mathrm{NaCl}} +$$

$$- 3869.5 \left\{\left[1 - (1 - \mathrm{X}_{\mathrm{AgCl}})^{0.95}\right] \mathrm{X}_{\mathrm{RbCl}}\right\} - 890.9 \left\{\left[1 - (1 - \mathrm{X}_{\mathrm{NaCl}})^{0.87}\right] \mathrm{X}_{\mathrm{RbCl}}\right\} \qquad (12)$$

From Eqs. (11) and (12) the values of both functions were calculated and plotted as isofunctions in figures 6 and 7. In figures 6 and 7 the isofunctions are traced at the temperature of 1073°K, $\Delta G'^*$ (fig. 6) every 50 cal, and $\Delta H'$ every 200 cal, respectively. Both plots are in good agreement with the results given in paper .[9] The plots of $\Delta G'^*$ and $\Delta H'$ for the AgCl—NaCl—KCl ternary solutions are presented in figs. 8 and 9 in a similar manner as for the AgCl—RbCl—NaCl system.

The experimental investigations for the AgCl—NaCl—KCl system were carried out by Guion *et al.* [19] but the calculations of $\Delta G'^*$ and $\Delta H'$ were not included.

It is interesting that the curves "O" appear on the plots as a result of the negative and positive deviations of binaries from the Raoult's law.

On the basis of the relation for activity coefficient in the ternary system it is simple to calculate ln γ_i when $\mathrm{X}_i = 0$. For example from Eq. (10) the relation ln γ_{AgCl} in the AgCl—KCl—LiCl system when $\mathrm{X}_{\mathrm{AgCl}} = 0$ takes the following form:

$$(\ln \gamma_{\mathrm{AgCl}})_{\substack{(\mathrm{Ag,K,Li})\mathrm{Cl} \\ \mathrm{X}_{\mathrm{AgCl}} \to 0}} = \omega_{(\mathrm{Ag,Li})\mathrm{Cl}}\, \mathrm{X}_{\mathrm{LiCl}} + \omega_{(\mathrm{Ag,K})\mathrm{Cl}}\, \mathrm{X}_{\mathrm{KCl}} -$$

$$- \omega_{(\mathrm{Li,K})\mathrm{Cl}} (1 - \mathrm{X}_{\mathrm{KCl}})^{m_{(\mathrm{Li,K})\mathrm{Cl}} - 2}\, \mathrm{X}_{\mathrm{KCl}}\, \mathrm{X}_{\mathrm{LiCl}}. \qquad (13)$$

The values of (ln γ_{AgCl}) $\mathrm{X}_{\mathrm{AgCl}} \to 0$ at a temperature of 823°K were calculated from Eq. (13) and then plotted in figure 10. On this plot, assuming the ideal behaviour of the LiCl—KCl system, a linear dependence is obtained by connecting the points corresponding to ln $\gamma^{\circ}_{\mathrm{AgCl}}$ in binary AgCl—KCl and AgCl—LiCl systems. When the relation for ln γ_{AgCl} is determined by Eq. (3) the values of ln $\gamma^{\circ}_{\mathrm{AgCl}}$ of both binaries may be calculated as the $\omega(T)$ function of both systems. The deviation from the linear dependence in figure 10 shows the influence of the LiCl—KCl system and from Eq. (13) is equal $- \omega_{(\mathrm{Li,K})\mathrm{Cl}} (1 - \mathrm{X}_{\mathrm{KCl}})^{m_{(\mathrm{Li,K})\mathrm{Cl}} - 2} \mathrm{X}_{\mathrm{KCl}} \mathrm{X}_{\mathrm{LiCl}}$. According

to Eq. (13) in the case when the components 2—3 of the LiCl—KCl system show the negative deviations from the Raoult's law, a positive departure from the linear dependence is obtained. The opposite case is also valid when the negative deviations from the straight line appear.

Figure 10 also includes the value ln γ°_{AgCl} from the Yang and Hudson's paper[20] obtained by means of extrapolation of the experimental ln γ_{AgCl} values in eutectic LiCl—KCl to $X_{AgCl} = 0$. It is seen that the value of ln $\gamma^{\circ}_{AgCl_{(Ag,Li,K)Cl}}$ obtained from the data of Yang and Hudson correspond to some slighter deviations of the LiCl—KCl solutions from the Raoult's law than those suggested by the last term of Eq. (13).

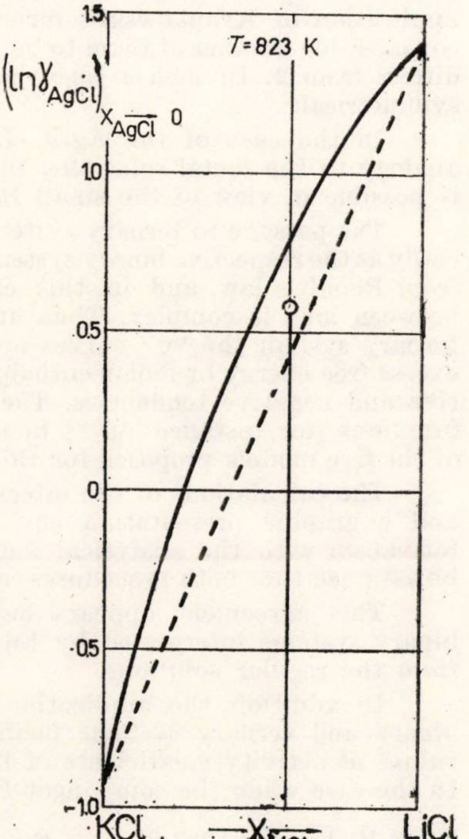

Fig. 10 — $(\ln \gamma_{AgCl})_{X_{AgCl}\to 0}$ *vs.* X_{LiCl} at 823 K in the AgCl—KCl—LiCl system.

DISCUSSION

Applying Krupkowski's formalism to the experimental data from literature the relations for activity coefficients of both components in liquid AgCl—RbCl, AgCl-KCl, AgCl-LiCl, NaCl-RbCl, AgCl—NaCl, NaCl—KCl and KCl—LiCl systems were determined. The resulting equations were used for the establishment of the relation of integral molar enthalpy of the given binaries. The value of $\Delta H'$ calculated from Eq. (6) is accurate to ± 100 cal when $X_1 = X_2 = 0.5$ molar fraction compared with calorimetric data.

This fact suggests that Eqs. (2)—(5) correspond well to the experimental data. On the basis of this fact and the relations (2)—(5) for respective binaries, equations for activity coefficients in ternary system were determined. Such a procedure enabled the calculations of activity and the tracing of isoactivity plots which show a good agreement with the experimental results corresponding to the AgCl—RbCl—NaCl system which were the subject of Pelton and Flengas's experiments .[9] Greater deviations between the experimental data and those from Eq. (10) were obtained at higher concentrations of AgCl as also shown in this paper. In a previous paper on the binary system AgCl$-$ACl (where A $=$ Na, K, Rb or Cs) Pelton and Flengas[14] drew attention to the mixed character of the bonding, namely the ionic – covalent one, which is also influenced by the magnitude of the ionic radius of component *A*. The application of Krupkowski's formalism to the binary systems shows a considerable number of them to be semi-regular solutions, when *m* slightly differs from 2. In such a case the thermodynamic functions are nearly symmetrical.

---

[20] L. Yang and R. Hudson, *Trans. TMS—AIME*, **215**, 589 (1959).

In the case of the AgCl$-$LiCl system $m > 2$ may suggest, by analogy to the metal solutions, the tendency to form complexes, which is possible in view of the small Li^+ion.

The passage to ternary systems seems to be more complicated especially as the respective binary systems show negative and positive departure from Raoult's law, and in this case the problem of the interactions between ions is complex. Then at a certain ratio of concentrations in ternary system the "0" curves appear on plots of isofunctions such as excess free energy or molar enthalpy as a result of the cancelling of positive and negative tendencies. The obtained plots of the integral molar functions (for instance $\Delta G'^*$) in the ternary system correspond to one of the five models proposed for this function by Markov.[10]

The calculations of the integral molar functions in ternary systems and a graphic presentation enabled the comparison of Krupkowski's formalism with the analytical Pelton and Flengas method.[9, 14] It may be assumed that both procedures result in similar values of $\Delta H'$ and $\Delta G'^*$.

This agreement appears because the experimental data of the binary systems interpreted by Eqs. (2)–(5) show only slight departure from the regular solutions.

In addition, the application of Krupkowski's formalism to both binary and ternary systems facilitates the calculation of the limiting values of activity coefficients of binary systems from Eqs. (2) and (3). In the case when the component *k* was applied to Eq. (3); $\ln \overset{\circ}{\gamma}_k = \omega_{jk}$, when to Eq. (2) then $\ln \overset{\circ}{\gamma}_j = \omega_{jk}\dfrac{1}{m_{jk} - 1}$. For symmetrical solutions when $m = 2$, $\ln \gamma = \ln \overset{\circ}{\gamma}_k = \omega_{jk}$.

Calculations of $(\ln \gamma_{AgCl})\, X_{AgCl} \to 0$ in the AgCl$-$LiCl$-$KCl system compared with the experimental results of Yang and Hudson[20] confirm the fact, that the departure from the linear dependence is produced by the term connected with the binary system 2$-$3, namely LiCl$-$KCl, which is also the case in metal solutions. The interpretation of the experimental data by the Krupkowski's method suggests the possibility of its successful application to the liquid salts systems with single charge ions. The good agreement of thermodynamic functions in binary and ternary systems with available experimental data indicates the applicability of the Krupkowski's method to the salt systems for the calculation of thermodynamic functions in multicomponent systems from binary systems, even when, as a result of the experimental difficulties, the experiments in multicomponent systems are impossible.

AN IMPROVEMENT OF HOFFMANN'S LCAO–MO METHOD

C. I. LEPĂDATU* and S. MOLDOVEANU**

* Center of Chemical Physics, Dumbrava Roşie, 23, Bucharest, Romania
** Faculty of Chemistry, University of Bucharest, Romania

Received May 31, 1973

The present paper describes a new method for MO calculations which may be considered as an improved Hoffmann method. The improvement consists in the introduction of the electrostatic interactions, screening constants, as well as the introduction of iterations of the VSIP's upon the charges as a result of the electron population analysis. Calculations performed for ethane in the staggered form are in good agreement with the results of the photoelectron spectroscopy.

One of the extended Hückel-type LCAO–MO methods which gives good results in the study of the hydrocarbons is the method proposed by Hoffmann.[1] This method is mainly used to obtain MO energies and wavefunctions for molecules with 1*s*, 2*s* and 2*p* AO's, taking into account all the overlap integrals.

The minimization of the energy of a molecule with n orbitals leads to :

$$\sum_{\nu=1}^{n} [H_{\mu\nu} - \varepsilon^{i} S_{\mu\nu}] c_{\nu i} = 0 \qquad (1)$$

$$\mu = 1,\dots n, \quad i = 1,\dots n$$

where $c_{\nu i}$ are the coefficients in the expression :

$$\psi_i = \sum_{\nu} c_{\nu i} \chi_\nu, \qquad (2)$$

ψ_i being the molecular orbitals, χ_ν the atomic orbitals in the given molecule, and

$$S_{\mu\nu} = \int \chi_\mu^* \chi_\nu \, \mathrm{dv} \qquad (3)$$

$$H_{\mu\nu} = \int \chi_\mu^* \hat{H} \chi_\nu \, \mathrm{dv} \qquad (4)$$

---

[1] R. Hoffmann, *J. Chem. Phys.*, **39**, 1397 (1963).

the overlap integral and the energy integral, $\widehat{H}$ being the hamilton operator of the system.

In the Hoffmann method $S_{\mu\nu}$ are exactly calculated but $H_{\mu\nu}$'s remain constant and independent of the charge density in the molecule.

The aim of the present paper is to find another way to estimate the $H_{\mu\nu}$'s, different of the recipe recommended by Hoffmann in his mentioned approach.

For this purpose, the one-electron hamiltonian has been approximated to:

$$\hat{H}^{\mu} = -1/2\,(\nabla^{\mu})^2 + V_A^{\mu} + \sum_{B\neq A} V_B^{\mu} \tag{5}$$

where the electron in the μ—AO belongs to the A-core, and B runs over all the other cores in the molecule.

Expression (5) is usually known under the name of Coulomb screened potential approximation, where:

$$V_B^{\mu} = -\,k\,(\mu,\ \mu)\ (Z_B/r_{AB}) \tag{6}$$

where Z_B is the effective charge on the B-core, r_{AB} the distance between the A and B cores.

What is new in our treatment is the introduction of the screening constant $k(\mu,\ \mu)$ determined by the electron densities in the outer shells enveloping the orbital "μ" which may reduce the interaction with the external Z_B charges on the other B cores in the molecule. This constant will be discussed later. In the one-electron approximation:

$$\hat{H}_{\text{mol}} = \sum_{\mu=1}^{n} \hat{H}^{\mu} \tag{7}$$

$$E_{\text{mol}} = \sum_{i=1}^{n} n^i\ \varepsilon^i \tag{8}$$

where n^i — is the electron number in the monoelectronic molecular orbital "i" given by (2), ε^i — the corresponding MO energy satisfying the equation:

$$\hat{\mathscr{H}}^{\mu}\ \psi_i = \varepsilon^i\ \psi_i. \tag{9}$$

Striking out the index μ in $\hat{\mathscr{H}}^{\mu}$ because of the identity of $\mathscr{H}^{\mu}$ for each of the μ orbitals, the equation (9) is reduced to:

$$\hat{\mathscr{H}}\ \psi_i = \varepsilon^i \psi_i, \tag{10}$$

which is solved in the LCAO—MO approximation according to (1).

The problem is now to have $S_{\mu\nu}$ and $H_{\mu\nu}$ values. According to (5) and (6), we have:

$$H_{\mu\mu} = \int \chi_\mu^* \left(-\frac{1}{2} \nabla^2 + V_A \right) \chi_\mu \, \mathrm{dv} - k(\mu, \mu) \sum_{B \neq A} \int \chi_\mu^* \frac{Z_B}{r_{AB}} \chi_\mu \, \mathrm{dv} \qquad (11)$$

where μ belongs to the A core.

If we take the first term in (11) as the valence state ionization potential (VSIP) with a changed sign, and putting down:

$$\int \chi_\mu^* \frac{1}{r_{AB}} \chi_\mu \, \mathrm{dv} = BI_{B\mu}, \qquad (12)$$

we obtain:

$$H_{\mu\mu} = - \mathrm{VSIP}\,(\mu) - k\,(\mu, \mu) \cdot \sum_{B \neq A} Z_B \cdot BI_{B\mu}, \qquad (13)$$

where Z_B is the effective charge on the B centres.

The VISP (μ) values are taken as a parabolic function of Z_A,

$$\mathrm{VSIP}\,(\mu) = \alpha Z_A^2 + \beta Z_A + \gamma \qquad (14)$$

where α, β, γ, are the coefficients found for each μ and element in the related literature.

To evaluate the $H_{\mu\nu}$ integrals we use the formula:

$$H_{\mu\nu} = - k\,(\mu, \nu) \cdot 0.5\ S_{\mu\nu}\ [(2 - |S_{\mu\nu}|)\ \ (\mathrm{VSIP}\,(\mu) + \mathrm{VSIP}\,(\nu)) +$$

$$+ (\sum_{B \neq A} Z_B BI_{B\mu} + \sum_{A \neq B} Z_A\, BI_{A\nu})], \qquad (15)$$

which comes from Cusach's approximation [2] if the electrostatic interactions and the screening constant $k(\mu, \nu)$ should be taken into account.

The expressions (13) and (15) show that the $H_{\mu\mu}$ and $H_{\mu\nu}$ values can be obtained if $S_{\mu\nu}$, $BI_{B\mu}$ and $k(\mu, \nu)$ as well as the effective charges on the cores in the molecule are known.

The overlap integrals $S_{\mu\nu}$ can be calculated using the master formulas given by Kruglyak *et al.*, [3] and the $BI_{B\mu}$ integrals using formulas given by Roothaan, [4] up to the orbital quantum number $l = 2$.

---

[2] L. Chopin-Cusach, *J. Chem. Phys.*, **43**, 1575(1965).

[3] Yu. Kruglyak, "Metody rascheta elektronnoi struktur i spektrov molecu l", Moscow, Dumca, Kiev, 1969.

[4] C. C. J. Roothaan, *J. Chem. Phys.*, **19**, 1445(1 951).

The effective charge on the cores in the molecule may be found from the electron population analysis:

$$Z_A = Z_A^0 - \sum_{\mu} q^{\mu} \tag{16}$$

where q^{μ} is the charge on the μ—AO, given by:

$$q^{\mu} = \frac{\sum\limits_{i=1}^{n} n^i - 0.5 \sum\limits_{\mu=1}^{n} \sum\limits_{i=1}^{n} n^i c_{\mu i} \sum\limits_{\mu \neq \nu} c_{\nu i} S_{\mu\nu}}{\sum\limits_{\mu=1}^{n} \sum\limits_{i=1}^{n} n^i c_{\mu i}^2} \sum_{i=1}^{n} n^i c_{\mu i}^2, \tag{17}$$

and the screening constant by:

$$k(\mu, \nu) = k'(\mu)\, k'(\nu), \tag{18}$$

where

$$k'(\mu) = [1 - (\sum_{i} n^i c_{\mu i}{}^2/m)]^{1/2}, \tag{19}$$

where $m = 2, 6, 10\ldots$ for the s-, p-, d-, ... — type AO's respectively.

ITERATION PROCEDURE

The iteration procedure is the following:

— We compute the $S_{\mu\nu}$ integrals, make an initial estimation of $k(\mu, \nu)$, Z_A, Z_B, etc. One computes the $BI_{B\mu}$ integrals and after that $H_{\mu\mu}$ and $H_{\mu\nu}$.

— We solve the equation system (1) and obtain ε^i and $c_{\nu i}$ values which are used to compute $k^{\text{new}}(\mu, \nu)$, Z_A^{new}, etc. using (16)—(19).

— then we put:

$$Z_A = 0.9\, Z_A^{\text{old}} + 0.1\, Z_A^{\text{new}}$$

. . . .

$$k(\mu, \nu) = 0.9\, k^{\text{old}}(\mu, \nu) + 0.1\, k^{\text{new}}(\mu, \nu),$$

and after that one computes new values for $H_{\mu\mu}$ and $H_{\mu\nu}$ which introduced in (1) give ε^i and $c_{\nu i}$. The procedure should be repeated until self-consistency.

The mixture of the output and input data during the iteration process has been made in order to speed up the convergence. [5]

The present method has been written by one of us (S.M.) in FORTRAN for an IBM 360/30 system digital computer for orbitals up to the orbital quantum number $l = 3$.

CALCULATION EXPERIMENT

The outlined method has been applied to ethane in the staggered form (symmetry group D_{3d}), using four iterations, after which the total energy remains constant.

---

[5] D. G. CAROLL, A. T. ARMSTRONG and S. P. MCGLYNN, *J. Chem. Phys.*, **44**, 1865 (1966).

For this purpose, the following interatomic distances were used; $r_{C-C} = 1.54$ Å; $r_{C-H} = 1.1$ Å. The AO set contains $1s_H$, $2s_C$ and $2p_C$ taken as Slater type orbitals. The corresponding VSIP's were taken as $A + BZ$ where Z is the effective charge, A and B constants being reported in the related literature.[6]

The bonding MO energies are collected in table 1 and compared with those obtained by different authors.[7-9]

Table 1

MO levels for ethane D_{3d} (energy in *eV*)

Level	Present method	Ref.[6]	Ref.[7]	Ref.[8]
$2a_{1g}$	−11.323	−14.11	−14.59	−13.32
e_g	−11.323	−13.76	−14.01	−13.93
e_u	−15.680	−15.86	−17.07	−15.60
a_{2u}	−18.734	−21.82	−23.37	−20.89
$1a_{1g}$	−25.053	−26.67	−28.30	−24.21

Table 2

Ionization potentials for ethane (*eV*)

Observed	Calculated	Ref.[8]
11.78	11.323	13.32
14.74	15.680	15.60
19.18	18.734	20.89

Table 2 shows the ionization potentials for ethane as they result from the photoelectron spectroscopy.[10] Assuming that during the ionization no molecular changes take place, i.e the Koopmans theorem holds, the observed ionization potentials should be equal to the MO energies with changed sign.

As may be seen from the tables 1–2, the MO levels obtained by the present method are comparable with those calculated by different authors. It must, however, be mentioned that the Hoffmann approach [7] leads to the inverted order $2a_{1g} < e_g$ which disagrees with the order obtained by other MO approximations or by the present method.

The atomization energy calculated for ethane (the total energy for the ethane in its ground state minus the total energy of the atoms) is found to be:

– 595.2 kcal/mol comparable with
– 671.6 kcal/mol, as experimentally evaluated.[11]

The authors express their thanks to Mrs. Agneta Caragheorghiopol, to Mr. Horia Căldăraru and to Mr. Andrei Savin for their help in the preparation of the present paper, and to the staff of the Computation Centre of University of Bucharest for the assistance in the use of IBM 360/30 system digital computer.

L'ACIDE ASCORBIQUE COMME AGENT RÉDUCTEUR. IV[1]

LA CINÉTIQUE DE LA RÉDUCTION DES IONS Pt(II) PAR ACIDE ASCORBIQUE EN PRÉSENCE DES IONS Pb(II)

RALUCA RIPAN, GH. POP et ILEANA POP

Institut de Chimie de Cluj, 65–103, str. Donath, Roumanie

Reçu le 14 mai 1973

On a étudié la cinétique de la réaction de réduction des ions Pt(II) par acide ascorbique, à 40°, dans un milieu d'acide chlorhydrique en présence des ions Pb(II) comme catalyseur. On a établi expérimentalement l'expression de la vitesse de réaction en fonction des facteurs qui l'influencent, selon la formule :

$$v = k[\mathrm{Pb}^{2+}]^2 \frac{[\mathrm{Pt}^{2+}][\mathrm{Asc}]}{[\mathrm{H}^+][\mathrm{Cl}^-]^2} \cdot e^{-\frac{E}{RT}} \qquad \text{(I)}$$

Nous avons abordé l'étude des systèmes redox dans le domaine des métaux précieux pour l'amélioration des méthodes d'analyse et de leur technologie de séparation. Ainsi l'étude de la cinétique de la réaction de réduction du Pd(II) par acide ascorbique [2] à été appliquée à la séparation de l'or, du palladium et du platine des solutions épuisées de l'électrolyse de l'or.[1,3]

Le réduction des ions Pt(II) à l'état de Pt métallique par acide ascorbique a lieu quantitativement conformément à la réaction :

$$\mathrm{Pt}^{2+} + \mathrm{C_6H_8O_6} \xrightarrow{\mathrm{HCl}} \mathrm{Pt} + \mathrm{C_6H_6O_6} + 2\mathrm{H}^+ \qquad \text{(II)}$$

à des concentrations d'acide chlorhydrique plus faibles que 0,07 N.

On a prouvé expérimentalement que la réaction redox (II) a lieu même à des concentrations plus fortes que 0,07 N HCl, en présence des ions Pb(II).

4. Solution de chlorure stanneux ch. p. 3,5 M
5. Acide chlorhydrique concentré *p.a.*

La vitesse de la réaction a été suivie en déterminant photocolorimétriquement la concentration du Pt(II), en présence du chlorure stanneux.[4] La température optimale de travail a été de 40° ou plus, étant donné qu'à plus basses températures la vitesse de réaction est trop faible. L'arrêt de la réaction a lieu dans un milieu de HCl 1,5 M à la température ambiante.

RÉSULTATS ET DISCUSSIONS

L'aspect général d'une courbe représentant la variation de la concentration du Pt(II) dans le mélange de réaction en fonction du temps est indiqué par la figure 1.

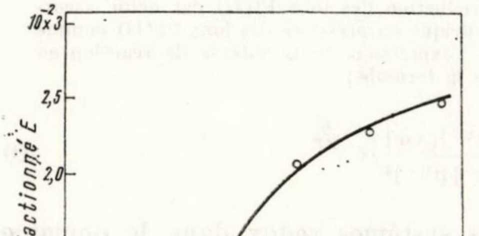

Fig. 1. — Réduction des ions Pt (II) par acide ascorbique dans un milieu de HCl 6.10^{-2} N, à 40°. /Pt^{2+} /= $2,92.10^{-2}$ N ; /Asc/ = 6.10^{-2} N.

On remarque la présence d'une période d'induction, comme dans le cas de la réaction de réduction des ions Pd(II) par l'acide ascorbique.[2] La vitesse de réaction (V) est mesurée par la méthode de tangentes au point où la concentration de ions Pt(II) est arrivée à la moitié de la concentration initiale.

INFLUENCE DE LA CONCENTRATION DES RÉACTANTS SUR LA VITESSE DE RÉACTION

La figure 2 rend l'influence de la concentration des ions Pt(II) sur la vitesse de réaction, à 40°, dans un milieu de HCl 6.10^{-2} N. On a représenté sur l'ordonnée la quantité de Pt(II) qui réagit et sur l'abscisse le temps. On remarque une croissance de la vitesse de réaction, proportionnelle à la croissance de la concentration de Pt(II), un phénomène également illustré par la figure 3.

L'influence de la concentration de l'acide ascorbique sur la vitesse de réaction est indiquée dans les figures 4 et 5. Les données expérimentales attestent une dépendance directement proportionnelle de la vitesse de réaction en fonction de la concentration de l'acide ascorbique.

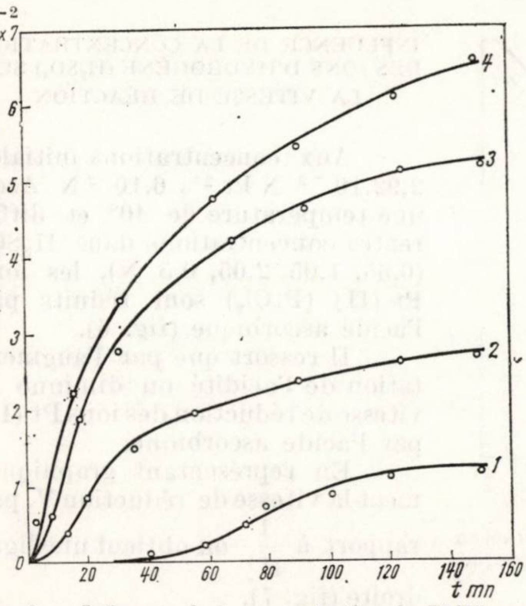

Fig. 2. — Influence de la concentration du Pt(II) sur la vitesse de réaction : dans un milieu de HCl 6.10^{-2} N et /Asc/ = $1,6.10^{-1}$ N ; t = 40°. 1 – 1,46 . 10^{-2}N Pt(II) ; 2 – 2,92.10^{-2} N Pt(II) ; 3 – 5,84.10^{-2} N Pt(II) ; 4 – 7,30.10^{-2} N Pt(II).

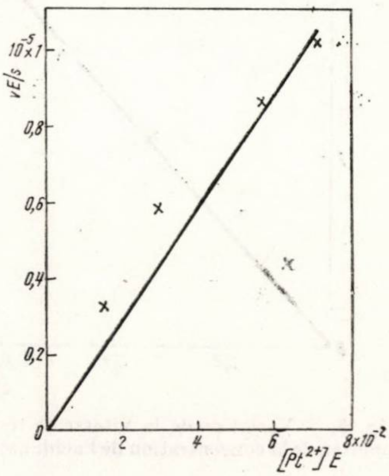

Fig. 3. — Dépendance de la vitesse de réaction de la concentration du Pt (II).

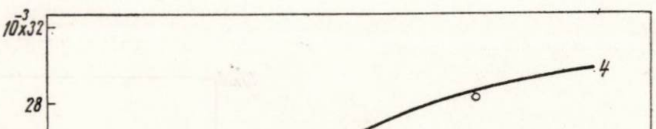

Fig. 4. — Influence de la concentration de l'acide ascorbique (Asc) sur la vitesse de réaction à 40°, dans un milieu de HCl 6.10^{-2} N (Pt^{2+} = 2,92. 10^{-2} N) ; 1 – 0,8.10^{-1} N Asc ; 2 – 1,6.10^{-1} N Asc ; 3 – 3,2.10^{-1} N Asc ; 4 – 6,4.10^{-1} N Asc.

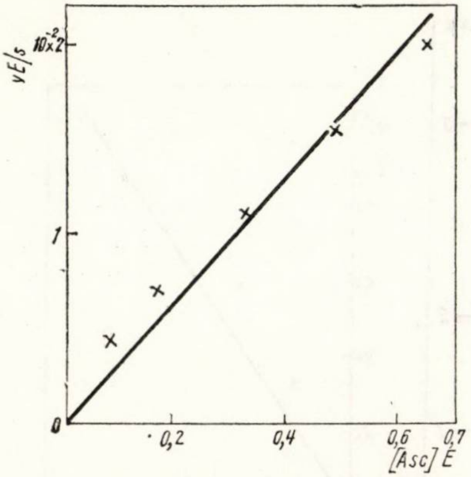

Fig. 5. — Variation de la vitesse de réaction en fonction de la concentration de l'acide ascorbique.

INFLUENCE DE LA CONCENTRATION DES IONS D'HYDROGÈNE (H_2SO_4) SUR LA VITESSE DE RÉACTION

Aux concentrations initiales $2{,}92.10^{-2}$ N Pt^{2+}, 6.10^{-2} N Asc., une température de 40° et différentes concentrations dans H_2SO_4 (0,55, 1,05, 2,05, 0,5 N), les ions Pt (II) ($PtCl_2$) sont réduits par l'acide ascorbique (fig. 6).

Il ressort que par l'augmentation de l'acidité on diminue la vitesse de réduction des ions Pt (II) par l'acide ascorbique.

En représentant graphiquement la vitesse de réduction V, par rapport à $\frac{1}{H^+_-}$ on obtient une ligne droite (fig. 7).

En examinant la figure 7, on peut déduire que la vitesse de réaction est inversement proportionnelle à la concentration des ions d'hydrogène.

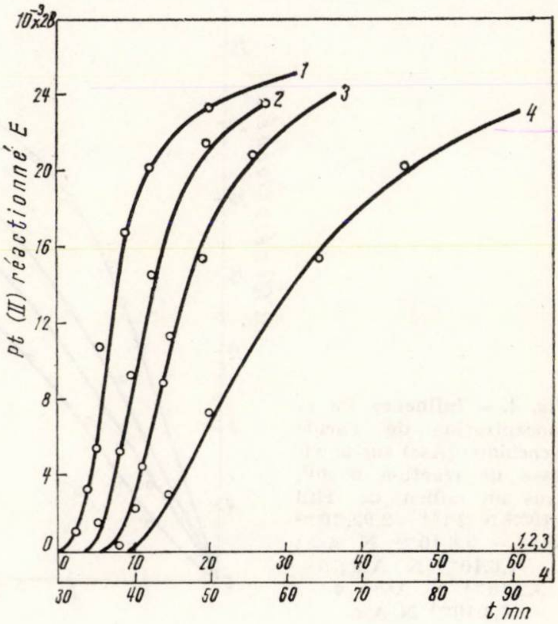

Fig. 6. — Influence de la concentration des ions $H^+(H_2SO_4)$ sur la vitesse de réduction des ions Pt (II) par l'acide ascorbique à 40° ($Pt^{2+} = 2{,}92.10^{-2}$ N ; Asc $= 6.10^{-2}$ N).1 — 0,55 N (H^+) ; 2 — 1,05 N (H^+) ; 3 — 2,05 N (H^+) ; 4 — 5 N (H^+).

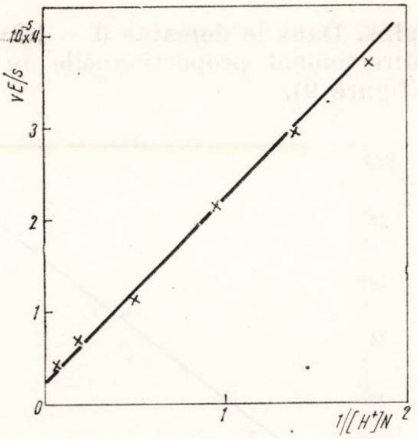

Fig. 7. — Dépendance de la vitesse de réaction, en fonction de l'inverse de la concentration des ions H^+.

INFLUENCE DE LA CONCENTRATION DE L'ACÉTATE DE PLOMB SUR LA VITESSE DE RÉACTION

La figure 8 donne la croissance de la vitesse de réaction d'une manière concomittante à la croissance de la concentration des ions Pb(II) présents dans le mélange de réaction. Mais la croissance a lieu seulement jusqu'à une certaine limite de la concentration de Pb(II), notamment $-6{,}4.10^{-3}$ N. Au-dessus de cette valeur la vitesse de réduction ne croît

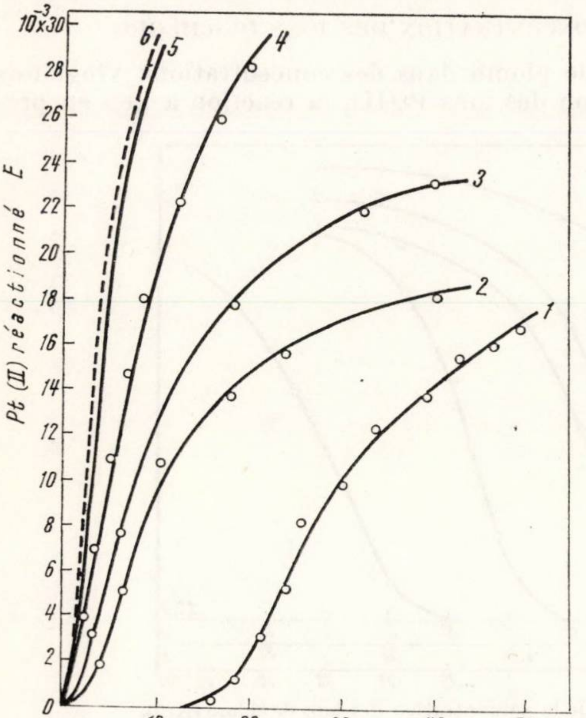

Fig. 8. — Influence de la concentration des ions Pb(II) sur la vitesse de réduction des ions Pt(II) par acide ascorbique à 40°, dans un milieu de HCl 6.10^{-2} N ($Pt^{2+} = 2{,}92.10^{-2}$ N, Asc $= 6.10^{-2}$ N). 1–0 N Pb(II) 2 – $0{,}32.10^{-3}$ N Pb(II) ; 3–$0{,}65.10^{-3}$ N Pb(II) ; 4–$1{,}30.10^{-3}$ N Pb(II) ; 5–$3{,}20.10^{-3}$ N Pb(II) ; 6–$6{,}40.10^{-3}$ N Pb (II).

plus. Dans le domaine 0 — $1{,}3.10^{-3}$ N Pb(II), la vitesse de réaction est directement proportionnelle au carré de la concentration des ions Pb (figure 9).

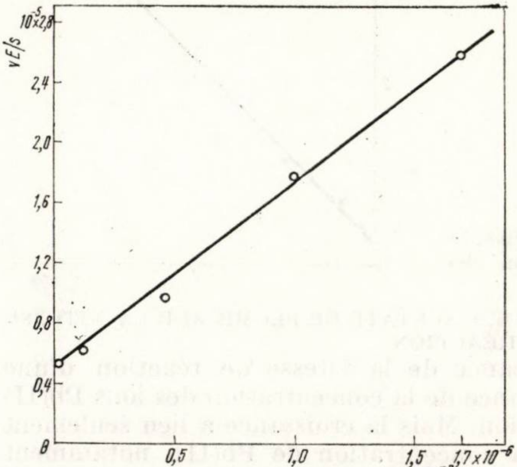

Fig. 9. — Variation de la vitesse de réaction en fonction de la concentration des ions Pb(II).

INFLUENCE DE LA CONCENTRATION DES IONS DE CHLORE

En présence des ions de plomb dans des concentrations vingt fois moindres que la concentration des ions Pt(II), la réaction a lieu en pré-

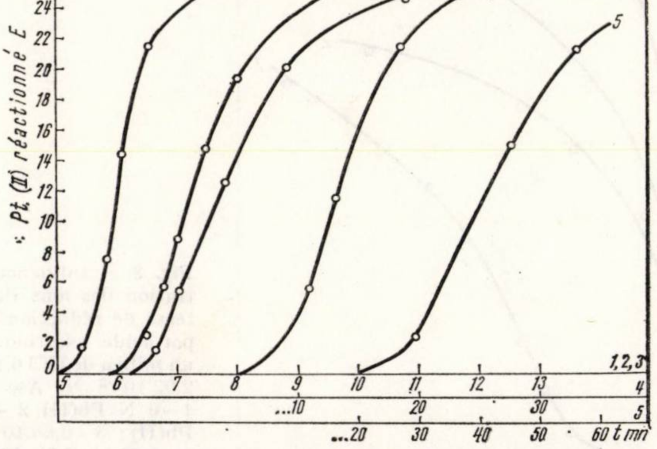

Fig. 10. — Influence de la concentration des ions de chlore (KCl) sur la vitesse de réaction, à 40°. $Pt^{2+} = (2{,}92.10^{-2}$ N ; Asc = $= 6.10^{-2}$ N ; $Pb^{2+} = 1{,}3.10^{-3}$ N ; $H^{+} = 0{,}1$ N). 1—$1{,}2.10^{-1}$ N Cl(I) ; 2—$1{,}7.10^{-1}$ N Cl(I) ; 3—$2{,}4.10^{-1}$ N Cl(I) ; 4 — $3{,}6.10^{-1}$ N Cl(I) ; 5—5.10^{-1} N Cl(I).

sence du chlorure de potassium de dilutions moindres que 0,5 N. La vitesse de la réaction de réduction des ions Pt(II) par l'acide ascorbique est inversement proportionnelle au carré de la concentration des ions de chlore (fig. 10 et 11).

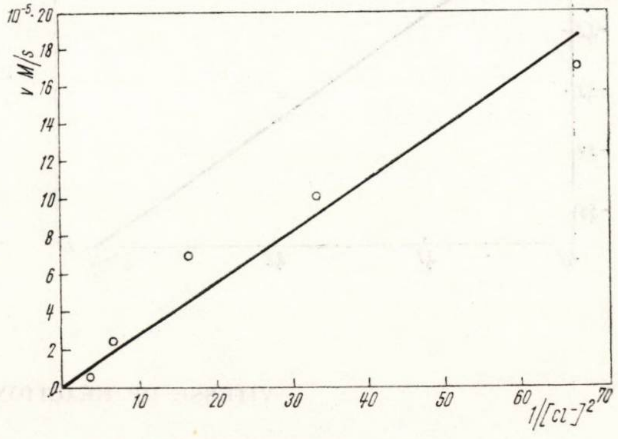

Fig. 11. — Variation de la vitesse de réaction en fonction de $1/Cl^{-2}$.

INFLUENCE DE LA TEMPÉRATURE

En étudiant l'influence de la température sur la vitesse de réaction dans un milieu de Cl^- 0,5 N et H^+ 0,1 N, en présence des ions Pb(II) ($1{,}3.10^{-3}$ N), on observe une croissance de la vitesse (figures 12 et 13) avec la croissance de la température.

La valeur obtenue pour l'énergie d'activation est : $E = 8$ *k*cal/mole.

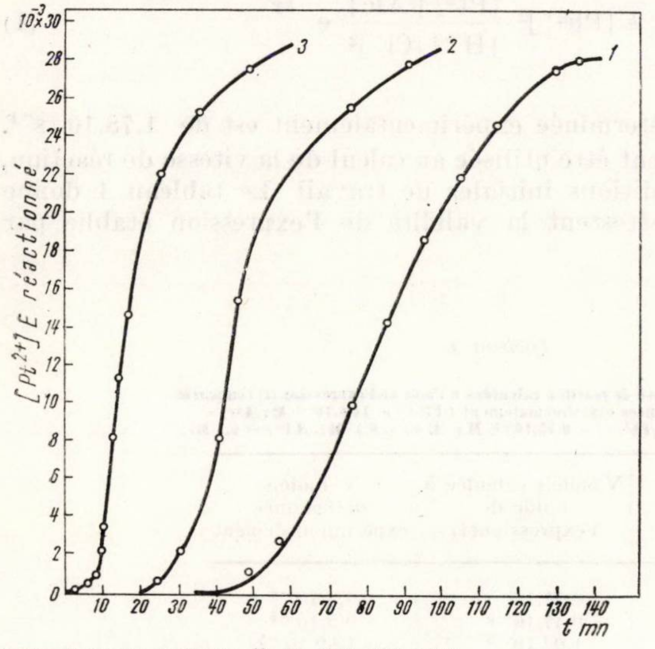

Fig. 12. — Influence de la température sur la vitesse de réaction dans un milieu de Cl^- 0,5 N et H^+ 0,1 N (Pt (II) $= 2{,}92.10^{-2}$ N Asc $=$ 6.10^{-2} N ; Pb (II) $=$ $1{,}3.10^{-3}$ N) ; 1 — 30° ; 2 — 40° ; 3 — 60°.

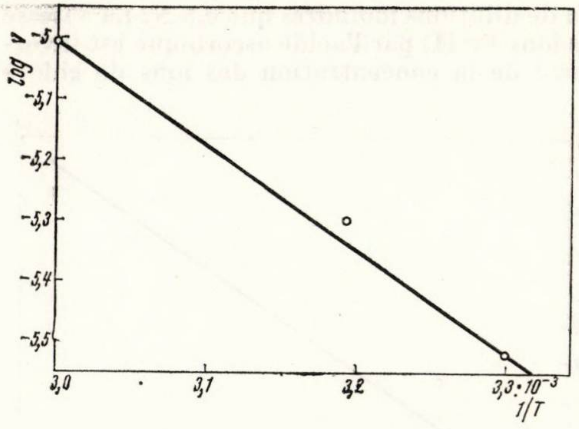

Fig. 13. — Variation de log V en fonction de 1/T.

VITESSE DE RÉACTION

Par l'interprétation des données expérimentales obtenues en étudiant l'influence des différents facteurs sur la vitesse de réduction des ions Pt(II) à l'état de Pt métallique à l'aide de l'acide ascorbique on est arrivé à l'expression suivante, caractérisant quantitativement la valeur v :

$$v = k\,[\mathrm{Pb}^{2+}]^2\,\frac{[\mathrm{Pt}^{2+}][\mathrm{Asc}]}{[\mathrm{H}^+]\,[\mathrm{Cl}^-]^2}\,e^{-\frac{E}{RT}} \qquad \text{(I)}$$

La valeur de k déterminée expérimentalement est de $1{,}78.10^{8}\,s^{-1}$.

L'expression (I) peut être utilisée au calcul de la vitesse de réaction, en connaissant les conditions initiales de travail. Le tableau 1 donne quelques données qui attestent la validité de l'expression établie par nous.

Tableau 1

Valeurs de la vitesse de réaction calculées à l'aide de l'expression (I) comparées à celles déterminées expérimentalement ($/Pt^{2+}/ = 14{,}6.10^{-3}$ M ; $/Asc/ = 29{,}2.10^{-3}$ M; $/Pb^{2+}/ = 0{,}75.10^{-3}$ M; $/H^+/ = 0{,}1$ M; $/Cl^-/ = 0{,}5$ M)

T °K	V mole/s calculée à l'aide de l'expression(I)	V mole/s déterminée expérimentalement
303	$0{,}31.10^{-5}$	$0{,}3.10^{-5}$
313	$0{,}47.10^{-5}$	$0{,}5.10^{-5}$
333	$1{,}02.10^{-5}$	$1{,}02.10^{-5}$

CONCLUSIONS

Les ions Pb(II) accélèrent la réaction de réduction des ions Pt(II) par acide ascorbique dans les limites de concentration $0-6{,}4.10^{-3}$ N.

Le mécanisme de la réaction n'a pas encore été élucidé, et continue à retenir notre attention.

L'étude effectuée par nous est applicable à la séparation du platine d'autres métaux précieux et à la détermination quantitative de celui-ci.

Received October 6, 1973

Potassium ferrate (VI) has been prepared by using the corresponding hypochlorite as an oxidizing agent and the corresponding hydroxide as a precipitation medium. By reprecipitations from alkaline solutions of KOH of various concentrations, the potassium ferrate (VI) may be purified. We have prepared the following salts containing ferrate (VI) ion and Ni(II) and Co(II) tetrapyridine — tetrapicoline complex combinations:

$NiPy_4[FeO_4]$; $CoPy_4[FeO_4]$; $Ni(\alpha\text{-pic})_4[FeO_4]$;

$Co(\alpha\text{-pic})_4[FeO_4]$; $Ni(\beta\text{-pic})_4[FeO_4]$; $Co(\beta\text{-pic})_4[FeO_4]$;

$Ni(\gamma\text{-pic})_4[FeO_4]$; $Co(\gamma\text{-pic})_4[FeO_4]$; $Ni(2,6L)_4[FeO_4]$

$Co(2,6L)_4[FeO_4]$ (L-Lutidine)

The infrared spectra of these compounds have been measured and reported.

INTRODUCTION

The preparation of potassium ferrate (VI) is well known.[1-4] The basis of all methods for its preparing is the oxidation of $Fe(OH)_3$ in a strong alkaline medium, the difference between methods consisting in the oxidizing agent utilized and in connection with this, the possibility of obtaining it with a high purity and a good yield.

Among the oxidizing agents, we mention: sodium hypochlorite[1], potassium hypochlorite[2], chlorine bubbled through a suspension of $Fe(OH)_3$ in alkaline medium[3], H_2O_2 in the presence of E.D.T.A. in an alkaline medium. Most of metal ferrates (VI) have been prepared by applying double exchange reactions between potassium ferrate (VI) and salts of different metals.

We prepared the ferrate (VI) ion salts with complex cations. Infrared spectra have been obtained both in potassium ferrate (VI) and complex ammines.

[3] B. Helferich and V. Lang, *Z. anorg. Chem.*, **263**, 169 (1950).
[4] F. R. Duke and T. W. Haas, *J. Phys. Chem.*, **65**, 304 (1961).

The data obtained are correlated with the existing ones given by Griffith[5], who studying the infrared spectra of the tetrahedral transition metal oxianions reports on the vibrational frequencies corresponding to $[FeO_4]^{2-}$ ion.

EXPERIMENTAL PROCEDURES

The method used for preparing potassium ferrate (VI) consists in the adaptation of the combined method of purifying and preparing the K_2FeO_4.[6]

This method reduces the losses and takes a short time for drying and washing off the compounds.

To obtain the ferrate (VI) ion salts with complex ammines of Ni(II) and Co(II) the corresponding Ni(II) and Co(II) tetrapyridine and tetrapicoline complexes have been prepared using the data from literature. The corresponding salts have been obtained by coupling these compounds with the ferrate (VI) ion.

The reagents used in this procedure were of high purity.

THE GENERAL PROCEDURE FOR PREPARING K_2FeO_4

0.3 mol Carbonate-free sodium hydroxide was added to 30 cm^3 distilled water. The resulting solution was cooled to 273 K with the help of a mixture of ice-sodium chloride.

By continuous stirring chlorine was slowly bubbled through this chilled solution. The chlorine was prepared in an auxiliary installation from $KMnO_4$ and concentrated HCl.

It is necessary to regulate the bubbling speed to a very small one, because an excess of chlorine would lead to a marked decomposition of the potassium ferrate obtained (VI). It is also necessary to regulate the temperature; a sharp rise is not permitted. This is maintained in the range 275 K — 279 K. The operation of chlorination lasts for about 40—45 min. The solution obtained was then made strongly basic by adding 0.9—1.0 mol of solid natrium hydroxide.

While the solution was constantly stirred, the temperature was allowed to rise up to 290 K when the hydroxide was added. The whole mixture was cooled in an ice-sodium chloride bath. After cooling, the precipitated alkali metal chloride was removed by filtration. The solution obtained was again introduced in the ice bath where it was kept for a period of 1/2 h.

After this, 13.5 mmol of pulverized nonahydrated ferric nitrate were added very slowly with continuous stirring. This operation must be performed very slowly, the necessary time was a period of 30—45 min. The temperature must be maintained at about 298 K ± 2 K.

The mixture obtained is rapidly filtered through a filter crucible (G_3 type) with the aid of a vacuum oil pump. In the resulting solutions, some solid potassium hydroxide was added by continuous stirring and maintaining the temperature below 300 K. The potassium ferrate (VI) was precipitated in the solution and recovered by rapid filtration through a filter crucible. The filtration was made with the aid of the same vacuum oil pump. The precipitated potassium ferrate (VI) was purified by dissolving and reprecipitating it in several solutions of potassium hydroxide. The dissolution took place in solutions of KOH 3M, and the reprecipitations in KOH 5M, KOH 6M solutions and saturated solution.

[5] W. P. GRIFFITH, *J. Chem. Soc.*, **1966**, 1467.

[6] G. W. THOMPSON, L. T. OCKERMAN and J. M. SCHREYER, *J. Amer. Chem. Soc.*, **73**, 1379 (1951).

The precipitation that has remained was washed on the filter with three 10 cm^3 portions of dry benzene in order to remove the water in excess and then washed with four 15 cm^3 portions of anhydrous ether. The ferrate (VI) sample was stored in a vacuum dessiccator to prevent a slow decomposition due to the traces of water. The results of the analyses using the method of total iron [7] gave good yield of K_2FeO_4.

With view to obtaining the salts containing the ferrate (VI) ion with complex ammines of nickel (II) and cobalt (II) the corresponding Ni(II) and Co(II) tetrapyridine and tetrapicoline compounds [8-10] have been prepared.

To prevent the loss of pyridine, picoline and lutidine, the compounds were maintained in a special container under pyridine α,-β-, γ-picoline and α-lutidine.

The following complex combinations have been prepared in this way :

$NiPy_4(SCH)_2$; $CoPy_4(SCN)_2$; $Ni(\alpha\text{-pic})_4Cl_2$;

$Co(\alpha\text{-pic})_4Cl_2$; $Ni(\beta\text{-pic})_4Cl_2$; $Co(\beta\text{-pic})_4Cl_2$;

$Ni(\gamma\text{-pic})_4Cl_2$; $Co(\gamma\text{-pic})_4(SCN)_2$; $Ni(\alpha\text{-lut})_4Cl_2$; $Co(\alpha\text{-lut})_4Cl_2$

These compounds have been analyzed : metal, halide and nitrogen have been determined. The results obtained correspond to the calculated data.

The procedure to obtain salts of ferrate (VI) ion with Ni(II) and Co(II) tetrapyridine and tetrapicoline complex compounds is explained below.

The tests containing 0.02 freshly prepared K_2FeO_4 which was previously dissolved in 5 cm^3 distilled water have been put in contact with the tests containing 0.03 mol tetrapyridine and tetrapicoline compounds. The potassium ferrate (VI) solution was previously kept in an ice-sodium chloride bath.

The ferrate (VI) ion salts containing Ni(II) and Co(II) complex ammines have been precipitated.
(The tetrapyridine compounds are dissolved in $CHCl_3$ and the tetrapicoline and tetralutidine compounds in dimethylformamide). All the operations were rapidly performed to prevent a possible decomposition of potassium ferrate (VI) with the formation of $Fe(OH)_3$. The resulting

[8] P. Moore and R. G. Vilkins, *J. Chem. Soc.*, **1964**, 3454.

[9] A. Logan and V. Carle, *J. Amer. Chem. Soc.*, **74**, 5224 (1952).

[10] A. Sinha, *J. Indian Chem. Soc.*, **32**, 414 (1952).

compound was rapidly filtered and dried by washing it with two 10 cm^3 portions of dry benzene in order to remove the excess water and then washed with three 10 cm^3 portions of anhydrous ether.

The same procedure was applied in all the cases. The following salts have been prepared:

$NiPy_4[FeO_4]$; $CoPy_4[FeO_4]$; $Ni(\alpha\text{-pic})_4[FeO_4]$;

$Co(\alpha\text{-pic})_4[FeO_4]$; $Ni(\beta\text{-pic})_4[FeO_4]$; $Co(\beta\text{-pic})_4[FeO_4]$

$Ni(\gamma\text{-pic})_4[FeO_4]$; $Co(\gamma\text{-pic})_4[FeO_4]$; $Ni(\alpha\text{-L})_4[FeO_4]$;

$Co(\alpha\text{-L})_4[FeO_4]$;

These compounds have been analyzed; iron, cobalt, nickel, nitrogen, carbon and hydrogen have been determined. The results obtained are shown in table 1.

For the determination of both cobalt and iron a complexonometric method was applied, using complexon III as complexing agent and salicilic acid as indicator [11].

The infrared spectra of the ferrate (VI) ion salts with Ni(II) and Co(II) complex ammines have been taken using a U.R − 10 Zeiss−Yena spectrometer with the method of diluted samples in KBr disks.

RESULTS AND DISCUSSION

We were able to obtain potassium ferrate (VI) of a purity range from 80−85%, by adapting the combined method of preparing and purifying K_2FeO_4 indicated by Thompson. [2]

We must mention some modifications brought to the procedure already existing in literature.

Thus, the decrease of chlorine bubbling speed through the alkaline solutions, combined with an extension of a chlorination time, led to a decomposition speed decrease of potassium ferrate (VI) which was formed in a previous stage.

All the operations were rapidly conducted and all the filtrations were made by means of a vacuum oil pump. In this way the necessary time for filtration decreased and in conclusion the decompositions existing on the walls of the filtration funnel were diminished. By treating the solution containing the ferrate (VI) ion with solid potassium hydroxide, K_2FeO_4 precipitated immediately. Using for the dissolving and reprecipitating procedure, KOH solutions of rising basicity, the losses in K_2FeO_4 were very much reduced.

Using only benzene and anhydrous ether for drying K_2FeO_4 the decomposition possibilities of the potassium ferrate (VI) are reduced.

Those elements would appear when the drying with different alcohols is used (as an effect of oxidizing reactions due to the high oxidation power of K_2FeO_4).

Although the tetrahedral oxianions belonging to nonmetals as ligands in complex combinations have been studied, the oxianions of transitional metals have not been sufficiently studied yet.

This fact is partly due to the possible existence of some oxidizing reactions or of those of precipitate formation in such cases.

Our results regarding the production of some ferrate (VI) ion salts with complex ammines of Ni(II) and Co(II) must be noted.These resulting salts are the first of this class; no other data have been previously reported in literature.

For these salts containing ferrate (VI) ion and complex ammines of Ni(II) and Co(II) studies of infrared spectra have been made. For comparison the infrared spectrum of potassium ferrate (VI) and the infrared spectra of tetrapyridine, tetrapicoline and tetralutidine compounds of Ni(II) and Co(II) have been recorded.

In the case of ferrate (VI) ion [5] the positions of ν_1, ν_3, ν_4, frequencies are 778 cm^{-1}, 800 cm^{-1}, 320 cm^{-1}, and the ratio $\nu_1/\nu_3 = 0.98$.

The frequency ν_2 is not observed and can often coincide with ν_4, or it is not recorded if having a too small intensity. It has to be remarked for the ferrate (VI) ion and transitional metal oxianions too, that the site symmetry is lower than T_d and is closer to C_s[12], as a result, ν_3 would appear in infrared as a triplet ($2A' + A''$) and ν_1 as a singlet (A'). Concerning the ferrate (VI) ion, ν_3 does not appear as a triplet but reported as a singlet at 810 cm^{-1} with a small shoulder at 835 cm^{-1} in good agreement with the recent studies made by Audette. [13]

These characteristic bands corresponding to ferrate (VI) ion have also been found among the bands corresponding to the salts containing ferrate (VI) ion. It has been established that it is possible to record the displacements from the characteristic bands in the case of ferrate (VI) ion when this ion is coupled with complex ammines of Ni(II) and Co(II). The results obtained are shown in table 2.

Table 2

[12] P. Tarte and G. Nizet, *Spectrochim. Acta*, **20**, 503 (1964).

[13] R. J. Audette and J. W. Quail, *Inorg. Chem.*, **11**, 1904 (1972).

The contribution made by the Ni(II) and Co(II) tetrapyridine and tetrapicoline complex combinations to the infrared spectra aspect must be discussed.

It is also remarked that in the case of the salts containing ferrate (VI) ion coupled with complex combinations, of Ni(II) and Co(II) the characteristic bands for these complexes have been found.

On the basis of the resulting data, in good agreement with the studies made by Allan[14] for the coordination compounds of pyridine and picoline with transitional metals, it is concluded that the vibrational frequencies of substituted pyridine and picoline do not change significantly when these are coordinated with the metals, so that, the infrared spectra of pyridine and substituted pyridine show a great similarity with the free ligand. Due to the lattice effects or because of the departures from the ideal symmetry, some shifts are split in the complex combination spectrum. The characteristic bands of the pyridine spectrum have been found with small deviations in the complex compound spectra.

The same aspect of the spectrum, common to pyridine, substituted pyridine and tetrapiridine, tetrapicoline and tetralutidine compounds of Ni(II) and Co(II) have been found in the infrared spectra corresponding to the salts of ferrate (VI) ion with the same complex compounds.

The fact that the characteristic frequencies for the $[FeO_4]^{2-}$ ion and for the complex compounds too, are found in the spectrum corresponding to the salts containing ferrate (VI) ion and complex combinations of Ni(II) and Co(II) (the salt's spectrum being a sum of these two spectra) gave us the possibility to characterize the band $[FeO_4]^{2-} - M(Ln)_4$ as a band of a preponderant ionic character.

CONCLUSIONS

Potassium ferrate (VI) has been prepared with good yield by adapting a method previously existing in literature, which underwent some modifications. With the help of the resulting potassium ferrate (VI), ten new salts containing ferrate (VI) ion with tetrapyridine and tetrapicoline complex compounds of Ni(II) and Co(II) have been prepared. The literature has not reported the data referring to the obtention of the salts of ferrate (VI) ion. The salts prepared by us are the first of this kind.

The infrared spectra have been taken and reported.

CHEMICAL GRAPHS. XXIII[1]

GENERAL CUBIC GRAPHS WITH ONE LOOP, AND HOMOVALENES OR THEIR DERIVATIVES

ALEXANDRU T. BALABAN

Institute of Atomic Physics, P.O.B. 35, Bucharest, Romania

(*Received May 28 1974*)

A table of planar general cubic graphs with one loop and 4, 6, 8, or 10 points is presented. It contains all possible classical constitutional isomers of homovalenes, homovalenones and their ions, or of π-excessive heterocycles with one heteroatom, the total number of points in their reduced structural graphs being 3, 5, 7 or 9 (one point of degree two, the remaining ones of degree three). The table for 11 points is available on request. Examples of such chemical systems are given.

1. INTRODUCTION

The structural theory of organic chemistry can be applied simply to acyclic structures. Therefore, it is taught without the mathematical counterpart of graph theory. The numbers of constitutional isomers of acyclic structures can be found by algorithms which are so simple that any undergraduate is supposed to be able to cope with them. Recently they have been formalized and translated into computer programs.[2]

On the other hand, cyclic structures are much less prone to simple intuitive approaches, as can be observed by trying to find all isomers of quite simple systems such as C_4H_4O or C_5H_8.[3] The general problem is rather difficult [3] and only recently was an analogous computer program devised for this scope.[4]

We tried to apply graph theory to some problems of cyclic structures. In particular, we defined valence-isomerism on graph-theoretical bases,[1,5] and enumerated [*n*]valenes (valence isomers of [*n*]annulenes).*

---

* For short, valence isomers of [*n*]annulenes will be henceforth called [*n*]valenes. The definitions of valence isomerism and reduced structural graphs may be found in ref.[1]. Homovalenes have an extra CH_2 group.

Cubic (trivalent) multigraphs are regular graphs where every point (vertex) has degree three. They represent reduced structural graphs of [*n*]valenes.

General graphs can have not only multiple bonds (i.e. circuits with two points) but also loops (i.e. circuits with one point). In a previous paper,[6] an algorithm for the stepwise construction of general cubic graphs was devised, and drawings of the general cubic graphs with $p = 2, 4, 6, 8,$ and 10 points were provided. It was pointed out that by replacing a point joined to one loop by a point of degree two, the general cubic graph of order p is converted into a graph with $p-2$ points of degree three and one point of degree two which may represent a structural reduced graph for valence isomers of heterocycles like oxepine or furan, of carbenium ions $(CH)_{p-1}^{\oplus}$ like tropylium or cyclopentadienylium, of homovalenes like tropylidene or cyclopentadiene, of homovalenones like tropone or cyclopentadienone, etc. In the previous paper, formulas for such systems with 5 and 7 points (carbon atoms or heteroatoms) were presented,[6] including both planar and non-planar graphs (here, planarity is a topological, not geometrical, concept).

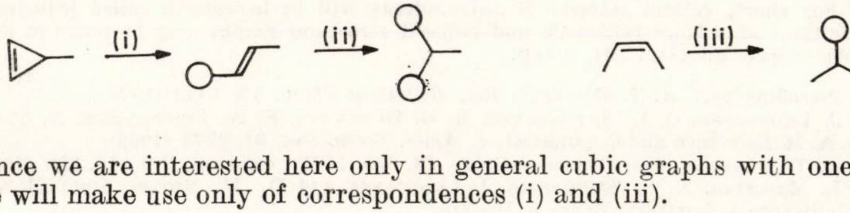
The tremendous developments of the last years in this field prompted us to expand in the present paper these tables to include systems with 3—11 points. Throughout this paper we will deal only with connected general cubic graphs with one loop. In order to restrict the number of graphs only to those which may have chemical counterparts, non-planar graphs will be omitted.

2. GENERAL CUBIC GRAPHS WITH ONE LOOP

There are at least four procedures for obtaining all possible general cubic graphs with one loop and p points.

1) The first consists in the algorithm mentioned above, which consists in taking general cubic graphs of order $p-2$ and in applying for each of these the following procedure : on each line or pair of lines mark two new points and join these points by a new line.

2) The second procedure relies on the preceding one, which gives the possibility of obtaining by recurrence the table of cubic multigraphs. If the table of cubic multigraphs with p points is available, then the table of general cubic graphs may be obtained by the following correspondences[6] :



Since we are interested here only in general cubic graphs with one loop, we will make use only of correspondences (i) and (iii).

---

[6] A. T. Balaban, *Rev. Roumaine Chim.*, **15**, 463 (1970).

Expressed in words, these correspondences consist in replacing a double bond by a point joined to a loop. In this process, the number of double bonds is reduced by one (excepting the case of cyclopropenyl rings), and if the double bond is endocyclic the ring size is reduced by one.

The numbers of planar cubic multigraphs are presented in table 1.[6-8] By the above correspondences, those graphs with $\beta \geqslant 1$ will be converted into general cubic graphs with one loop. However, because of correspondence (i), the numbers of general cubic graphs with one loop and $\beta = 0$ will not be equal to those of planar cubic mutigraphs with $\beta = 1$. The numbers of planar general cubic graphs with one loop may be seen in table 2.

Table 1

Planar cubic multigraphs with n points and β double bonds

n \ β	0	1	2	3	4	5	6	Total
4	1	0	1	—	—	—	—	2
6	1	1	2	1	—	—	—	5
8	3	4	5	4	1	—	—	17
10	9	16	22	16	7	1	—	71
12	32	75	112	86	41	10	1	357

Table 2

Planar general cubic graphs with one loop [a]

$p-1$ \ β	0	1	2	3	4	5	Total
3	0	1	—	—	—	—	1
5	1	1	2	—	—	—	4
7	3	6	6	3	—	—	18
9	13	29	32	18	4	—	96
11	62	164	201	126	44	5	502

[a] Table 3 presents the graphs with $p-1 = 3, 5, 7$, and 9 from the present table.

13) Also relying on the table of cubic multigraphs, but with $p-2$ points, there is the following procedure for obtaining the general cubic graphs with p points and one loop : mark on each non-equivalent line a new point and join it to a loop.

4) There is a one-to-one correspondence between general cubic graphs with p points and one loop, and irregular graphs with $p-2$ points of degree three and one point of degree two. In fact, this is how the table of the latter graphs was compiled for $p = 2$ and 4.[3] If the table of the latter graphs is available, this constitutes a fourth approach to the solution of the problem.

For our purpose all four approaches may be useful. For $n = 4-10$, all-approaches give consistent results.

The tables of ref. [6] obtained by the first procedure can be applied directly for $p = 2$, 4, 6, 8, and 10. We will check the results by the fourth procedure [3] for $p = 2$ and 4, and by the second procedure[7] for all p values given above. In addition, the second procedure enables us to compile the table for $p = 12$.[8]

In table 3 the results are presented as a table of irregular graphs with $p-2$ points of degree three and one point of degree two as in the

fourth procedure, but it will be understood that this is a simplification of the drawing and that we use the convention that the point of degree two should be imagined as joined to a loop. Accordingly, we will use the notation of the corresponding general cubic graphs.

The notation consists in a string of numbers, giving in order :

— p, the number of points in the general cubic graph with one loop : according to the convention of the preceding paragraph all graphs have in fact $p-1$ points.

— λ, the number of loops (circuits with one point) : in the present paper, this number will be always 1.

— β, the number of double bonds (circuits with two points).

— t, the number of triangles (circuits with three points).

— q, the number of quadrilaterals (circuits with four points).

— s, a serial number, which is 1 unless two or more graphs have the same values for all preceding numbers, when s discriminates among them. In order to make the assignment of s values non-arbitrary, a set of precedence rules * were recently devised :[5,9]

1) The discrimination is to made on the basis of increasing numbers of 5-, 6-, 7-circuits, etc.

There exist algorithms for finding out the number of r-membered rings in a graphs.[10-18] Visually this is easy for $r = 3$ and 4, and increasingly more difficult for $r = 5$, 6, 7 etc. Since, however, in the present paper the determination of the number of larger rings ($r \geqslant 6$) was necessary only occasionally, this was possible without using these algorithms. One can, however, concede that for $p > 12$ their use will be mandatory for this notation system.

2) When the preceding criterion fails, (i.e. for graphs which have the same set of rings) those graphs have precedence when they have the loops attached to :

— exocyclic points over those attached to rings (e.g. I—II, III—IV).

— smaller rings, over those attached to large rings (e.g. V and VI).

---

* In earlier papers,[3 6,8] these rules were not applied.

Table 3 contains graphs with $p - 1 = 3$, 5, 7 and 9 points (one of which has degree two since it is imagined to be joined to a loop, and the remaining ones have degree three) with their notations. They are presented as function of p and β, and are arranged in the alphanumerical order of their notations. The table with the 502 graphs with $p-1 = 11$ points is available on request.

3. CHEMICAL COUNTERPARTS

The point of degree two can be a CH_2, CO, $CR^{\oplus}$, $CR^{\ominus}$ group or a heteroatom. A fascinating chemistry is presented by the carbenium ions [19] $(CH)_n^{\oplus}$ with odd n, owing to the readiness with which they rearrange (some of them presenting degenerate rearrangements), and to the unusual structures of some of these ions. The chemistry of these ions was reviewed.[19-21]

Three-membered systems. Only one valence isomer is possible and is illustrated by cyclopropene as a homovalene, cyclopropenone as a homovalenone, or cyclopropenylium as a homovalenium ion. Corresponding heterocycles (acetylene-oxide) are expected to be unstable because of their antiaromaticity.

Five-membered systems. In addition to the examples presented in the previous paper,[6] the photochemical valence isomerization of five-membered heterocycles 6–1–2–0–0–1 involving cyclopropene derivatives 6–1–2–1–0–1 was reviewed, [22] e.g. 2,5-disubstituted furans rearrange photochemically to 2,4-disubstituted furans.[23] A di-π-methane rearrangement[24] would convert 6–1–2–0–0–1 into 6–1–1–1–1–1.

It should be emphasized that table 3 presents only "classical" structures. The structure of the $(CH)_5^{\oplus}$ cation was predicted theoretically by Stohrer and Hoffmann [25] to be, however, reminiscent of pentaborane (tetragonal pyramid XIII) rather than any of the classical structures XIV–XVII. This unusual structure XIII for electron-deficient compounds is calculated to have lower energy than "classical" structures XIV–XVI. This prediction was confirmed both experimentally[26] and theoretically using different methods for the calculation of energies[27,28] (no calculation has, however, estimated the energy of the vinylic cation XVII, which was also omitted in other reviews[21]).

Seven-membered systems. Leone and Schleyer[21] discussed the following $C_7H_7^{\oplus}$ cations : 8–1–0–1–3–1, 8–1–0–2–1–1, 8–1–2–0–0–1, 8–1–2–0–1–1, and 8–1–3–0–0–1.

The thermal valence isomerization of cycloheptatriene–norcaradiene was discussed at length in Maier's monograph,[20] which also includes heterocyclic analogues such as azepine–benzenimine,[29] or diazepine–diazanorcaradiene.[30]

Graphs from table 3 may also be useful in rationalizing the carbon scrambling on electron impact in C_7H_8, C_5H_6, or their heterocyclic congeners.[31] Meyerson's original observation on the appearance of tropylium in mass spectra of benzyl derivatives [32] was subsequently substantiated

by many additional data,[33] but the mechanism of the scrambling is not yet clear.[34]

Photochemical rearrangements of various C_7H_8 derivatives[35] were investigated.

The valence isomers of the unusually stable carbene resulted by loss of a proton from tropylium are not to be found in table 3 because some of these valence isomers have quaternary carbons corresponding to points of degree four.[36]

Nine-membered systems. In Leone and Schleyer's review[21] the following $C_9H_9^{\oplus}$ cations were discussed: 10−1−0−0−4−1, 10−1−0−2−5−1, 10−1−2−0−0−1, 10−1−2−1−0−1, 10−1−3−0−0−1, 10−1−3−0−0−2, 10−1−3−0−0−3, and 10−1−4−0−0−1. Some newer data on these cations exist.[37−39] Heterocyclic analogues (heteronins and their valence isomers) were reviewed by Anastassiou.[40] Valence isomers of C_9H_{10} hydrocarbons or their derivatives (e.g. barbaralene, deltacyclane, barbaralone were reviewed by Maier,[20] and some newer references follow.[41−43] Photochemical and catalytical interconversions (by transition metal ions, or by acids) between systems 10−1−2−0−2−1, 10−1−1−2−2−1 and 10−1−0−0−4−1 are known.[44]

Goldstein and Hoffmann's predicted bicycloaromaticity[45] in bicyclic delocalized systems caused by frontal overlap of π-orbitals was experimentally confirmed by the stabilization of an anion[46] corresponding to graph 10−1−3−0−0−1.

Eleven-membered systems. The same incentive, experimental proof for bicycloaromaticity, led **Goldstein** to prepare and protonate several ketones $C_{11}H_{10}O$ (XVIII–XX).[47]

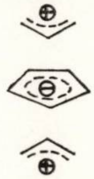
XVIII XIX XX



XXI

The stability of several cations $C_{11}H_{11}^{\oplus}$ is in agreement with theoretical predictions.[48] However, one isomer of $C_{11}H_{11}$ was found to present an unexpected NMR spectrum which could be interpreted [48] as an "organic sandwich complex" XXI. Hydrocarbons $C_{11}H_{12}$ are also known.[49]

Larger systems. Annulenones with 13,[50] or more, carbon atoms were prepared.[51] Little is yet known, however, about their valence isomers or the corresponding hydrocarbons.

THE PROTONATION EQUILIBRIA AND INDICATOR BEHAVIOUR OF E-1,3-DIMETHYL-6-(*p*-X-β-STYRYL)-2,4-DIOXO-1H, 3H-1,3,5-TRIAZINES IN 50 VOL% AQUEOUS-ETHANOLIC SOLUTIONS IN THE PRESENCE OF SULPHURIC ACID

M. SAFTA and G. OSTROGOVICH

Laboratory of Organic Chemistry, Polytechnic Institute, Timişoara,
str. Bocşa 6, Romania

Received December 21, 1973

The pK_a values and the H'_0 acidity function scale were determined by the UV- and Vis.-spectrophotometric method, for the compounds and the solvent-system, specified in the title. The determinations were performed with a satisfactory accuracy due to the fact that at a H_2SO_4 concentration higher than the minimum value necessary for the complete protonation of the indicators, there exists a linear relationship with a finite slope between $C_{H_2SO_4}$ and the medium effect. This fact allows the determination of the log $C_{BH^{\oplus}}/C_B$ value by the complete protonation. It is to be observed that the scale of the function H'_0 of these systems is practically identical with that of the azo-compounds, in the same media containing $HClO_4$, and therefore coincident with the scale of the function H_0 of the nitroaniline standards. This fact proves that the β-styryl-s-triazine compounds have a typical Hammett base behaviour.

In a previous paper [2] we studied qualitatively by the spectrophotometric method in the ultraviolet and visible region the protonation of the fundamental unmethylated compounds. These precursor compounds were insufficiently soluble even in neutral or acidic 50% vol. aqueous-ethanol medium, a feature which made impossible the exact determination of their basicity and also the quantitative characterization of their behaviour as indicators.

For this purpose (as well as for a study concerning the activity of the methyl group from the mother compound, 6-methyl-2,4-dioxo-1H,

---

*) Part XIV[1]. A lack of attention caused several older papers from this series not to be numbered in their order of publication. This fact determined an error of numbering which affects three of the published notes, even those by the present authors. Thus, the paper published by us as the IVth in *Rev. Roumaine Chim.*, **15**, 799 (1970), is actually the Vth since number IV belongs in fact, to the work which appears in *Tetrahedron* **24**, 2701 (1968) (authors G. Ostrogovich, R. Bacaloglu and Elwine Fliegl). Similarly, the order numbers of the papers published by us in *Rev. Roumaine Chim.*, **17**, 2043 and 2055 (1972) as the Vth and the VIth are, in fact, the XIth and the XIIth.

[1] Part XIV., M. Safta and G. Ostrogovich, *Bul. St. Tehn. Inst. Politeh. Timişoara, Ser. chim.*, (1974), under press.

[2] G. Ostrogovich and M. Safta, *Rev. Roumaine Chim.*, **15**, 799 (1970).

3H-1, 3, 5-triazine and their N-mono-, di- and trimethylated compounds[3]) we have synthetized the 1,3-dimethylated analogous,[4] which are the subject of this paper and which, of course, are more soluble in 50% vol. aqueous ethanol.

The present paper gives the basicity measurements which were performed on these compounds, as entirely analogous substances with the initial ones, from which they differ only by the aprotic character of the *s*-triazinic part of the molecule. Since the basicity of these substances is relatively weak, the characterization of their indicator behaviour imposed an extension of the spectrophotometric studies on some more acidic solutions and, therefore, the determination of the H_0 function after the method of Hammett-Deyrup,[5] in medium conditions, which are also revealed by the title.

Although the actual literature data offer many examples for the determination of some H_0 functions in alcoholic or aqueous-alcoholic solutions,[6,7] we have found only a single case in which the authors used as a solvent a 50% volume aqueous-ethanol. We refer to the works of Vetesnik *et al.*,[8] who studied from this point of view a series of 2-hydroxy-azobenzenic indicators (besides the 2- and 4-nitroaniline) but towards perchloric acid. They found, in accordance with the literature data of Jaffé *et al.*[9,10] concerning some aromatic azo-derivatives in aqueous-ethanol 20% vol. as compared to H_2SO_4, that all the studied compounds, and all the primary nitranilinic standards in the same solvent present a satisfactory parallelism of the dependence log $C_{BH\oplus}/C_B$ *versus* $C_{H_2SO_4}$.

It is known that the verification of this parallelism represents the primordial condition for the construction of any function of acidity H_0, that is for the anchorage of the determined function in the case of a given organic substratum to the $pK_{BH^\oplus}$ value of the primary nitranilinic standard (which was determined at well defined values of pH in the same solvent).

For underlining the character of the Hammett bases (H_0 indicators) of the azoic compounds and at the same time the fact that the determinations were performed in aqueous-alcoholic solvents, the above mentioned authors have denoted the functions thus obtained with the symbol H_0', a notation which, as will be seen in the following, is justified in the case of our compounds too.

The protolytic equilibrium, for which we have determined the $pK'_{BH^\oplus}$ values and the acidity function H_0' in ~50% vol. aqueous ethanolic media with H_2SO_4, is the following :

I_B $I_{BH^\oplus}$

The applicability of the Hammett equation (1) concerning the determination of pK values by the spectrophotometric method

$$\mathrm{pK} = H_0 + \log \frac{C_{BH^\oplus}}{C_B} = H_0 + \log \frac{\varepsilon - \varepsilon_B}{\varepsilon_{BH^\oplus} - \varepsilon} \qquad (1)$$

was connected to the properties of the indicator substratum, that is by the following conditions :

1) It must be a suitable region of the spectrum in which the absorbances of the B and $BH^\oplus$ species are different enough.

2) Their absorbance curves must be independent of the concentration of the mineral acid in the medium.

As the first of these requirements is satisfactorily achieved in most cases, it is known that the latter condition is seldom completely achieved, especially when the $BH^\oplus$ species exhibits a high intensity band.[11-12]

In several cases, for a small lateral displacement of this band, it was proved the possibility to perform some corrections.[13,14] Several methods for the determination of the $\lambda_{BH^\oplus}$ and $\varepsilon_{BH^\oplus}$ values[12-22] were proposed, but a few number of these ones solved the problem of the medium effects which implied not only a lateral displacement of the main band $BH^\oplus$, but also a more or less pronounced shift in the intensity of the $\varepsilon_{max.BH^\oplus}$ values parallel with the increasing of the mineral acid concentrations.[20-22]

RESULTS AND DISCUSSIONS

a) THE DETERMINATION OF THE $\lambda_{BH^{\oplus}}$, $\varepsilon_{BH^{\oplus}}$ AND $C_{BH^{\oplus}}/C_B$ VALUES

As seen from fig. 1 concerning the particular case of the I_{4B} compound (see table 1) the protonation of the bases of type I is associated with a strong medium effect (as a function of sulphuric acid concentration) with a very considerable lateral shift and a simultaneously increasing of the intensity of their conjugated acid $I_{4BH^{\oplus}}$ band.

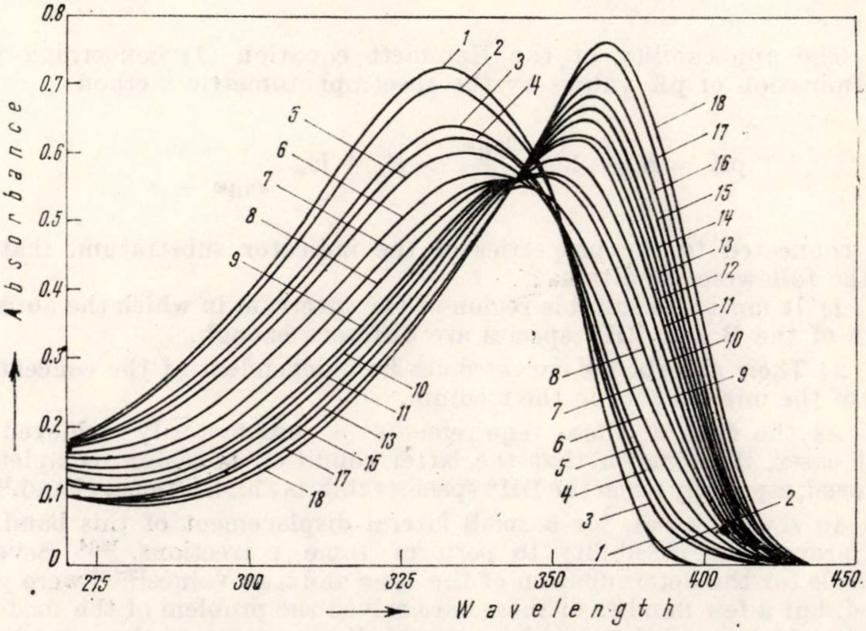

Fig. 1. – The changes of the spectra for compound $I_{4B}{}^{\oplus}$ and $I_{4BH}{}^{\oplus}$(see table 1) as a function of $C_{H_2SO_4}$ in a 50 % vol. aqueous-ethanol ($C_{I_{4B}} = 2.5.10^{-5}$ molar, cell width 1 cm) :

Curve N°	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18
$C_{H_2SO_4}$ (val/l)	0	0.1	0.5	0.8	1.0	1.5	2.0	2.5	3.0	3.5	4.0	5.0	6.0	7.0	8.0	9.0	10	12.0 N

Consequently, for achieving the correct values of the $\lambda_{BH^{\oplus}}$ and $\varepsilon_{BH^{\oplus}}$ we used the Haldna method[20] which involves the plotting of the dependence $\varepsilon_{max.BH^{\oplus}} = f(C_{acid})$ not only in the limit of the titration curve but also in the range of the concentrations higher than the minimum value for the complete protonation. This makes possible the determination of the last one due to the fact that at this value the sinusoidal titration curve becomes linear with a finite slope. This fact allows to find the point indicating the beginning of the linear dependence and consequently to choose – from the extinction curves which were successively recorded at much higher concentration – the curve, which characterizes the $BH^{\oplus}$ species at the moment at which the B species disappear.

From the equation (1) it is evident that the most exact determination of the $C_{BH^{\oplus}}/C_B$ ratio can be achieved in the wavelength region in which the difference between $\varepsilon_{BH^{\oplus}}$ and ε_B is maximum. From fig. 1 results that in the respective particular case, this region is centered around $\lambda = 380$ nm, even bigger than $\lambda_{max.}$ of the most intensive band which we have recorded for the conjugated acid $I_{4BH^{\oplus}}$ at a value $C_{H_2SO_4} = 12$ N.

Fig. 2 presents, for the same particular case as fig. 1, the graphic aspect of the above mentioned procedure after Haldna (l.c.) that is the variation of the absorbance as a function of $C_{H_2SO_4}$ at 380 nm.

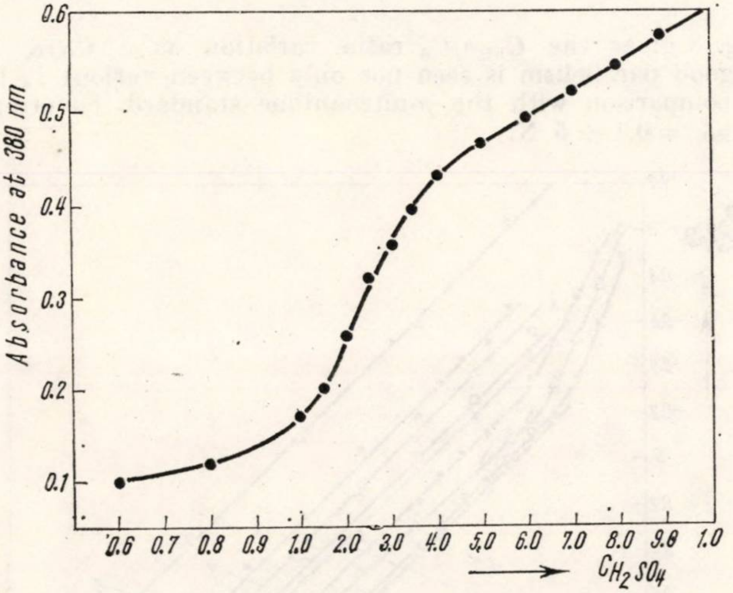

Fig. 2. – The titration curve of the base I_{4B} at 380 nm in a 50% vol. aqueous-ethanol ($C_{I_{4B}} = 2.5 \cdot 10^{-5}$ molar, cell width 1 cm).

It may be observed that the linearization of the curve begins at the moment when the H_2SO_4 concentration becomes 4N, that is, beginning with curve N° 11 from fig. 1. The accurate analysis of the phenomena and the relations performed by Haldna outline that the linearization is not other than the expression of a monotonous variation in the hydrated state of the $BH^{\oplus}$ species.

b) THE DETERMINATION OF THE pKa VALUES AND OF THE H_0' SCALE

The previous determinations with informative purposes have shown that the indicator with the most close basicity to our compounds is *p*-nitroaniline (*p*—NA) which therefore we choose as a reference indicator. The pKa value of their conjugated acid in a 50% vol. aqueous-ethanol was determined by Vetesnik [23] which found $pK_{(p-NA)} = +0.239$ at 20°C.

The estimation of the $(pK_{BH^+})_{I_n}$ values is based on the equation :

$$(pK_{BH^+})_{p-NA} - (pK_{BH^+})_{I_n} = \log\left(\frac{C_{BH^+}}{C_B}\right)_{p-NA} - \log\left(\frac{C_{BH^+}}{C_B}\right)_{I_n} + \log\left(\frac{f_B}{f_{BH^+}}\right)_{I_n}\left(\frac{f_{BH^+}}{f_B}\right)_{p-NA} \quad (2)$$

Fig. 3 gives the $C_{BH^\oplus}/C_B$ ratio variation as a $C_{H_2SO_4}$ function. A very good parallelism is seen not only between various I_n bases but also in comparison with the *p*-nitroaniline standard, covering all the field $C_{H_2SO_4} = 0.1 \div 5$ N.

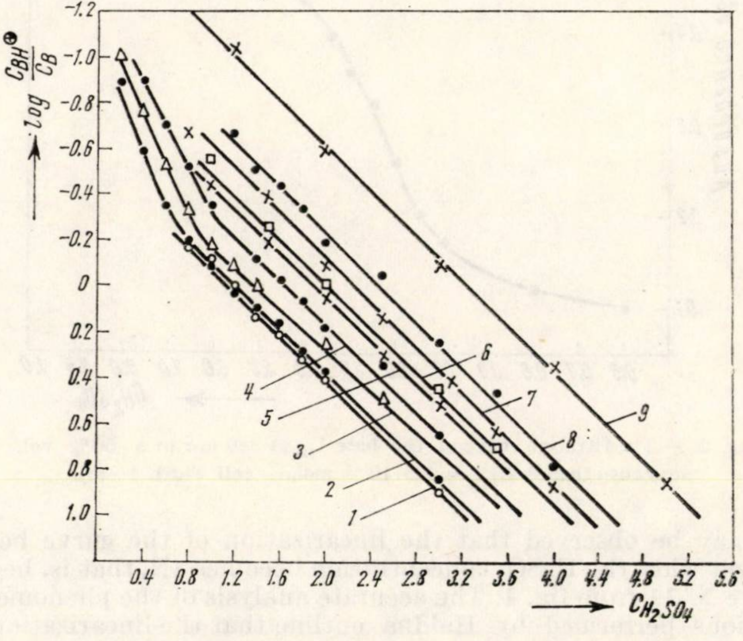

Fig. 3.— The functions log $(C_{BH^\oplus})/C_B$ *versus* $C_{H_2SO_4}$ for variously indicators I_n and for the *p*-NA standard :

Straight	1	2	3	4	5	6	7	8	9
X	*p*-OH	Standard	*p*-OCH_3	*m,p*-O-CH_2-O-	*p*-CH_3	*p*-$CH(CH_3)_2$	*p*-H	*p*-Cl	*p*$\overset{\oplus}{N}Me_3$

---

[23] P. Vetesnik, private communication.

Because this aspect denotes that both species B and $BH^{\oplus}$ possess the same activity coefficients it is right to consider that the latter term of the second member of the equation (2) is zero. Therefore the equation which can be used for the calculation is:

$$(pK_{BH^+})_{p-NA} - (pK_{BH^+})_{I_n} = \log\left(\frac{C_{BH^+}}{C_B}\right)_{p-NA} - \log\left(\frac{C_{BH^+}}{C_B}\right)_{I_n} \cdot \quad (3)$$

The $(pK_{BH^+})_{I_n}$ values calculated in this way are presented in table 1. Introducing these values in equation (1) the $(H'_0)_{I_n}$ values are obtained (see table 2).

Table 1

c) COMPARISON OF THE $(H'_0)_{I_n}$ SCALE WITH OTHER H'_0 SCALES IN AQUEOUS-ETHANOLIC SOLUTIONS AND WITH $(H_0)_{NA}$ SCALES

Fig. 4 presents this comparison for the indicators type and for the media noticed in the same plotting.

As can be observed, the $(H'_0)_{I_n}$ scale of our compounds in the 50% vol. aqueous-ethanolic with H_2SO_4 media coincides practically excellently with Vetesnik's *et al.* scale [8] for the azocompounds, which is performed in the same solvent but with $HClO_4$. It is well known that up to a high limit of the acidity, the sulphuric- and perchloric acid power is practically identical. [6] On the other hand, this coincidence denotes that

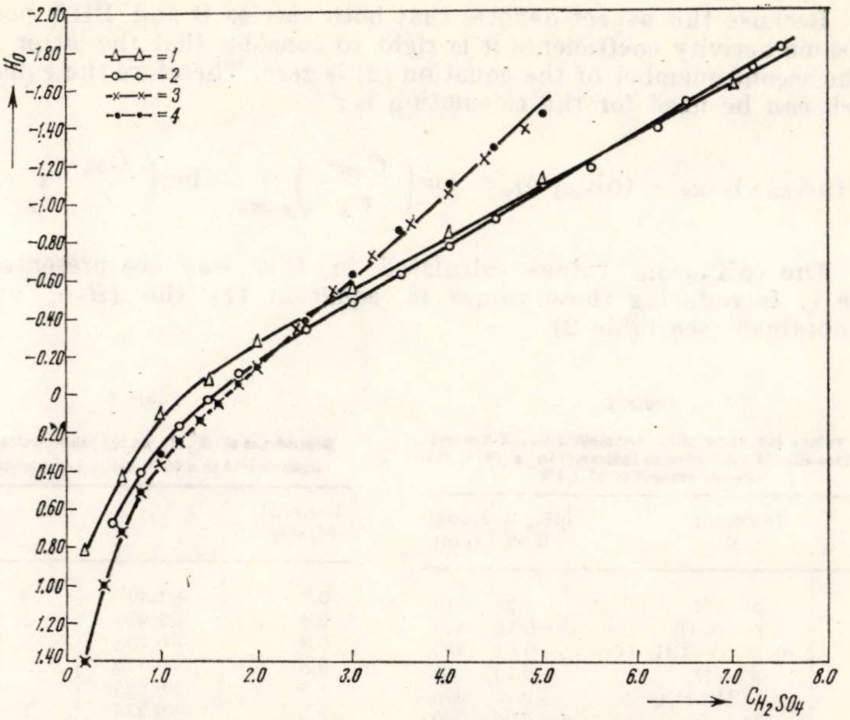

Fig 4. — H_0' (and H_0) scales for various types of indicators in various media

Curve	Indicator	Solvent system	Mineral acid
1	*p*-Nitroaniline	H_2O	H_2SO_4
2	Azo-compounds	$EtOH/H_2O$ 20/80 v	,,
3	,,	$EtOH/H_2O$ 50/50 v	$HClO_4$
4	$I_n$compounds	,,	H_2SO_4

both our type I bases and those from the azo-compounds series behave as Hammett bases (the corresponding H_0' scale was practically identical with that of the nitroaniline indicators in the same medium and in all our region).

From Fig. 4 it results similarly that in the range of low sulphuric acid concentrations the H_0' values for the aqueous-ethanolic sulphuric acid are more positive than H_0 for the aqueous sulphuric acid. This is in accordance with the generally known effect that the addition of dilute water-acid mixtures to organic solvents and to ethanol[24-31] decreases the

activity of the hydrogen ion.[31] At acid concentrations $C_{H_2SO_4} > 3N$ in the case of 50% vol. aqueous-ethanol, the H_0' function increases linearly with the normality of the acid and namely more rapidly than in an aqueous solution. The H_0 slope increases proportionally with the ethanol percentage (0% EtOH < 20% EtOH < 50% EtOH).

This phenomenon is due to the fact that in the ethanol-water system the proton is preferentially solvated by water i.e., water is a stronger base than ethanol [13,24,32–34] and the equilibrium

$$\mathrm{Et\overset{\oplus}{O}H_2 + H_2O \rightleftharpoons H_3O^{\oplus} + EtOH}$$

is displaced to the right.

EXPERIMENTAL

THE PREPARATION OF THE COMPOUNDS

The *E-1,3-dimethyl-6-(p-X-β-styryl)-2,4-dioxo-1H, 3H-1,3,5-triazine* bases were prepared according to ref. 1 (for the compound I_{8B}) and 4 (for all the others).

MEASUREMENT OF LOG $C_{BH^{\oplus}}/C_B$ VALUES

6,25 ml of a solution containing the styryl-dioxo-s-triazine (1.0×10^{-4} M) in 96% ethanol a.r. was dropped into a 25 ml graded flask which then was filled near to the mark with aqueous sulphuric acid of the appropriate strength and with twofold distilled water. Solutions of exactly 0.1, 1.0, 10 and 30 N aqueous sulphuric acid were used. After cooling at room temperature (25 ± 1°C) it was filled to the mark by pipetting with twofold distilled water. The solution was than transferred in an 1 cm silica cell and the spectrum of the solution was recorded in the range 200–600 nm, using an UNICAM SP–8000 instrument. A blank solution prepared in the same manner with the same acid stock solution (using a U.C.B., a.r., sulphuric acid) was used in the reference beam.

The solutions were freshly prepared and kept in the dark before the determinations in order to avoid *trans-cis* photoisomerization. The use of the solution was made in a dark room using a red light.

DECOMPOSITION OF ORGANIC HYDROPEROXIDES IN THE HETEROGENEOUS CATALYSIS. II*

DECOMPOSITION OF CUMENE HYDROPEROXIDE ON STRONGLY ACIDIC CATIONITES

L. CORMOŞ, A. POP and V. SBERA

Department of Organic and Technological Chemistry of the Faculty of Chemistry, Cluj,
Str. Arany Ianoş, 11, Romania

Received July 1, 1973

The present paper studies the macrokinetics of the decomposition reaction of cumene hydroperoxide in dilute solutions, on some strongly acidic cationites. The following cationites were used: amberlite I.R.-200, ostion KSP, zerolite-225 and lewatite S-200. The reaction rate constants were determined at three different temperatures for each separate cationite and the activation energies were calculated. A static working condition was used, the reactants being vigorously stirred. The cumene hydroperoxide solutions in cumene were about 10%.

In recent years, a series of solid catalysts were used in view of eliminating the drawbacks presented by the cumene procedure for obtaining phenol, by which the decomposition of cumene hydroperoxide occurs in a homogeneous catalysis.

Thus the decomposition of cumene hydroperoxide took place on silicagel,[1,2] on natural[3–5] or synthetic[6–9] silica-alumina and on various salts of metals with a variable valence.[10]

A number of research-workers[11-14] used for this purpose some strongly acidic cationites among which we mention Wofatite-P, Wofatite-F, KU-1, KU-2, Vionite CS-2, Vionite CS-3, Vionite CS-3A and Vionite CS-4A.

The present paper attempts to extend the investigations made so far to other cationites which have not yet been tested in this reaction.

EXPERIMENTAL

The following cationites were used in the model reaction: Amberlite IR-200, Ostion KSP, Zerolite-225 and Lewatite-S-100. Some of these cationites are found in H form, others, in Na form. For this reason the Na-Type ion-exchangers were introduced into a column and converted into H form, by treating with 10% sulphuric acid prior to the beginning of the experiments. The cationites were washed with deionized water, to remove the excess of acid.

Some determinations were made on the characteristics of the cationites used in this reaction.

The data obtained are listed in table 1.

Table 1

Characteristics of the utilized cationites

Cationite	Active groups	Exchange capacity in mval/ml		Structure	Maximum working temperature	Producing country
		Total	Useful			
Amberlite IR-100	$-SO_3Na$	1.75	0.7−0.9	micro-porous	120°	U.S.A.
Ostion KSP	$-SO_3H$	1.4−1.7	—	micro-porous	120°	Czechoslovakia
Zerolite-225	$-SO_3Na$	2.0	0.5−1.44	gel	120°	England
Lewatite S−100	$-SO_3Na$	2.2	1.8	gel	120°	W. Germany

The experiments were conducted in a thermostated glass device fitted with an inner cooling coil for a quantitative overtake of the heat released during the decomposition reaction. In this way, the local overheatings of the catalyst are avoided and a constant temperature is maintained during decomposition.

During our experiments we monitored the macrokinetics of the cumene hydroperoxide decomposition reaction at three different temperatures for each separate cationite; 25 ml solution 10% cumene hydroperoxide in cumene and about 2 grams of cationite were used for each determination.

The reaction was monitored by taking samples of 0.5 ml each, from time to time for the iodometric titration[15] of the non-decomposed hydroperoxide.

Table 2 presents the experimental data obtained from the decomposition on Amberlite IR-200 at temperatures of 20, 29.5 and 39.6°. The table contains:

n —number of determinations

X—time span from the start of the experiment until the samples were taken for the titration of the nondecomposed hydroperoxide, in minutes

α— conversion in %

Using the relation for the calculation of the most probable straight line, where : Y-which is lg $100/(100-\alpha)$ and n-number of determinations;

$$k = \frac{n\,\Sigma XY - \Sigma X \Sigma Y}{n\,\Sigma X^2 - (\Sigma X)^2}$$

the reactions rate constants were calculated for each temperature and listed in table 3.

Table 2

---

[15] H. Hook and H. Kropf, *Angew. Chem.*, **69**, 313 (1957).

A similar procedure was applied in the case of the other cationites. Table 4 presents the data on the decomposition on Ostion-KSP and table 5 refers to the decomposition on Zerolite-225. In the case of Lewatite the reaction rate has been found to be extremely low, the conversions of cumene hydroperoxide being below 15% even at 90° and after a delay of 10 hours after the onset of the experiment. That is why we consider that these data present no practical interest.

Table 4

INTERPRETATION OF RESULTS

By plotting lg 100/(100-α) as a function of time, figs. 1, 2 and 3 illustrate that the straight lines are obtained for Amberlite IR-200, Ostion KSP and Zerolite-225 for conversions between 10–95%. This

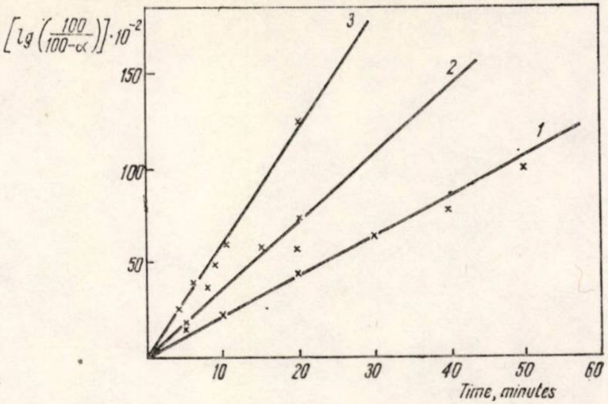

Fig. 1. — Linearization of first-order kinetic curves for the decomposition of cumene hydroperoxide on Amberlite IR-200.

proves that the decomposition reaction on these cationites occurs according to a first-order kinetics.

By plotting lg *k* as a function of $1/T$, fig. 4, (for Amberlite) it was possible to calculate the activation energies.

It has been found that the activation energies are comprised between 10–12 kcal/mole for Amberlite IR-200, Ostion KSP and Zerolite-225. The calculation of the activation energy in the case of a reaction on Lewatite – when values around 25 kcal/mole are obtained – shows that in this case the reaction rate is small.

CONCLUSIONS

1. The decomposition of cumene hydroperoxide also occurs on acid-type cationites : Amberlite IR-200, Ostion KSP, Zerolite-225 and Lewatite S-100, tested for the first time in this reaction.

2. The decomposition takes place according to a first order kinetics relative to cumene hydroperoxide for the same catalyst/reactant ratio.

3. The specific reaction constants were determined at various temperatures for each utilized cationite and the activation energies were also calculated.

ALTERNATING TENDENCY IN COPOLYMERIZATION. II[1]

COPOLYMERIZATION OF 1,1–DIPHENYL ETHYLENE WITH ACRYLIC MONOMERS

DAN SORIN VASILESCU

Laboratory of Macromolecular Chemistry, Polytechnical Institute, Calea Victoriei 149, Bucharest, Romania

Received November 14, 1973

The copolymerization of methacrylonitrile and acrylonitrile with 1,1 diphenyl ethylene at 80° was studied. The reactivity ratios r_i of these pairs of monomers as well as the copolymerization rates were calculated. This paper deals also with the alternating tendency in these systems.

INTRODUCTION

1,1–diphenyl ethylene (DPE) is a well-known monomer for its inability to homopolymerize. The impossibility to produce by a radicalic way a homopolymer of DPE, was proved long time ago.[2]

The radicalic affinity of phenyl ethylenes may be considered from the viewpoint of the steric hindrance in the addition reaction of the radical to olefin, or in terms of the resonance stabilization of the newly formed radical; it seems that the former effect might be a factor of less importance than the latter.[3] Nevertheless, DPE can copolymerize with various vinyl monomers. Thus, the copolymers of DPE with acrylonitrile (AN)[4] are known; the reactivity ratios ($r_1 = 0$ and $r_2 = 0.028$) show a tendency towards an alternating structure for this system. In such copolymerizations, the DPE content in copolymer cannot exceed 50% (molar percentage); consequently, in a copolymer two successive units of DPE are not possible. This fact was proved by Ito and Yamashita,[5] who investigated the triad distribution in the DPE (1)–methyl acrylate (2) copolymer, determined from the NMR studies; only 222, 221 and 121 triads were found. The above specified authors reported the $r_1 = 0$ and $r_2 = 0.092$ values.

Also, DPE cannot homopolymerize by ionic way; dimers of DPE could be obtained in the presence of several typical cationic catalysts as $SnCl_4(H_2O)$ or $Sb_2Cl_2(HCl)$.[6] The DPE anion is very stable and does not produce poly-DPE, but may initiate the anionic polymerization of other monomers. As the olefin is prevented from polymerizing by its steric hindrance, it provides a useful tool for the study of initiation processes.[7] Yuki and co-workers[8] described the anionic copolymerization of styrene and DPE; an alternating copolymer is obtained in the presence of a large excess of DPE. Szwarc *et al.*[9] reported more elaborated data about the behaviour of this system. The rate constant of DPE addition to the "living" polystyrene was found to be 250 l/mole sec for a $\text{-S}^-\text{Na}^+$ ion pair; the addition of styrene to $\text{-D}^-\text{Na}^+$ was proved to be reversible.[9] The alternating character in the anionic copolymerization of DPE and 2,3 dimethyl butadiene (DMB), was attributed to the high reactivity of DPE toward an anion, owing to the high resonance stabilization of its anion, in spite of the lack of homopolymerizability, and by the lower reactivity of DMB.[10]

In the present work, we report some data regarding the radicalic copolymerization of DPE with acrylic monomers. The reactivity ratios and other kinetic features were determined; the obtained polymers were also investigated in order to elucidate their structure.

EXPERIMENTAL

MATERIALS

1,1—diphenyl ethylene was prepared according to the method described by Allen.[11] The phenyl magnesium bromide reacts with an aliphatic acetate and $CH_3C(C_6H_5)_2O$ Mg Br results; after hydrolysis, the dehydration of diphenyl methyl carbinol follows, getting DPE. DPE was distilled in vacuum (b.p. 107—109°/1 mm. Hg) over sodium and found to be practically pure on the basis of the gas-chromatography measurements.

The methacrylonitrile (MAN), acrylonitrile (AN), acrylamide (AA), azobisisobutyronitril (AIBN) and the solvents were purified by usual methods, as we reported in detail in an earlier work.[1]

COPOLYMERIZATION PROCEDURE

The operation way, chosen to avoid any contact with air during the copolymerization process, was also widely described.[1] The precipitation of the reaction mass was made with petroleum ether.

ANALYSES OF POLYMERS

The reprecipitated and dried products were submitted to the micro-Dumas nitrogen analysis, to establish their compositions.

Intrinsic viscosities of the copolymers were reckoned from the data obtained on dilute solutions (less than 0.2 g/dl) in chloroform at 25°; the viscosity measurements were carried out with an Ubbelohde viscometer.

In order to obtain further positive data regarding the DPE presence in the copolymer chain, IR absorption spectra of the copolymers were recorded; the tests were accomplished on a PYE-Unicam, SP—200 spectrophotometer in potassium bromide pellets.

The MAN—DPE copolymers were tested by means of differential thermal analysis (DTA). The measurements were carried out on a CNRS-type apparatus endowed with a "Sefram"—"Graphispot" recorder; we led the warming in purified and dried nitrogen atmosphere at the rate 6.5°/min.

RESULTS AND DISCUSSION

As we reported above, the DPE radical is stabilized; this fact acts on the rate of the copolymerization process. The preliminary tests showed the requirement to work at a higher temperature and with an increased initiator amount ($[M_1] + [M_2]/[\mathrm{AIBN}] = 100$).

Table 1

Copolymerization of acrylic monomers with DPE (M_2) at 80°; molar ratio ($[M_1]+[M_2])/([\mathrm{AIBN}]) = 100$

20	AA	2.96	48	4.96	20.12	—
10	AA	3.28	59	2.46	19.68	—

Even in the specified conditions, the reaction times are rather long. Accordingly, it would arise the danger of some secondary reactions (e.g. oxidation); on the other hand, the more volatile monomer evaporation may occur. It might result a change into the monomer feed composition and, obviously, errors in the reactivity ratios calculation. Thus, the chosen operation way (in argon medium, in sealed off ampoules) appears as single reasonable; in this way the above described troubles were prevented and the reproducibility of the results was assured.

As is shown in table 1, the initial molar concentration of both monomers was not kept constant, but it varied in fairly good limits. This fact is due to the different molecular weights and densities of monomers, in the conditions where the total mole number was kept constant.

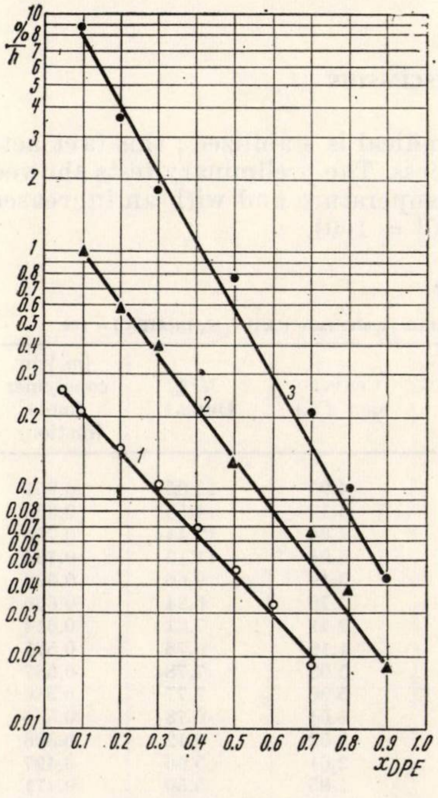

Fig. 1. — The effect of DPE (M_2) molar fraction on the copolymerization rate at 80°.

M_1 = MAN (1); AN(2); AA(3). ($[M_1] + [M_2])/[AIBN] = 100$.

In the tests involving AA, acetone was used as a solvent, because of the limited solubility of the monomer and, consequently, the total molar concentrations were correspondingly dropped.

As, generally, small conversions were obtained, the initial copolymerization rates could be determined, assuming a linear dependence of the conversion on time, in the first step.

The influence of the monomer composition feed on the reaction rate is evident — even in the conditions when differences in the molar concentration exist.

In all cases, DPE acts as a retarder of the copolymerization process.

On the other hand, as a function of the structure of the acrylic monomer, important differences in reactivity may occur; for instance, the higher the "e" value of the monomer, the higher the rate of the process. This effect is so significant, that it was necessary a logarithmicc scaale to represent the rates of all copolymerization processes in the same figure (fig. 1).

As the syntheses required a higher temperature and a rather large initiator amount, the molecular weights of the resulted products are of course reduced.

Thus, the intrinsic viscosities of the AN—DPE copolymers determined in chloroform vary between 8.72 cm³/g (58% AN) and 6.25 cm³/g (47% AN); this change is too small to be attributed to the molecular weight variation.

Values of more than 50% of the DPE content were observed at several copolymers with AN (e.g. tests 13, 14 and 15 — table 1); we consider that the differences from the equimolecular composition are negligibly small.

The nitrogen analyses results were used to establish the copolymer composition. These data were afterwards analysed by the least-square

method[12] (table 2). The use of this method to reckon the reactivity ratios eliminates some subjective interpretations, which are characteristic of the graphic methods; this calculation way was chosen in a previous paper [1] too.

The r_1 and r_2 reactivity ratios for these systems are small; little errors in the nitrogen content estimation lead to some difficulties in the reactivity ratios assessment by the Mayo and Lewis's intersection method.[13]

Some typical results are plotted in figures 2a and 2b.

One may remark that only for the MAN−DPE and AN−DPE pairs, analytical data could be used in order to obtain the copolymerization ratios. In the AA containing systems the great scatter of the N concentrations obtained makes any definite conclusion impossible. For these systems the intrinsic viscosities also had rather low values: 13.7 cm³/g (Test 16-table 1) and 5.3 cm³/g (Test 22-table 1).

b) M_1 = AN M_2 = DPE

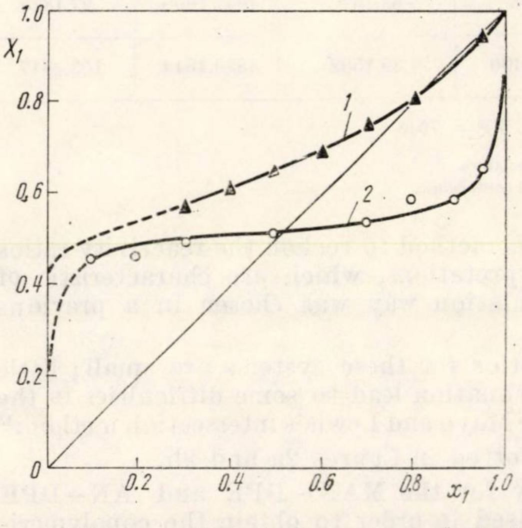

Fig. 3. — Copolymer/monomer feed composition curves for binary copolymerization of:
1. MAN(M_1) — DPE(M_2).
2. AN(M_1) — DPE(M_2).

The results of the accomplished reckonings are summarized in table 3. The r_1 and r_2 values obtained for the MAN—DPE pair are different from those predicted by the "Q-e" scheme [14]; the corresponding values for the AN–DPE pair are also distinct from those theoretically foreseen[14] and, moreover, from those reported many years ago. [4]

Reactivity ratios in copolymerization of acrylic monomers (M_1) with 1,1 diphenyl ethylene (DPE – M_2) at 80°

Monomer M_1	Experimental data				Calculated data from the Alfrey and Price's scheme	
	Least-squares method		Mayo and Lewis method			
	r_1	r_2	r_1	r_2	r_1	r_2
MAN	0.850	0.0087	0.896	0.014	0.129	0.072
AN	0.045	0.022	0.04	0.01	0.0187	0.079
AA*	—	—	—	—	0.025	0.035

The values r_1=0.028 and r_2=0 were earlier reported.[4]

It is notable a great alternating tendency for the AN–DPE system as the resulting copolymer composition tends to 50% in a wide range of the monomer feed composition.

Even for the MAND–PE pair, 1,1–diphenyl ethylene is present in copolymer in an appreciable proportion. This fact was evidenced by spectral analysis.

In table 4 the characteristic vibration frequencies of the MAN–DPE copolymers at various compositions are given; the same copolymer amount (2 mg) was submitted to the spectral analysis. The three spectra shown differ only by the intensity of the various absorption bands. Proportionally as the DPE content increases, the absorption bands at 710 cm^{-1} and 765 cm^{-1} (characteristic of the phenyl group) increase too; at the same time the bands from 2235 cm^{-1} (nitrile) and 1470 cm^{-1} (mehyl) [15] decrease. The peaks for methylene (2990 cm^{-1}; 2945 cm^{-1}) remain practically constant. These complementary data are in good agreement with the nitrogen analysis results.

Table 4

The absorbance noticed in the IR spectra of some MAN-DPE copolymers

Characteristic vibration frequencies ν cm^{-1}	Absorbance		
	Copolymer with 57.1 % MAN	Copolymer with 79.8 % MAN	Copolymer with 95.1 % MAN
2990	0.23	0.25	0.27
2945	0.21	0.21	0.23
2235	0.17	0.21	0.24
1470	0.27	0.31	0.34
1455	0.41	0.34	0.34
1395	0.14	0.16	0.17
1375	0.11	0.12	0.12
1220	0.14	0.16	0.19
765	0.32	0.25	0.12
710	0.78	0.52	0.28

The IR absorption spectra for the products obtained from AA and DPE are more complex than those of poly-AA described by Hümmel[16] (720 s, 820 s, 840 s, 890 w, 960 s, 990 s, 1050 w, 1135 s,

[16] Hümmel/Scholl "Infrared Analysis of Polymers, Resins and Additives — An Atlas", 1, part 2, Wiley-Interscience, New York–London, 1969, p. 1239.

1280 s, 1355 vs, 1425 vs, 1610 vs, 1670 vs, 1950 w, 2810 m, 3180 vs, 3360 vs, —where w-weak, m-medium, s-strong, vs-very strong and the values are in cm^{-1}) and do not permit us to draw certain conclusions.

The literature [17] indicates the glass-transition temperature (T_g) for poly-MAN at 120°. For the copolymers studied, the T_g values vary between 62° and 89° as a function of composition. This fact might show, that poly-MAN long sequences do not appear in the copolymer chain and that the volume effects brought about by the DPE substituents are important. Indeed, for a MAN—DPE copolymer (57%MAN) one may reckon the run number (according to Harwood[18]) $R = 62.4$, thus being pointed out the alternating tendency for this system too.

All the samples present endothermal processes in the range 320° to 390°.

The author is indebted to Mrs. Florina Mărculescu for the IR spectra achievement and expresses his sincere gratitude to Mrs. Elena Maftei for thermal measurements.

MÉTHODES DE DÉTERMINATION DE L'AZOTATE DE PILOCARPINE. SPECTRE EN VISIBLE ET INFRAROUGE DU COMPOSÉ RÉSULTÉ ENTRE L'AZOTATE DE PILOCARPINE ET LE REINECKATE D'AMMONIUM

GRIGORE TEODORESCU

Institut Polytechnique de Bucarest, Chaire de Chimie inorganique et analytique,
Bucarest, 1, str. Polizu

Reçu le 17 décembre 1973

On présente des méthodes de détermination de l'azotate de pilocarpine, réalisées par la combinaison avec le reineckate d'ammonium, la dissolution du composé obtenu dans l'acétone, suivie de la précipitation de l'anion reineckate comme reineckate d'argent et titrage de l'excès d'azotate d'argent avec du thiocyanate d'ammonium. Vu que le composé formé est soluble en acétone, résultant une solution colorée, le composé a été déterminé aussi colorimétriquement. La structure du complexe obtenu a été vérifiée par la détermination de la masse moléculaire, à l'aide des spectres en visible, pour le reineckate d'ammonium et le reineckate de pilocarpine. La structure du reineckate de pilocarpine a été caractérisée aussi par le spectre en IR de l'azotate de pilocarpine et de son composé.

La pilocarpine est un alcaloïde (le stéréoisomère dextrogire) de la classe des alcaloïdes avec le composant N-méthyl-imidazolique.[1] La principale action physiologique de la pilocarpine réside dans excitation de la sécrétion des glandes salivaires, sudoripares, lacrymales (effet antagoniste de l'atropine). Elle est employée pour la constriction de la pupille sous forme de chlorhydrate ou d'azotate de pilocarpine.

La méthode classique de détermination utilisée est basée sur le titrage alcalimétrique du chlorhydrate ou de l'azotate.

Pour avoir le minimum d'erreur dans cette méthode, il faut employer des substances de pureté avancée ($> 99{,}5\%$).

Pour pouvoir faire aussi des déterminations sur des substances moins pures, on a établi une méthode de détermination basée sur la réaction de combinaison de l'azotate de pilocarpine avec le reineckate d'ammonium $[NH_4Cr(NCS)_4(NH_3)_2]$, abrégé $NH_4^+Rc^-$, réactif utilisé par l'auteur aussi à la détermination d'autres produits.[2-6]

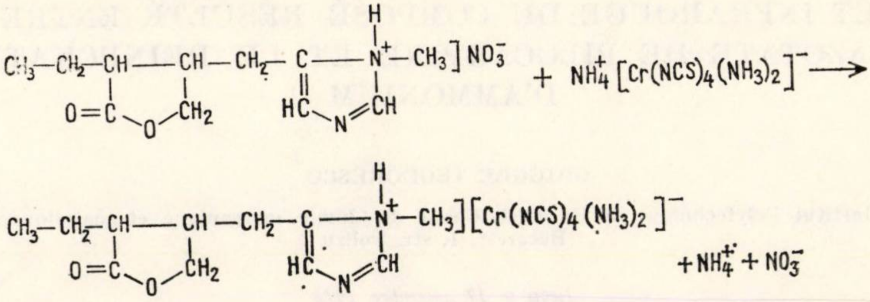
L'azotate de pilocarpine (abrégé PCP) utilisé est soluble dans l'eau (1 partie de substance à 8 parties d'eau) avec une faible réaction acide. La réaction de combinaison est due à l'existence dans la molécule du PCP d'une position N-méthyl-imidazolique qui confère un caractère d'*oniu* et a lieu selon le schéma suivant :



La réaction de combinaison avec le NH_4^+ Rc^- a été utilisée à la détermination du PCP, par les méthodes : volumétrique, colorimétrique et spectrale.

1. MÉTHODE VOLUMÉTRIQUE

La combinaison du PCP a lieu dans une solution aqueuse d'acide azotique avec le NH_4^+ Rc^-. Le précipité cristallin obtenu, de couleur rose, est filtré, lavé et ensuite dissous en acétone. La solution résultée est traitée par un excès de solution d'azotate d'argent 0,1 N, quand précipite le reineckate d'argent conformément à la réaction :

$$[Cr(NCS)_4(NH_3)_2]^- + Ag^+ \rightarrow Ag[Cr(NCS)_4(NH3)_2]$$

Après filtrage et lavage on titre l'excès d'azotate d'argent par thiocyanate d'ammonium en présence de l'alun de fer(III) et d'ammonium.

MODE OPÉRATOIRE

Du produit pharmaceutique dissous dans l'eau, de concentration 0,00534 g/ml, on prend des épreuves entre 0,0320–0,0800 g, on ajoute 0,5–1 ml d'acide azotique, 20 ml d'eau distillée et après, goutte à goutte, sous agitation continue, la solution fraîchement préparée de 3% NH_4^+ Rc^-. Il précipite le composé cristallin nâcré-rose-violet.

Le composé formé est filtré sur un creuset à filtre G_3, entraîné par une solution de $NH_4^+Rc^-$ 0,1 %, lavé ensuite à l'eau distillée (4°C), jusqu'au moment où la solution passe incolore et, finalement, 2–5 fois avec 5–10 ml d'éther.

On dissout le composé directement sur le creuset à filtre avec 10–20 ml d'acétone, jusqu'à dissolution totale. On lave finalement le creuset à 20 ml d'eau distillée et on prend la solution et les eaux de lavage dans un verre de 250 ml. On ajoute 100 ml d'eau distillée, 10 ml d'azotate d'argent 0,1 N et 3–4 gouttes d'acide azotique 2 N.

Le précipité de reineckate d'argent formé est filtré, lavé par décantage à l'eau distillée. Le filtrat et les eaux de lavage sont mis dans un flacon de 750 ml. On ajoute 3–4 ml de solution saturée d'alun de fer(III) et d'ammonium (environ 40 %), 3–4 gouttes d'acide azotique 2 N et on titre l'excès d'azotate d'argent par thiocyanate d'ammonium 0,1 N au facteur connu (F 0,1 N = 1,0526).

Un ml d'azotate d'argent 0,1 N correspond à 0,02713 g d'azotate de pilocarpine. Les résultats obtenus sont rapportés au tableau 1.

Tableau 1

Détermination volumétrique de l'azotate de pilocarpine

PCP dans l'épreuve g	PCP déterminé avec $NH_4^+Rc^-$		PCP déterminé alcalimétriquement %	Données statistiques
	g	%

0,0587	0,0586	99,82	99–100	$(P = 99\,\%,\ \nu = 9) = 3,25$
0,0640	0,0637	99,53	99–100	du tableau
0,0694	0,0690	99,42	99–100	Résulté = 99,32 ± 0,26 %
0,0747	0,0740	99,06	99–100	
0,0800	0,0794	99,02	99–100	

2. MÉTHODE COLORIMÉTRIQUE

Principe de la méthode colorimétrique. On précipite le PCP avec du NH_4^+ Rc^-, selon le même procédé, dans le rapport molaire 1 : 1. Vu que le composé formé est soluble en acétone, résultant une solution colorée en rouge, le PCP peut être déterminée aussi colorimétriquement.

MODE OPÉRATOIRE

On applique la méthode des courbes étalon. A cette fin on a employé une solution de NH_4^+ Rc^- avec $T = 0,0560$ g/ml dont on a pris des volumes correspondants, dans des ballons jaugés de 100 ml, dilués avec 50 ml d'acétone et complétés avec de l'eau distillée, afin d'obtenir des solutions avec des concentrations $T = 0,00028$; 0,000560 ; 0,000840 ; 0,00112 ; 0,001680 g. Les déterminations ont été faites à l'aide du photocolorimètre de type B. Lange, en utilisant des filtres verts (λ = 533 nm) et on a tracé la courbe étalon.

De la solution de PCP avec $T = 0,00534$ g/ml on a prélevé des épreuves entre 0,000320 et 0,000534 g et l'on a précipité avec du NH_4^+ Rc^- selon la méthode volumétrique.

Après précipitation, filtrage et lavage, les épreuves ont été quantitativement dissoutes avec de l'acétone, en prenant la solution dans des ballons jaugés à 100 ml. Après l'homogénéisation, les épreuves ont été colorimétrées, les résultats obtenus étant indiqués au tableau 2.

3. ÉTUDE SPECTRALE

3.1. CARACTÉRISATION DU SPECTRE EN VISIBLE DU REINECKATE DE PCP

Dans le cas de la pilocarpine, comme dans le cas d'autres composés qui contiennent plusieurs atomes d'azote cationisable, il est utile de vérifier si la structure du complexe inclut un ou deux anions de reineckate.[7] La structure peut être vérifiée par la détermination de sa masse moléculaire, à l'aide de l'absorbance (A) et de l'absorptivité (K).

Les déterminations ont été faites avec le spectrophotomètre Zeiss de type VSU —1, avec une cuve de grosseur $l = 0{,}5$ cm et une concentration $g_1 = 0{,}1\,\%$.

Les chiffres trouvés ont été pour NH_4^+ Rc^- :

nm	Absorbance
394	0,138
420	0,102
452	0,030
482	0,093
520	0,155
560	0,105

et pour le reineckate de PCP :

nm	Absorbance
390	0,086
420	0,060
450	0,031
490	0,064
520	0,098
558	0,075

---

[7] KUM-TATT-LEE, *J. Pharm. Pharmacol*, **12**, 666 (1960).

Une caractéristique commune des spectres en visible du NH_4^+ Rc^- réside dans le fait que le maximum d'absorption (λ_{max}) est approximativement le même, $\lambda_{max} = 520$ nm pour NH_4^+ Rc^- (dans l'éthanol 95%) et $\lambda_{max} = 520$ nm pour le reineckate de PCP (aussi dans l'éthanol 95%).

L'absorptivité a été déterminée conformément à la relation :

$$K = (A/c)l$$

sur le $NH_4^+Rc^-$, dans l'éthanol 95% à la concentration $c = 0{,}00297$ mole gramme $NH_4^+Rc^-$, à une grosseur de la cuve $l = 0{,}5$ cm et pour l'absorbance $A = 0{,}155$ et correspondant à la valeur maximale $\lambda_{max} = 520$ nm.

La valeur K déterminée pour le $NH_4^+Rc^-$ peut être considérée dans les limites des erreurs acceptables, comme étant valable aussi pour le reineckate de PCP, étant donné que λ_{max} pour le reineckate de PCP est égal (ou presque égal) à λ_{max} pour le $NH_4^+Rc^-$.

La masse moléculaire (*Md*) est déterminée selon la relation :

$$Md = g_1/100.\ (K/\mathrm{A})\ l.1000 \tag{1}$$

Pour le cas $g_1 = 0{,}1$ g de reineckate de PCP pour 100 ml solution, la relation (1) devient :

$$Md = (K/\mathrm{A}).l \tag{2}$$

Pratiquement la détermination de l'absorption en visible du reineckate de PCP est faite dans l'éthanol 95%. L'absorbance pour $\lambda_{max} = 520$ nm à la concentration de 0,1% et à une cuve avec $l = 0{,}5$ cm (dans les mêmes conditions de travail) est de 0,098. En remplaçant dans la relation (2) on obtient :

$$Md = (103{,}70/0{,}098).0{,}5 = 529$$

Bien que la pilocarpine ait les deux atomes d'azote du noyau imidazolique quaternisables, la masse moléculaire du reineckate de PCP établie expérimentalement comparée à celle résultée du calcul pour le monoreineckate de PCP (Mc = 527,48) indique que la structure du composé obtenu est du type monoreineckate et non pas direineckate.

Caractéristique en infrarouge du reineckate de PCP. Le reineckate de PCP a été structuralement caractérisé aussi par spectre en infrarouge, que l'on a interprété par comparaison avec le spectre du $NH_4^+Rc^-$ (tabl. 3) et le spectre de l'azotate de PCP[8-12] (tabl. 4).

3238	(f)		28
3315	(f)		27

f = faible
i = intense
t.f = très faible

Le spectre en IR du composé présente des bandes pouvant être attribuées aux groupements NH_3 et NCS de l'anion reineckate du complexe retrouvées aussi dans le spectre en IR du reineckate d'ammonium. Les bandes apparaissent à 499 cm^{-1} (δ_{NCS}), 1265 m^{-1} ($\delta\,\overset{\text{sym}}{\underset{\text{N-H}}{\text{NH}_3}}$) 2085 cm^{-1} ($\nu_{C-N}$), 3165—3330 cm^{-1} ($\nu\overset{\text{sym}}{\underset{\text{N-H}}{\text{NH}_3}}$). Le spectre présente aussi des bandes correspondant à la base organique (tabl. 4). Ces bandes existant à 617 cm^{-1}, 1190 cm^{-1}, 1620 cm^{-1}, 1725 cm^{-1}, 1762 cm^{-1}, 3130 cm^{-1} sont très peu modifiées comme position et intensité dans le spectre en IR du composé étudié, étant une nouvelle preuve pour le schéma donné.

Les spectres ont été déterminés avec un spectrophotomètre enregistreur en infrarouge type UR—20 Zeiss Jéna, utilisant la technique des pastilles de bromure de potassium. On a utilisé des prismes de KBr (400—700 cm^{-1}) NaCl (700—1800 cm^{-1}) et LiF (1800—4000 cm $^{-1}$).

MEMBRANE-ELECTRODES OF A METALLIC WIRE–PLASTIC MEMBRANE TYPE. I

K^+-SELECTIVE MEMBRANE ELECTRODE

ELENA HOPÎRTEAN, C. LITEANU and EUGENIA ŞTEFĂNIGĂ
"Babeş-Bolyai" University, Cluj, Department of Analytical Chemistry,
str. Arany János 11, Cluj

Received: January, 7, 1974

The paper discusses the manner of obtaining a K^+-selective electrode of a Pt wire type covered by a plastic membrane formed of PVC, plasticizer and potassium tetraphenylborate. Comparative studies are made on electrodes obtained with plasticizers : 3-nitro-*o*-xylene, dibutylphthalate and diisooctylphthalate. The basic characteristics of the resulted electrodes are established to this end, *viz.* : electrodic function, selectivity, electric resistance and response rate. Electrodes are used in the determination of potassium with sodium or calcium tetraphenylborate by potentiometric titration.

1. INTRODUCTION

One of the ion-selective membrane-electrode categories is that which involves a polymer as a support. A number of authors[1–10] successfully used PVC as a support, obtaining selective membrane-electrodes at H^+, K^+, Ca^{2+} ions, organic cations, etc. An important role in the operation of polymer matrix-based electrodes is played by the plasticizer used which may provide both a high degree of semipermeability to certain ions and some suitable physico-chemical properties (elasticity, resistance to tearing, etc.).

A recent trend in achieving membrane-electrodes consists in directly covering a platinum wire by an ion-selective membrane[11–16] thus eliminating the internal solution. The electric conductance of this type of electrodes is based on the combination of the electronic type conduction mechanism with the ionic one.[17,18]

As to K^+-selective electrodes with polymer support (PVC) the active electronic component used is observed to be the tetraphenylborate or the *p*-chlortetraphenylborate ion.[7,8,10,14]

In a previous work[19] we used $Na[B(C^6H_5)_4]$ to obtain a K^+-selective liquid electrode, employing cyclohexanone as a solvent and glass frit as a support.

This paper introduces a new manner of obtaining K^+-selective electrode by coating the Pt wire with a membrane formed of PVC, plasticizer and $K[B(C_6H_5)_4]$. The characteristics of the resulting membrane-electrode are studied: electrodic function, selectivity, electric resistance and response rate. The electrode is used in the determination of potassium found in solution in the absence or in the presence of other ions (Na^+, Ca^{2+}, Mg^{2+}), by potentiometric titration with sodium or calcium tetraphenylborate.

2. EXPERIMENTAL

2.1. MANNER OF OBTAINING THE ELECTRODE

Dosage of appropriate amounts of potassium tetraphenylborate, PVC and plasticizer resulted in a paste having the following composition: 3% $K[B(C_6H_5)_4]$, 35% PVC, 62% plastifier. An as homogeneous as possible paste is obtained by finally dispersing potassium tetraphenylborate into the plasticizer and by adding finely-ground PVC thereafter. Potassium tetraphenylborate was vacuum-dried at 120° prior to use. After becoming homogeneous, the paste is heated at about 200° and an approx. 5 mm long Pt wire (1) fixed at the end of a glass tube is introduced therein (2). The Pt wire is coated by a 0.2–0.3 mm thick membrane (3) over a span of about 5 mm of the glass tube. A thin paraffin layer is then applied over

the membrane on the glass tube and over approx. 2 cm of the tube, to provide optimum operating conditions for the electrode by avoiding an incidental Pt-solution contact. The diagram of the electrode achieved is presented in fig. 1.

2.2. CHARACTERISTICS OF THE ELECTRODE

2.2.1. *E-pK electrodic function.* The e.m.f. of the following electrolytic chain was measured to this end:

Pt | membrane | test solution | salt bridge | reference electrode Ag/AgCl

Potential measurements were performed at room temperature under non-stirring conditions, using a MV—11 pH-meter. The accuracy of measurements is ±1 mV. In order to avoid the contamination of the sample with K^+ ions of the reference electrode, a salt bridge $NaNO_3$ 10^{-1} M containing 1% agar-agar was used. *E-pK* electronic functions were established both in KCl pure solutions and in the presence of some interfering ions: Na^+, Ca^{2+}, Mg^{2+}.

b) electrode ; $K[B(C_6H_5)_4]$ + dibutylphthalate + PVC ;
c) electrode ; $K[B(C_6H_5)_4]$ + diisooctylphthalate + PVC.
1, without interfering ions ; *2*, background 10^{-2} M NaCl ;
3, background 10^{-2} M $CaCl_2$; *4*, background 10^{-2} $MgMCl_2$.

In view of deciding on the optimum plasticizer, electrodes were prepared using the following plasticizers: 3-nitro-*o*-xylene[9,10] dibutylphthalate[9,10] and diisooctylphthalate. The electrodic functions obtained for K^+ ion in the absence of interfering ions, using the electrodes formed of the mentioned plasticizers, are presented in fig. 2.

Fig. 3 illustrates the electrodic functions obtained for K^+ with the same electrodes in the presence of interfering ions Na^+, Ca^{2+}, Mg^{2+} at a 10^{-2} M concentration.

In the case of the electrode with 3-nitro-*o*-xylene, electrodic functions were established for K^+ ion in the presence of NaCl at various concentrations (fig. 4).

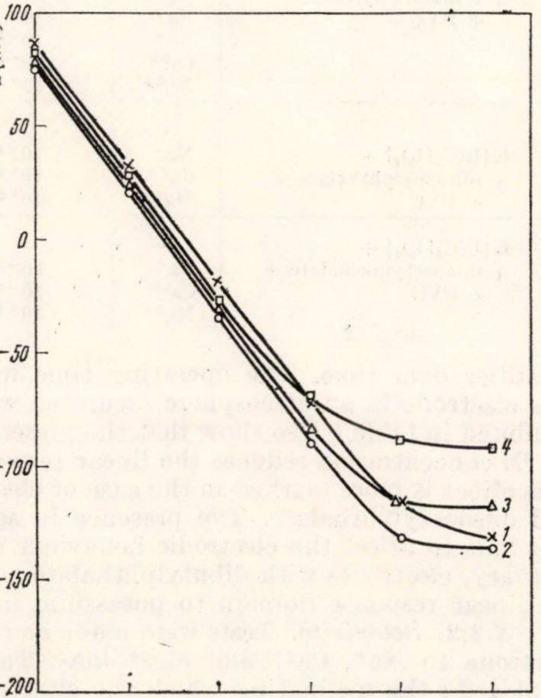

Fig. 4. — *E-pK* electrodic functions. Electrode: $K[B(C_6H_5)_4$ + 3-nitro-*o*-xylene + PVC.
1, without NaCl; *2*, background 10^{-3}M NaCl; *3*, background 10^{-2}M NaCl; *4*, background 10^{-1}M NaCl.

In order to have a good reproducibility of the electrode behaviour, their conditioning is indicated prior to use, by immersion in a 10^{-2} M KCl solution for roughly 30 min.

Values of the slopes of electrodic functions presented in figs. 2, 3 and 4 and also the linearity domain are shown in table 1.

Data supplied by table 1 with regard to the electrodic behaviour in the absence of interferences illustrate a better behaviour of the electrode with 3-nitro-*o*-xylene, particularly in relation to the concentration range of the linear response. In contrast, the operating time of electrodes with dibutylphthalate and diisooctylphthalate is longer (over 3 weeks) than of that with 3-nitro-*o*-xylene (2–3 days) which loses its electrodic capabilities within a shorter while due to a more pronounced loss of the plastifier over time. The operating time may be extended by keeping this electrode in an atmosphere saturated with plasticizer vapours. Data exhibited in table 1 also show that the presence of Na^+ ion a higher than 10^{-2}M concentration reduces the linear response domain of the electrode. This effect is more marked in the case of electrodes with dibutylphthalate and diisooctylphthalate. The presence in solution of Ca^{2+} and of Mg^{2+} ions fails to affect the electrodic behaviour to K^+ in either case. On the contrary, electrodes with dibutylphthalate and diisooctylphthalate extend the linear response domain to potassium in the presence of these ions.

Table 1

Electrodic behaviour

Electrode	Interfering ion	Concentration of interfering ion	Slope (mV/*pK*)	Concentration range (*pK*)
$K[B(C_6H_5)_4]$ + + 3-nitro-*o*-xylene + + PVC	—	—	53	0–3.7
	Na^+	10^{-3}M	55	0–3.7
	Na^+	10^{-2}M	53.5	0–3.2
	Na^+	10^{-1}M	53	0–2.5
	Ca^{2+}	10^{-2}M	54	0–3.7
	Mg^{2+}	10^{-2}M	54	0–3.7
$K[B(C_6H_5)_4]$ + + dibuthylphthalate + + PVC	—	—	52	0–3.0
	Na^+	10^{-2}M	52.5	0–2.5
	Ca^{2+}	10^{-2}M	53.5	0–3.7
	Mg^{2+}	10^{-2}M	54	0–3.7
$K[B(C_6H_5)_4]$ + + diisooctylphthalate + + PVC	—	—	51	0–2.8
	Na^+	10^{-2}M	52.5	0–2.5
	Ca^{2+}	10^{-2}M	53	0–3.7
	Mg^{2+}	10^{-2}M	53	0–3.3

2.2.2. *Selectivity.* Tests were made on the selectivity of the obtained electrode to Na^+, Ca^{2+} and Mg^{2+} ions. To do this, two methods were employed : the method by which the electrode potential has been determined in separate solutions of the two ions (K^+ ion and interfering ion), and the method using the electrode potentials determined in solutions containing the mixture of the two ions.[20]

In the case of the second method used, the alternative was selected in which the primary ion, K^+, has a constant concentration, the concentration of the interfering ion being modified by known additions of a concentrated solution (1 M) of the latter or even of the solid salt of the interfering ion for the 1 M concentration.

Selectivity constants exhibited in table 2 were calculated by the method suggested by Srinivasan and Rechnitz,[20] according to which this magnitude is given by the activity ratio of the two ions, primary and interfering, respectively, which determine the same electrode potential.

---

[20] K. Srinivasan and G. A. Rechnitz, *Analyt. Chem.*, **41**, 1203 (1969).

Table 2

Selectivity constants

Electrode	Selectivity constant		
	K_{KNa}	K_{KCa}	K_{KMg}
$K[B(C_6H_5)_4]$ + 3-nitro-*o*-xylene + PVC	2.8×10^{-2}	$\sim 10^{-4}$	5×10^{-3}
$K[B(C_6H_5)_4]$ + dibutylphthalate + PVC	7.0×10^{-2}	10^{-3}	$\sim 10^{-4}$
$K[B(C_6H_5)_4]$ + diisooctylphthalate + PVC	8.0×10^{-2}	10^{-3}	10^{-3}

Selectivity constants in table 2 are really supported both by the electrodic functions obtained for K^+ in the presence of interfering ions (fig. 3) and by the results presented in fig. 5.

Inspection of the data included in table 2 shows that the electrode with 3-nitro-*o*-xylene plasticizer provides a better potassium-sodium selectivity, which is an evidence of the role of the plasticizer in the behaviour of such types of electrodes, concerning the different permselectivity manifested to various ions. As to the selectivity of electrodes to Ca^{2+} and Mg^{2+}, respectively, a practically similar behaviour of electrodes formed of the three plasticizers has been found. The high electrode selectivity to Ca^{2+} and Mg^{2+} suggests the extension of the linear response domain in the case of electrodes with dibutylphthalate (fig. 3b) and diisooctylphthalate (fig. 3c). The presence of these practically indifferent electrolytes favours the electrode response to low potassium concentrat ions.

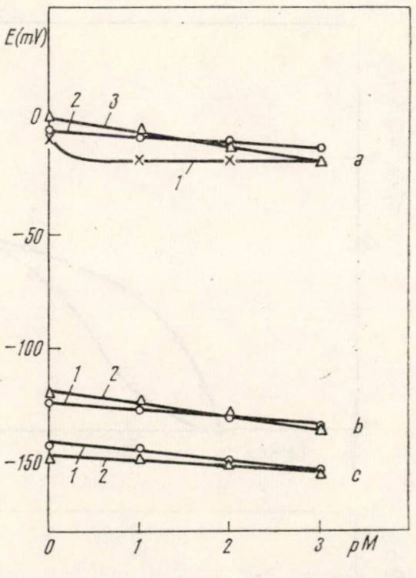

Fig. 5. — Response of the electrode in 10^{-2} M KCl solution depending on the concentration of the interfering ion.

a) electrode; $K[B(C_6H_5)_4]$ + 3-nitro-*o*-xylene + PVC; *1*, Na^+; *2*, Ca^{2+}; *3*, Mg^{2+}.

b) electrode; $K[B(C_6H_5)_4]$ + dibutylphthalate + PVC; *1*, Ca^{2+}; *2*, Mg^{2+}.

c) electrode; $K[B(C_6H_5)_4]$ + diisooctylphthalate + PVC; *1*, Ca^{2+}; *2*, Mg^{2+}.

2.2.3. *Electrical resistance and response rate*. The electric resistance was measured in a saturated KCl solution using a RLC type 221 bridge and a platinum counterelectrode.

The response rate was determined by recording the electrode potential on a Radelkis OH102 polarograph. Recordings were made both in the absence and in the presence of interfering ions of a 10^{-2} M concentration in solutions in which the concentratio- of K^+ ion was higher than 10^{-3} M. Results regarding the electric resist. ance and the response time of the electrodes studied are listed in table 3u

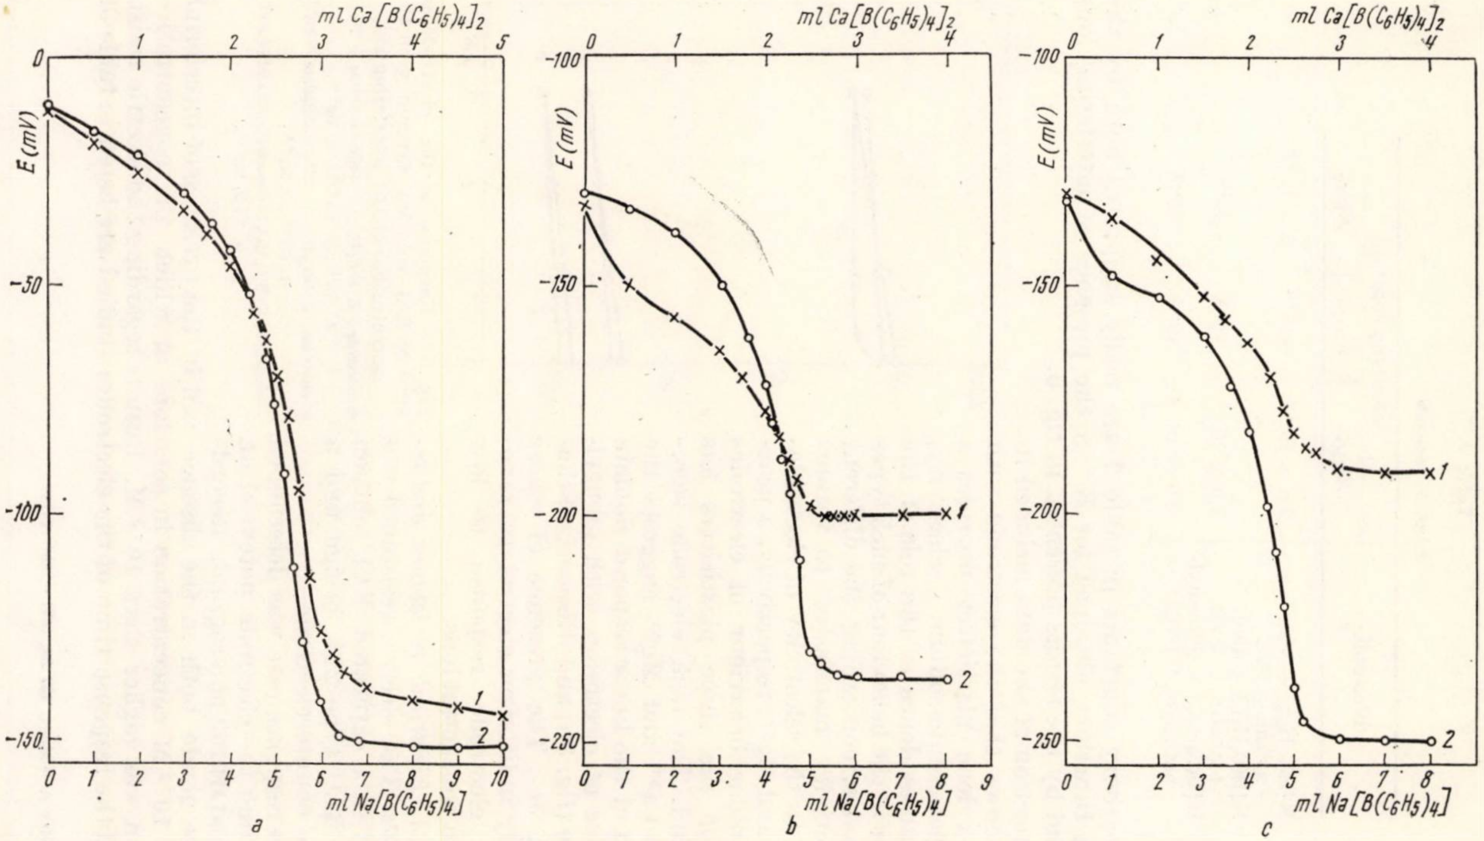

Fig. 6. — Titration of 10^{-2}M KCl with $\sim 5 \times 10^{-2}$M $Na[B(C_6H_5)_4]$ (*1*) and with $\sim 10^{-1}$M $Ca[B(C_6H_5)_4]$ 2 respectively (*2*).

a) electrode: $K[B(C_6H_5)_4]$ + 3 nitro-*o*-xylene + PVC;

b) electrode: $K[B(C_6H_5)_4]$ + dibutylphthalate + PVC;

c) electrode: $K[B(C_6H_5)_4]$ + diishooctylpthalate + PVC.

Table 3

Electric resistance and response time

Electrode	Electric resistance (ohms)	Response time (sec)
$K[B(C_6H_5)_4]$ + 3-nitro-*o*-xylene + PVC	1.1×10^7	60
$K[B(C_6H_5)_4]$ + dibutylphthalate + PVC	5.8×10^6	70–80
$K[B(C_6H_5)_4]$ + diisooctylphthalate + + PVC	6.5×10^7	30–40

In solutions in which the concentration of K^+ ions is below 10^{-3} M, the electrode response time is a few minutes (3–4 min).

2.3. ANALYTICAL USE

The electrodes developed were analytically used in the potentiometric titration of potassium with sodium or calcium tetraphenylborate. The resulted titration curves are plotted in fig. 6.

As a result of a good potassium-sodium selectivity of the electrode formed 3-nitro-*o*-xylene plastifier, the titration curve obtained with sodium tetraphenylborate as a titrant shows a distinct potential jump at the equivalence point ($\Delta E_{\pm 1\%} = 20$ mV) which is close to that obtained when using calcium tetraphenylborate as a titrant ($\Delta E_{\pm 1\%} = 25$ mV) (fig. 6a). Due to a lower potassium-sodium selectivity of electrodes with dibutylphthalate and diisooctylphthalate, respectively, titration curves obtained by using sodium tetraphenylborate as titrant have a small potential variation at the equivalence point (figs 6b and 6c). In the case of these electrodes, calcium tetraphenylborate is recommended as a titrant, obtaining in the case of both electrodes a potential variation around the equivalence point, $\Delta E_{\pm 1\%}$, of about 20 mV.

Titrations of K^+ were also performed together with Na^+, respectively, with Ca^{2+} or Mg^{2+} using the electrode with 3-nitro-*o*-xylene plasticizer and sodium tetraphenylborate as titrant. Titration curves obtained are presented in fig. 7.

Since, as seen in fig. 7, potassium determination can be successfully performed in the presence of any of the three tested ions (Na^+, Ca^{2+}, Mg^{2+}), the electrode may find various concrete practical applications.

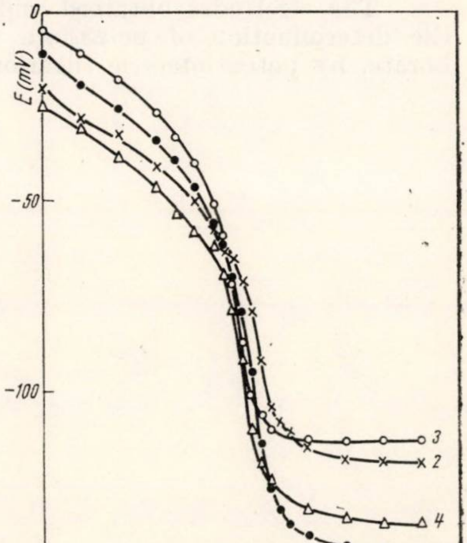

Fig. 7. — Titration of 10^{-2}M KCl with ~5×10^{-2} M $Na[B(C_6H_5)_4]$.

1, without background; *2*, background NaCl 10^{-2} M; *3*, background 10^{-2}M $CaCl_2$; *4*, background 10^{-2}M $MgCl_2$. Electrode: $K[B(C_6H_5)_4]$ + 3-nitro-*o*-xylene + PVC.

CONCLUSIONS

The paper presents an original manner of achieving a K-selective electrode of a platinum wire type coated by a plastic membrane formed of $K[B(C_6H_5)_4]$, plasticizer and PVC.

An analysis of the behaviour of electrodes with plasticizers : 3-nitro-*o*-xylene, dibutylphthalate and diisooctylphthalate results in the following :

— the electrode containing 3-nitro-*o*-xylene as a plastifier provides the advantage of a larger concentration range of the linear response yet it offers a short operating time.

— electrodes with dibutylphthalate and diisooctylphthalate, respectively, provide linear response in a somewhat more restricted concentration range offering, however, the advantage of a much longer operating time than the electrode with 3-nitro-*o*-xylene.

— potassium-sodium selectivity of all three types of developed electrodes is good. Particular mention is made of the fact that Ca^{2+} and Mg^{2+} ions do not practically disturb the electrode functioning. Therefore, the electrodes have a high potassium-calcium, and potassium-magnesium selectivity, respectively.

The electrodes obtained and studied may be successfully used in the determination of potassium with sodium or calcium tetraphenylborate, by potentiometric titration.

APPLICATION OF NIOBIUM POLAROGRAPHIC REDUCTION IN HYDROCHLORIC ACID-THIOCYANATE MEDIUM TO THE ANALYSIS OF FERRONIOBIUM ALLOYS

SOFIA MARCHIDAN
Centre of Physical Chemistry, Str. Galaţi 31, Bucharest, Romania

Received January 31, 1974

A polarographic method for the determination of niobium concentration in the presence of iron is described. The average value polarographically obtained for niobium content differs by + 0.59 % from the given value by chemical analysis. The developed method is fairly rapid, accurate and very suitable, since it may be applied directly, in the presence of the other alloy constituents (Fe, Ti, Si, Al, Cr, Ta etc.) without preliminary separations.

In the production of alloyed steels with niobium addition, ferroniobium alloys containing also other elements (Ti, Si, Cr, Al, Ta, etc.) in lower concentration are used rather than pure niobium. The polarographic reduction of niobium in HCl-thiocyanate-acetone medium has been applied to the determination of niobium concentration from the above mentioned alloy, without preliminary separations.

1. GENERAL CONSIDERATIONS

In a previous paper,[1] iron interference in the polarographic determination of niobium with thiocyanate has been described.

Experiments performed for the same niobium concentration ($2 \cdot 10^{-3}$ M), but variable iron concentrations, have shown that the height of niobium reduction wave decreases with the increase in iron concentration (figure 1, curve *1*), and the results are not quite reproducible.

Similar effects have also been met with other niobium concentrations. All these results suggested that it is not possible to obtain a suitable and quite precise method for niobium determination in the presence of iron, because of the following :

— the iron concentration in the sample should be determined beforehand ;

— the height of niobium wave strongly and nonlinearly decreases with the increase in iron concentration ;

— a two-dimensional regression analysis is needed which complicates the calculations.

---

[1] S. Marchidan, C. Drăgulescu and Gh. Facsko, *Rev. Roumaine Chim.*, **16**, 399 (1971).

When a large amount of titanium trichloride is added[2] the wave height, at the same niobium concentration, is much less sensitive to iron concentration and, beginning with the ratio Fe : Nb = 1 : 1 up to the maximum studied ratio of 5 : 1, it remains practically constant (figure 1, curves *2–4*).

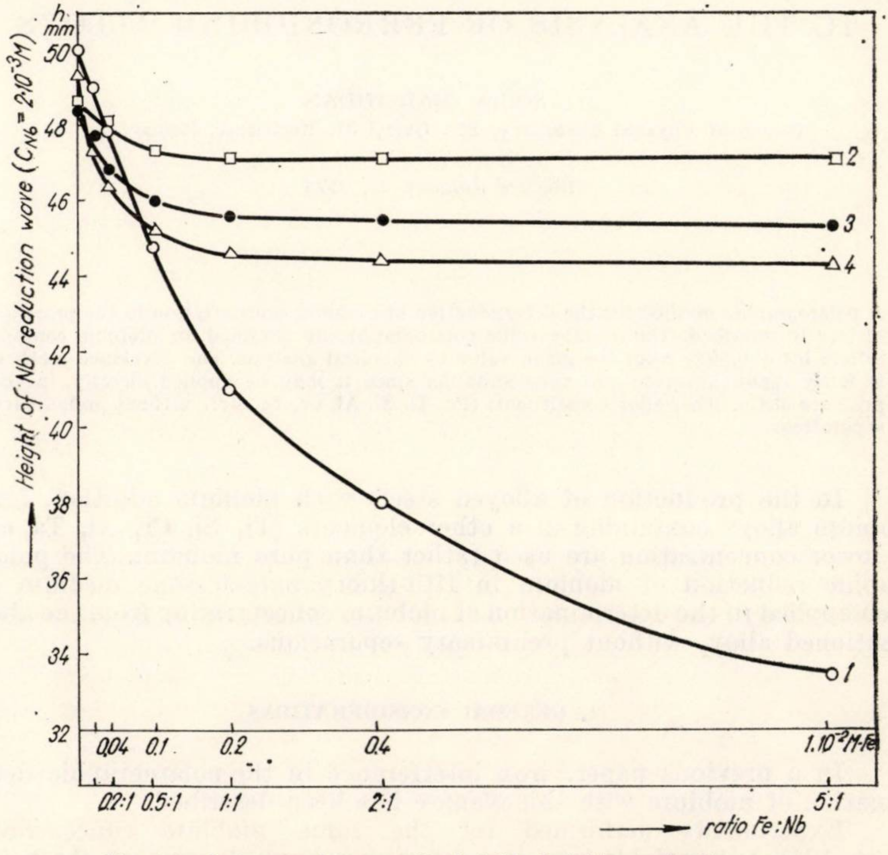

Fig. 1. — Influence of iron on the height of niobium reduction wave.

1 ; without $TiCl_3$ addition ; *2–4*, with $TiCl_3$ addition ; *2*, hydrochloric acid solutions without tartaric acid addition ; *3*, tartaric acid solutions 0.05 M ; *4*, tartaric acid solutions 0.2 M.

Although this effect of titanium trichloride addition does not completely remove iron interference, it shows that the previous determination of iron concentration is no longer needed, provided that, an iron excess is ensured (Fe : Nb ratio ⩾ 1 : 1) in Nb + Fe solution.

In tartaric acid solution (obtained from a niobium standard solution in tartaric acid, which is stable and very easy to prepare), the polarographic wave height of niobium, within the Fe : Nb = 1 : 1 ÷ 5 : 1 range, is smaller than the wave height of pure niobium standard. Obviously this fact has a slight influence upon the sensibility.

---

[2] S. Marchidan, C. Drăgulescu and Gh. Facsko, *Rev. Roumaine Chim.*, **16**, 813 (1971).

Additional experiments have been carried out in order to find out the conditions under which this decrease of the wave height is minimum. Thus, the influence of tartaric acid concentration was studied. Although the presence of tartatic acid does not affect the wave height of pure niobium standard solution,[3] it was found that in the solution containing both niobium and iron, the diminution percent of niobium wave height *versus* pure niobium standard, decreases with the decrease of tartaric acid concentration (figure 1, curves *3* and *4*), reaching a minimum value of about 3% in its absence (curve *2*).

When tartaric solutions are used, in order to increase the sensibility, it is recommended that the tartaric acid concentration should be as low as possible while for reproducibility reasons this concentration should be the same in both standard and sample.

The height of niobium reduction wave, in the presence of titanium trichloride and of a suitable iron excess at the same tartaric acid concentration, does not depend on iron concentration and allows niobium determination from ferroniobium alloys.

This problem can be solved in two different ways.

a) The influence of iron in the presence of titanium trichloride (and several tartaric acid concentrations) at different niobium concentrations should be studied by experiments similar to those described above, in order to find out whether or not a range of common values exists for the Fe : Nb ratio in which the wave height does not depend on iron concentration. Further on, if such a range exists, it must be verified by regression analysis whether these heights follow or not a linear dependence on the niobium concentration. If a linear dependence is found, a method may be advanced for niobium determination in the presence of iron, using the calibration graph and a statistic calculation of experimental data which will give the equations for the concentration estimation, standard deviation and confidence interval. If the dependence is not linear, the precision of such a method would be considerably lower.

b) A method can be advanced based only on the experimental results obtained in the studies of iron influence on the reduction wave of niobium in the presence of titanium trichloride at one niobium concentration ($2 \cdot 10^{-3}$ M). This concentration is in the middle of the linearity range found for the pure niobium standard[4,5] and for which all the interference studies were carried out.[1,2] This method only implies finding that aliquot from the stock solution which in the same volume, medium and conditions as standard Nb + Fe solution ($C_{\mathrm{Nb}} = 2 \cdot 10^{-3}$ M and Fe : Nb$\geqslant$1) will give a wave height whose difference *versus* standard should not be statistically significant. Thus, in the analysed solution the niobium concentration may be estimated as equal to that of standard and, the aliquot being known, the niobium percent in the sample is obtained by a simple calculation.

---

[3] C. Drăgulescu, S. Marchidan and Gh. Facsko, *Rev. Roumaine Chim.*, **14**, 737 (1969).

[4] S. Marchidan, Gh. Facsko and C. Drăgulescu, *Rev. Roumaine Chim.*, **12**, 635 (1967).

[5] C. Drăgulescu, S. Marchidan and Gh. Facsko, *Rev. Roumaine Chim.*, **14**, 1501 (1969).

In order to determine niobium concentration in a ferroniobium alloy, we have chosen this second procedure which is much simpler.

2. DETERMINATION OF NIOBIUM CONCENTRATION IN A FERRONIOBIUM ALLOY

Table 1 presents the heights of niobium reduction wave, *h*, (for hydrochloric or tartaric acid standard niobium solutions) in HCl-thiocyanate-acetone medium for values of Fe : Nb ratios ranging between 0 : 1 and 5 : 1 at the same niobium concentration of $2\cdot10^{-3}$ M. Curves 2 and 3 in figure 1 represent the averages of these values.

Table 1

Influence of iron on the height of niobium reduction wave ($C_{\mathrm{Nb}} = 2\cdot10^{-3}$ M)

Ratio Fe :Nb	Niobium hydrochloric standard solution		Niobium tartaric standard solution	
	h (mm)	$\bar{h}$ (mm)	h (mm)	$\bar{h}$ (mm)
0 :1	49.0	48.7	49.1	48.7
	48.8		48.3	
	48.4		48.6	
0.2 :1	48.3	48.1	46.8	46.8
	48.1		47.0	
	47.8		46.7	
0.5 :1	47.6	47.5	46.1	46.1
	47.3		45.9	
	47.7		46.2	
1 :1	46.8	47.2	46.0	45.7
	47.3		45.4	
	47.4		45.8	
2 :1	46.8	47.1	46.0	45.5
	47.4		45.3	
	47.0		45.2	
5 :1	47.4	47.1	45.4	45.5
	46.8		46.0	
	47.0		45.2	

The data listed in table 1 were obtained with a pure niobium hydrochloric or tartaric standard solution to which iron was added. It can be seen that for both, hydrochloric or tartaric solutions (concentration of tartaric acid in the final solution for polarographic measurements being the same, that is 0.05 M), the last nine values, corresponding to the ratios Fe : Nb = 1 : 1, 2 : 1 and 5 : 1, do not depend on iron concentration and may be considered as estimations of polarographic wave height of niobium for the interval Fe : Nb = 1 : 1 ÷ 5 : 1 and niobium concentration of $2\cdot10^{-3}$ M.

These values lie around the average of 47.1mm (standard deviation $s_1 = 0.091$) when a hydrochloric standard was used and around the average of 45.6 mm (standard deviation $s_2 = 0.119$) when a tartaric standard was used. The standard deviations were calculated by the equation :

$$s = \sqrt{\frac{\Sigma d^2}{n(n-1)}} \tag{1}$$

where $n = 9$ and d represents the deviation of an individual value from the average value, $\bar{h}$.

In conclusion, at a significance level of 99%, when the Student's variable for $n - 1 = 8$ degrees of freedom is $t = 3.36$, the two confidence intervals are:

$47.1 \pm 0.091\ t = 47.1 \pm 0.3$ for the hydrochloric standard solution

$45.6 \pm 0.119\ t = 45.6 \pm 0.4$ for the tartaric standard solution.

The experiments with mixtures of Nb + Fe standard led to the conclusion that, at a significance level of 99%, a solution of $C_{Nb} = 2 \cdot 10^{-3}$ M and Fe : Nb $\geqslant 1$, will give a polarographic wave height between 46.8 and 47.4 mm when hidrochloric niobium solution was used and of 45.2—46.0 mm with tartaric niobium solution. The very close confidence intervals, within which all the measured waves heights lie, prove a good reproducibility and ensure a good precision.

Once these confidence intervals are known, the following simple procedure for niobium determination in a ferroniobium alloy is advanced. A sample of m grams is weighed and a stock solution is obtained. Then, iron is added so that Fe : Nb $\geqslant 1$. Let V-ml be the volume of solution obtained this way. By some attempts the aliquot part, n-ml, is found which, in the volume, v-ml, used for polarographic analysis, in the same medium and conditions as standard solution, will give a height of polarographic wave placed within the confidence interval of the standard. It results that at a significance level of 99%, niobium concentration in v-ml sample solution may be estimated as being the same, that is $2 \cdot 10^{-3}$ M Nb. Consequently, in the n-ml aliquot there are:

$$\frac{2 \cdot 10^{-3} \times 92.906}{1000} v = 1.858 \cdot 10^{-4}\ v \text{ grams niobium} \tag{2}$$

where 92.906 is the molecular weight of niobium. The percentage of niobium in the alloy was calculated by the equation:

$$\% \text{ Nb} = 1.858 \cdot 10^{-2} \frac{vV}{nm} \tag{3}$$

and for $v = 10$ ml and $V = 100$ ml

$$\% \text{ Nb} = \frac{18.58}{nm} \tag{3'}$$

3. PROCEDURE

The polarographic behaviour of niobium in HCl-thiocyanate-acetone medium has been studied using hydrochloric or tartaric standard niobium solutions; these were prepared by fusing niobium pentoxide with potassium pyrosulfate.[4,5] The interference studies of different cations with the niobium reduction wave were also carried out and checked on synthetic samples containing mixtures of oxides which were made soluble by fusion with $K_2S_2O_7$ and dissolving the melt in tartaric acid.[1,2]

For ferroniobium alloys, as well as for metallic niobium, the method described in the literature consists of dissolution in hydrofluoric acid with or without nitric acid addition, depending on the composition of samples.

A sample of $m = 0.4015$ grams ferroniobium finely ground was weighed in a platinum crucible; then 4–5 ml hydrofluoric acid (40%) and 1–2 ml concentrated nitric acid was added. The crucible was carefully heated until complete dissolution has been reached and then its walls and lid were washed with 1–2 ml hydrofluoric acid. Further heating, close to complete evaporation, was followed by addition of a few drops of concentrated sulfuric acid to ensure the complete removal of silica. Then, 2–3 ml concentrated sulfuric acid was added and heated for a long time up to the formation of SO_3 fumes for complete removal of hydrofluoric acid and nitrogen oxides. After cooling, the sample was dissolved and transferred into a $V = 100$ ml volumetric flask with concentrated hydrochloric acid. At the same time a proper amount of ferric chloride was added to ensure an iron excess in the stock solution. Besides the niobium tartaric standard solution, a hydrochloric one was prepared from metallic niobium of spectral purity (Johnson Matthey) following exactly the same solubilization procedure as for the sample.

The solutions for polarographic measurements were obtained from n-ml aliquot (hydrochloric stock solution, hydrochloric acid, thiocyanate and titanium trichloride solution, acetone) which were pipetted and made up to $v = 10$ ml in volumetric flasks so that the final composition of the medium be optimum [2,4,5] and identical to that used for the standard, that is: $C_{HCl} = 6.0$ M; $C_{NH_4SCN} = 0.60$ M; $C_{TiCl_3} \cong 1.10^{-2}$ M; $C_{acetone} = 20\%$ for comparison with the hydrochloric standard and the same composition plus 0.05 M tartaric acid when

a tartaric standard was used. The working conditions were as previously established, that is $t = 25 \pm 0.1°C$ and the time elapsed from thiocyanate addition to the recording of the polarogram, between 40 and 50 minutes.

By a few preliminary attempts it was found for $n = 0.87$ and 0.88 ml aliqout which gave a height of the reduction wave within the confidence interval (47.1 ± 0.3 in the absence and 45.6 ± 0.4 in the presence of 0.05 M tartaric acid). Equation (3′) was applied and the following niobium percents in the sample were found :

1 a/ *versus* hydrochloric standard : 1 b/ *versus* tartaric standard :

$$\% \text{ Nb} = \frac{18.58}{0.87 \times 0.4015} = 53.19 \qquad \% \text{ Nb} = \frac{18.58}{0.88 \times 0.4015} = 52.60$$

i.e. very close results. This shows that the result of the determination does not depend on the kind of standard (hydrochloric or tartaric) which was used for comparison.

In order to verify these results, three more stock solutions were prepared with different quantities of alloy and following the same procedure as that described above.

Table 2 exhibits the polarographic results in comparison with the data from chemical and spectral analysis of the alloy.

As shown in table 2, the average value obtained for niobium percent, determined by the polarographic method differs by +0.59% from the value certified by chemical analysis, while the individual values differ from + 1.06 to − 0.47%.

It might be concluded that the polarographic method is fairly precise leading to results which are not significantly different from those obtained by chemical analysis. The proposed polarographic method is much more suitable since it may be applied directly in the presence of other alloy constituents, such as Si, Fe, Ti, Al, Cr, Ta etc., without preliminary separations.

DETERMINATION OF LITHIUM IN SILICATE ROCKS AND MINERALS USING A SIMPLE FLAME PHOTOMETER

SHAMSHAD AHMAD KHAN *
Pakistan Council of Scientific and Industrial Research Laboratories, Karachi, Pakistan
and
MAURICE STONE
Department of Geology, University of Exeter, England

Received October 22, 1973

A method is proposed for the determination of lithium in silicate rocks and minerals in the presence of other ions on the solution 'B', obtained after digestion in HF and H_2SO_4 or HF and perchloric acid [1,2] by a simple flame photometer. Interference due to potassium was overcome by the addition of 2000 p.p.m. K_2O (as K_2SO_4) "buffer". The precision and accuracy of this method has been tested by replicate analyses of rocks and standard, by adding known amounts of standards to the sample and by comparing the results with the atomic absorption method. The method is suitable for the rocks containing 95 p.p.m. to 3000 p.p.m. lithium corresponding to 200 p.p.m. to 6000 p.p.m. lithium oxide. This method could easily be incorporated into the analytical scheme of Shapiro and Brannock [1] and Riley[2].

INTRODUCTION

The rapid method described by Shapiro and Brannock [1] and Riley[2] for analysing major and minor elements present in silicate rocks do not provide a method for analysing lithium and as this element also occurs in significant quantities in many of the silicate rocks and minerals, so it was deemed desirable to develop a suitable analytical method for this element. This work was carried out in the Department of Geology, University of Exeter, England.

Lithium in rocks can be determined by gravimetric, [3,4] colorimetric, [5–8] spectrographic,[9] atomic absorption[10] and flame photometric methods.[11-17] « The gravimetric methods are rather slow and time consuming and are less accurate.[5] Both direct and indirect colorimetric methods for the determination of lithium require the separation of lithium from other metals, which makes the method more difficult.[5-8] Although spectrographic[9] and atomic absorption methods[10] are more accurate and sensitive but are very expensive.

Flamephotometric determination of lithium can be carried out in two ways: (i) Flame spectrophotometric and (ii) Flame photometric. Numerous references for flame spectrophotometric methods are cited in literature.[11-17] These are more sensitive owing to the variable slit-width control and monochromatic light source than those using a filter photometer.

As far as the authors are aware a simple filter flame photometer has not been used for the determination of lithium in rocks and minerals.

In this note a method has been designed to determine lithium in the presence of other ions. The method can be applied safely to a concentration range from 200 p.p.m. to 6000 p.p.m. Li_2O corresponding to 95 and 3000 p.p.m. lithium, covering the concentration range given for Diorite, Granite, Nepheline, Aegirine, Lipidomelane[18], Biotite[19] Tourmaline,[20-28] Tregonning-Godolphin Granite complex[24-26] and data given by other workers.[27-28]

EXPERIMENTAL

In all the analytical work on lithium, an E.E.L. flame photometer supplied with a lithium interference filter was used.

EMISSION–CONCENTRATION CURVE

In order to determine the relation between flame emission and concentration of lithium, a series of solutions containing known amounts of lithium was used. These were prepared from a stock solution containing Li_2CO_3 dissolved in dilute hydrochloric acid and diluted to one litre. A graph of the scale reading against concentration of lithium (from 0 p.p.m. — 10 p.p.m. Li_2O) is shown in fig. 1. The relationship is clearly linear and the line passes through the origin.

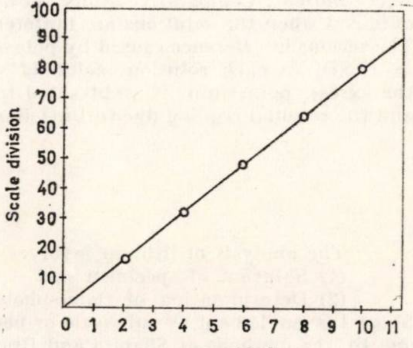

Fig. 1. — A graph of flame emission and concentration of lithium.

INTERFERENCE

A study of the literature shows that calcium, magnesium, sodium and potassium interfere in the determination of lithium by flame-photometry. The extent of such interference was determined by adding known concentrations of cations and anions like, calcium, magnesium, sodium, potassium, iron, aluminium, sulphate, nitrate and chlorate to the standard solution of Li_2O. It was found that some of these are negligible while others cancel out the effect of one another (for reference see tables 5,6,7,8)[29] except that a serious interference is caused by potassium [25] which was investigated by adding 10,25,50,100,150 and 200 p.p.m. K_2O, corresponding with 1.0, 1.25, 2.5, 5.0 and 10.0 percent K_2O in the rock, to standard solution of Li_2O. The measurements are made with and without 2000 p.p.m. K_2O "buffer". The comparative results are given in table 1. These gave differences of 5,10,15,25,30 and 35 scale division corresponding with 0.66, 1.33, 2.0, 3.3, 4.0 and 4.6 p.p.m.Li_2O, respectively, equivalent to 0.033, 0.066, 0.1, 0.16, 0.2 and 0.23 per cent Li_2O in the rock, as indicated in table 1. It is quite clear from table 1 that interference by potassium is very serious when the solutions are not "buffered" by 2000 p.p.m. K_2O.

10 p.p.m.K_2O without buffer (i.e. without 2000 p.p.m. K_2O) gave a reading of 5 scale divisions, corresponding to 0.66 p.p.m. Li_2O and 100 p.p.m. K_2O gave a reading of 25 scale divisions, equivalent to 3.3. p.p.m. Li_2O, while the same 100 p.p.m. K_2O in the presence of 2000 p.p.m. K_2O "buffer" gave a reading of only 1.5 scale divisions. This is quite small, and virtually linear, so that it can readily be corrected graphically.

Table 1

The interference due to potassium with and without 2000 p.p.m. K_2O "buffer"

Without 2,000 p.p.m. K_2O					With 2,000 p.p.m. K_2O

REMOVAL OF INTERFERENCE DUE TO POTASSIUM

Attempts were, therefore, made to remove interference from potassium by precipitation and solubility methods.[5] These were proved not satisfactory and time consuming. Some organic reagents like picric acid and tartaric acid were tried; these also proved failure as lithium was also coprecipitated. Attempt was also made to overcome the interference due to potassium, an amount of K_2O equivalent to that present in a suit of rock was added to the standard and blank, the rocks were analysed for lithium and the same rocks were analysed using 2000 p.p.m. K_2O "buffer". Comparative study shows that higher and probably more accurate results are obtained when the solutions are buffered with 2000 p.p.m. K_2O (for reference see table 12).[29] The serious interference caused by potassium was finally overcome by adding 2000 p.p.m. K_2O as K_2SO_4 to each solution including sample, standard and blank. The reading caused by the excess potassium is subtracted from the total reading due to potassium and lithium, and the residual reading due to Li_2O alone, are plotted graphically,

METHOD

The analysis of lithium involves two stages :

(1) Solution of specimen and

(2) Determination of flame-photometry.

Stage I is carried out by sulphuric or perchloric acid digestion with hydrofluoric acid according to the methods of Shapiro and Brannock [1] and Riley. [2] Analysis of lithium, therefore, is performed on "Solution B" of these authors.

1. *Apparatus*.E.E.L. Flame-photometer and lithium filter supplied by E.E.L. Ltd.
2. *Reagents*. All reagents are of analytical grade.

Sulphuric acid Analar. Concentrated 98 percent, sp. gr. 1.84. Stock sulphuric acid 5 N. Dilute about 140 ml of concentrated sulphuric acid to one litre.

Hydrofluoric acid Analar. 40 per cent w/v

Hydrochloric acid Analar. Concentrated, sp. gr. 1.18 and diluted : dilute 1 part of concentrated hydrochloric acid with 5 parts of water.

Nitric acid Analar. Concentrated, sp. gr. 1.42.

Potassium sulphate. Solution containing 10,000 p.p.m. K_2O. Weight accurately 18.5 g potassium sulphate and dilute to 1 litre.

Standard lithium solution. Weigh accurately 0.24 g lithium carbonate (Matthey "specpure"), dried at 110° for 2 hours, add 12.5 ml of 1 :5 hydrochloric acid, and dilute to 1 litre. 1 ml of this solution contains 100 μg Li_2O/ml.

PROCEDURE

Weigh accurately about 0.4 g (0.2g/100 ml when only lithium is to be determined) of powedered rock sample which has been crushed to pass through a 120 mesh sieve, and dried at 100°, into a platinum crucible. Add 15 ml of concentrated sulphuric acid. Cover the crucible with a lid and place it on a water bath. Allow the sample to digest until solution is complete. Remove the lid and reduce the volume to about 3 ml. Add 1 ml concentrated nitric acid. Remove the crucible from the water bath and heat gently on an electric hot plate, until fumes of sulphur trioxide are evolved. Cool, nearly fill the crucible with distilled water, transfer the solution to a beaker, add about 50 ml distilled water, and boil until the residue dissolves. Cool, transfer the solution to a 200 ml measuring flask and make up to the volume with distilled water. Transfer the solution immediately to a polyethylene container.

Pipette 15 ml of the solution into a 25 ml measuring flask, add 5 ml of 10,000 p.p.m. K_2O solution, and make up to the mark with distilled water; prepare zero setting solution by pipetting 20 ml of 10,000 p.p.m. K_2O and 10 ml of 5 $N.H_2SO_4$ into a 100 ml measuring flask and make up to the mark with distilled water.

Pipette 10 ml of 100 p.p.m. Li_2O standard solution into a 100 ml measuring flask, add 20 ml of 10,000 p.p.m. K_2O solution, and 10 ml of 5 $N.H_2SO_4$ and make up to the mark with distilled water.

Turn the sensitivity control of the flame-photometer clockwise to its fullest extent or until the 10 p.p.m. Li_2O standard gives a scale reading of *ca.* 80.

Determine the Li_2O content of the sample by comparing the scale readings with 10 p.p.m. Li_2O standard. Measure the zero and standard before and after taking each reading. Also run a blank solution.

The concentration of the sample solution is adjusted by diluting until it lies within the range of measurement.

Calculations

$$\% \, Li_2O \text{ rock} = \frac{\text{Scale reading of unknown}}{\text{Scale reading of standard}} \times 5/3X0.5/10$$

(On the basis of 0.4 g. rock sample, dissolved in 200 ml of distilled water and 15 ml of this sample solution diluted to 25 ml)

RESULTS AND DISCUSSIONS

The proposed method has been tested thoroughly for its precision and accuracy. Precision is obtained by replicate analyses and accuracy by analysing the standard firebrick N° 315, but much of the test of accuracy is dependent upon the "addition method", because in the author's opinion the addition method is superior or equal to that method which uses standard as a means of testing accuracy. Besides the analysis of standard firebrick, (B.C.S. N° 315) the results have also been compared with the atomic absorption method.

A variety of silicate materials has been analysed. These range from tourmaline, pelite and firebrick, on the one hand, and more acid members, including elvans and granite on the other hand. The granite includes both biotite-bearing and "lithionite"-bearing types.

PRECISION

Replicate analyses of Pelite and Granite

Analyses of a variety of rocks have been carried out. Each rock (including two "lithionite" granites, a pelitic state and pelitic hornfels) was analysed at six different times, i.e. the whole batch was determined on six separate occasions (for reference, see tables 13, 13A, B, C, D, and E)[29]. A summary of all the data is given in table 2. The data are also compared to the data reported by earlier workers and to those provided by the atomic absorption method, shown in table 2A. Close results have been obtained, which shows that the method has good precision.

ACCURACY

Accuracy of this method has been tested by the following three methods.

a) ANALYSIS OF STANDARD
(B.C.S. N° 315, Firebrick)

The results of eight analyses (consisting of 22 determinations) of B.C.S. N° 315, Firebrick are shown in table 3, and the results are compared with the data obtained by eight different analysts listed in the certificate supplied by the Bureau of Analysed Samples, Ltd.

The two sets of data agree reasonably well, and standard deviations and errors are similar, which confirms the accuracy of the method.

Table 3

The analysis of B.C.S. N° 315, Firebrick

Result : 0.09 % Li_2O

B.C.S. – Bureau of Chemical Standards

b) ADDITION METHOD

The accuracy of the method has been further tested by the addition of known amounts of lithium (i.e. 4 p.p.m. Li_2O) to standard firebrick. The results have been calculated on the average scale division of sample and standard. A 0.312 scale division has been substracted from the scale division of firebrick due to K_2O present in firebrick. The data are given in table 4. This shows a satisfactory recovery of lithium which further confirms the accuracy of the method.

Table 4

The analysis of B.C.S. N° 315, Firebrick by the addition method (i.e.4.p.p.m. Li_2O. standard was added to firebrick and recovered)

+							
Firebrick	—	44.75	0.312	44.45	5.2	0.4334	—
Firebrick	—	9.9	0.312	9.59	1.1	0.091	—

Result : 0.09 % Li_2O

c) COMPARISON OF THE RESULTS WITH THE ATOMIC ABSORPTION METHOD

Two rocks, namely slate (WA_3) and hornfels (025a) have been analysed by this method as well as by atomic absorption spectra (Hilger and Watts AA2 atomic absorption spectrophotometer) method. The comparative results given in table 2A, which are fairly close to one another, show that the method is accurate.

SUMMARY AND CONCLUSIONS

60 determinations have been made in all for 24 different silicate rocks and minerals which include granites, tourmaline, slate, firebrick and other rocks containing 95 p.p.m. – 3000 p.p.m. lithium.

This method has been tested for its precision and accuracy by replicate analyses, by comparing the results with the results obtained by earlier workers and by the atomic absorption method, by analysing standard firebrick N° 315 and by adding known amounts of Li_2O standard to firebrick as well as to rocks. The results, standard deviations and standard errors are similar to the earlier results and data obtained with the firebrick and atomic absorption method. The recovery of the known added standard is satisfactory and the results are within the expected range and are reproducible.

The main advantage of this method is that lithium can be determined satisfactorily and rapidly in the presence of other ions and the serious interference caused by potassium can be overcome by adding 2000 p.p.m. K_2O "buffer" to the sample, blank and standard.

The method is sensitive, cheap, simple and rapid and can be applied to the determination of lithium in silicate rocks and minerals.

The method can be fitted in the scheme for analysing rocks and minerals provided by Shapiro and Brannock[1] and Riley.[2]

The authors wish to thank technical staff, Mr. J. Sanders, Mr. Raymond Ellis and Mr. Willmington in the Department of Geology, University of Exeter, England. In particular, thanks go to Professor Scott Simpson for providing facilities and for help at many stages.

COMPTES RENDUS

J. JORTNER, N. R. KESTNER. *Electrons in fluids.* Springer Verlag, Berlin, Heidelberg, New York, 1973, 485 p.

This volume provides a record of the lectures, communications and discussions that took place at colloque Weyl III. The original aim of this colloque was to contribute to the understanding of metal-ammonia solutions. Colloque Weyl III extended the scope to include related works on electrons in polar and non-polar liquids and in dense fluids, the electronic states of disordered systems and the metal-insulator transition, thus the chemical and physical properties of electrons in fluids from a general point of view.

In the first article recent model calculations of an electron in a polar fluid are reviewed with primary emphasis on electrons in ammonia and water. These static calculations are compared with each other and with experimental data. These models are capable of explaining qualitatively and in most cases, quantitatively, the effects of variables such as temperature, pressure, molecular structure and density of the solvent. On this theoretical basis, brief qualitative statements about electrons in polar vapours, in solutions of higher metal (and electron) concentrations and in a wide variety of fluids, are made.

The articles concerning the dilute region of metal-ammonia solutions discuss their physical properties, the effect of electrolytes on the hydrogen-bonded structures of liquid ammonia, the nuclear spin relaxation phenomenon, the cases of the proton and nitrogen in these solutions, the chemical equilibria between anions and the ammoniated electron. It is well known that the decomposition of solutions of metals in ammonia is limited by the reverse reaction between the amide ion and hydrogen gas leading to the formation of solvated electrons. In the title paper is shown that such an equilibrium may exist between other anions and the solvated electrons in the presence of hydrogen.

A following paper reviews the most recent studies of metal solutions in amines and ethers, rich in information about distinguishable species. By studying the behaviour of these species as a function of temperature, solvent and metal, it has become possible to identify their stoichiometry and to measure some of their properties.

Some articles are devoted to ultrafast optical processes. Those of the order of 10^{-12} sec can be studied experimentally with picosecond pulses generated by lasers. Informations on solvated and quasi-free electrons obtained from photoelectron emission spectroscopy are also discussed. In the determination of the near infrared spectrum of the solvated electron in liquid ammonia, an anomaly, evidenced by a large transparence of the solutions, has been observed at wavelengths corresponding to the bands of ammonia in the 1500–2300 nm region. This anomaly appears in the presence of relatively high concentrations of KNH_2 and large hydrogen pressures. The increase of the anomaly with the concentration of the solvated electron suggests the formation of a complex between $\bar{e}$, KNH_2 and a certain number of ammonia molecules strongly linked so that they do not participate in the vibrational modes corresponding to the quoted wavelengths.

Studies of Raman spectroscopy of metal-ammonia solutions using a laser Raman spectrometer and infrared spectroscopy of the solvent are also reported.

A brief review is made of current understanding of the electronic structures of disordered materials. The basic band model for disordered materials is introduced and used to explain the basic experimental facts about amorphous semiconductors. The history of localization theory, which gives the formal justification of the basic band model is then reviewed and its present status assessed. Remarks are made on the relevance of these considerations for the theory of metal-ammonia solutions.

Some papers concern concentrated metal-ammonia solutions. A review is made of the properties of concentrated solutions. Comparison of transport and magnetic effects suggests that the temperature dependence results from density-of-state effects. Interpretation of these phenomena is given in terms of a model based on the assumption that solutions were composed of solvated ions, nonsolvating NH_3 molecules and free electrons.

Nuclear magnetic resonance studies of cesium-ammonia solutions as well a :conductivity measurements in the frequency range 0–70 GHz are also presented. Another article relates the strange magnetic behaviour and phase relations of metal — ammonia compounds of lithium, calcium, strontium and barium. The magnetic susceptibility has been measured down to 1.5 K; phase structure and ESR studies under pressure are indicated.

In another note the system $M'-NH_3$ (M' = metallic chalcogenide) has been studied. Based on the theory of electron donor-acceptor complexes it is assumed that the intermolecular forces between the crystalline layer material and small intercalate molecules are due to dispersion and charge transfer interactions.

An interesting discussion concerns the existing data and thermoelectric power of potassium, cesium and mercury, as a function of the density at supercritical temperatures, as well as a relation between the thermodynamic phase transition from a dense liquid to a low density vapour and the metal-nonmetal transition.

The volume includes interesting large reviews of the studies devoted to mobility of excess electrons in nonpolar hydrocarbons and to optical absorption spectrum of the solvated electron in ethers and in the binary liquid system.

On the whole, the different topics of the volume concern inorganic chemistry, theoretical chemistry, physical chemistry of fluids, theoretical physics, physics of fluids, radiation chemistry, solid state physics. This full and up-to-date account reveals the interrelationships between the chemistry and physics of electrons in disordered media in a variety way that appears to physicists as well as to chemists. The interdisciplinary nature of this field and related areas is clear from the range of contributors, which includes both theoretical and experimental chemists and physicists.

Florica Popea

M. FLORESCU, *Twenty Years of Progress in Socialist Romania's Chemical Industry*, Meridiane Publishing House, Bucharest, 1973, 300 p., 97 tables

The development of the Romanian chemical industry and the outstanding progress recorded particularly in the last 20 years have been thoroughly and comparatively presented in this book. The book is perfectly documented and contains over 90 tables providing significant data on the present and long-range development of the Romanian chemical industry, and also 8 figures illustrating the trends and use to great advantage of some raw materials. The book is also of a particular value owing to the fact that its author, engineer M. Florescu (corresponding member of the Academy of the Socialist Republic of Romania) is the Minister of the Chemical Industry.

The book includes a number of 11 chapters which review the Romanian chemical industry since its beginnings up to the future development plans. The book also reviews the related activities which make a direct and decisive contribution to its successful development (education, research, etc.)

Thus the first three chapters review stringent aspects of Romania's economic conditions between the two World Wars, the early stages of the chemical industry and the more important results obtained before World War II. The author makes an in-depth analysis of the situation considering that the formation of the chemical industry cannot be separated from the economic problems, the social aspects and primarily the political aspects of Romania.

After the end of the war and the take-over of the industry by the State, the Romanian people, determined to turn to account natural resources for its own benefit, has started the country's industrialization. These aspects are presented in Chapter 4 which shows that industrialization is the main objective of a modern economy.

From the 5-th chapter on, the author presents the modern Romanian chemical industry, the main technical-economic indices and the ways of reducing the production cost price. Figures illustrate the investments made in the chemical industry, the foreign trade of chemical products and the targets for the years 1971–1975. The main sub-branches of the Romanian chemical industry (Chapter 6) hold a major place in the book and refer to: inorganic chemical industry (chlorosoda products, sulphuric acid, etc.), chemical products for agriculture (fertilizers, pesticides and biostimulators), the plastic and synthetic resin industry, the synthetic fibre and yarn industry (Relon, Melana, Terom, etc.), the rubber industry, the varnish, paint and printing ink industry, the dye and organic pigment industry, the drug industry and last but not least, the building industry of equipment, fitting, pumps and measure- and control apparatus necessary for the chemical industry.

As shown above, the author places a special emphasis, in chapters 7 and 8, on the training of the labour force necessary for this industry and on the fact that scientific research is the main factor in the development of the chemical industry. Data are provided on the secondary and higher education in this field and on the manner in which the higher education will secure the specialized staff required.

The book presents the traditions of the Romanian school of chemistry, it recalls the names and activities of brilliant pioneers of the Romanian chemistry and also the early research activity. Similarly, the book presents technological or applied research units and basic research units pointing to their close cooperation relations. Chapter 8 ends by a review of the long-range development of research in the field of Romanian chemistry.

Chapter 9 deals with the organization of technological design while Chapter 10 elaborates on the use of electronic computers in the chemical industry (automation, modelling, data processing and systems, etc.).

The last chapter points to the ways and means for the future development of the Romanian chemical industry. Figures indicate the production values and the types of new materials for each separate sub-branch. The book concludes with some final thoughts of the author's.

D. I. Marchidan

D. A. ARMITAGE, "*Inorganic rings and cages*", Edward Arnold. (Publishers), Ltd., London, 1972, X+ 388 p.

This book deals with some very important aspects of modern inorganic chemistry, one of those interdisciplinary fields, which border apparently unrelated topics, in this case metal-organic chemistry, coordination chemistry, non-metal and non-transition metal chemistry. The formation of cyclic compounds, thought before as characteristic only of organic chemistry, appears now as an important feature of inorganic chemistry as well. The formation of polycyclic systems, known as "cage structures" is more typical of inorganic chemistry.

The book reviewed is a very readable presentation of the subject. It is intended to serve as a source for final year courses, but it is more than that and it is a very useful guide to the literature of inorganic rings and cages, giving the interested reader carefully selected examples and references to illustrate the ability of elements other than carbon to form ring systems, and sufficient details to suggest the full scope of the field.

The introduction clearly defines the aims and the scope of the book. Rings containing carbon (e.g. chelates) or non-metal heteroatom organic systems, transition-metal clusters and bridged complexes, were not treated. These topics do not realy pertain to the subject and in many cases are already treated in other monographs. Including such topics would have produced not only a much larger book, but a very unhomogeneous one. The careful selection of the material allows a clear delimitation of the field, which, however, borders various branches of organic and inorganic chemistry.

The book has an Introduction and seven chapters, plus Formula Index, Specific Index of Compounds and General Index. Chapter 1 (p. 1—7) deals with rings containing alkali-metals (e.g. in alkoxides, amides, etc.). Chapter 2 (pp. 8—40) discusses rings of beryllium and magnesium (including inorganic salts; hydrides; amides, alkoxides and organo-derivatives). Chapter 3 (pp. 41—151) is necessarily very comprehensive and deals with derivatives of the Group III elements (among which boron hydrides; carboranes; borazines and other boron-nitrogen compounds; phosphino and arsino-borines; borates and boroxines; cyclic sulphur and halogen derivatives). Another extensive chapter is Chapter 4 (pp. 152—265), discussing the ring systems of Group IV elements (cyclopolysilanes, -germanes, -stannanes; cyclosilazanes, cyclosiloxanes and related germanium and tin derivatives; sulphur-containing rings of the same elements). Chapter V (pp. 266—337) presents the rings made up of Group V elements (important topics covered are cyclopentazoles; cyclopolyphosphines and -arsines; cyclophosphazanes and cyclophosphazenes; cyclic oxygen and sulphur derivatives). Chapter 6 (pp. 338—360) is devoted to sulphur, selenium and tellurium rings (the main topics being element allotropes and sulphur-nitrogen compounds). A shorter Chapter 7 (pp. 361—363) mentions some cyclic interhalogen compounds.

A total of some 1400 references (published up to December 1970), some of them included in Appendixes to each Chapter, give the interested reader the key to more detailed information. Apparently, all important reviews are quoted; therefore, the reader can either be satisfied with the selection of the literature given by the author, or go further to the full literature, which can be recovered through these reviews.

The book is warmly recommended to anyone interested in getting a picture of a modern branch of inorganic chemistry, which did not receive the deserved attention until rather recently. This is a very useful, well-balanced, interesting presentation of the subject, and it does a good service to the field.

Ionel Haiduc

K. DIMROTH, "Phosphorus—Carbon Double Bonds" Fortschr. Chem. Forsch., **38**, 1973, Springer—Verlag, Berlin, 1973, 147 p.

This well-written book is intended to a large community of chemists familiar with those topics as well as to the general scientist who has no adequate background of phosphorus chemistry. The book is divided into three main sections, flanked by an Introduction and Outlook.

The first section is devoted to Phosphamethine-cyanines (13 pages), the second section deals with λ^3—Phosphorins (50 pages) while the third discusses λ^5—Phosphorins (70 pages). In each section the pattern of discussion is the following: Synthesis, Physical Properties, Bonding, Chemical Properties. In addition, an X-ray analysis of Phosphamethine-cyanines is presented and for λ^5 — Phosphorin an Introduction and a Review is given.

This volume gives an exhausted literature coverage of a topic traced back as early as 1964 up to early 1973. The reader will find in this book a model of clarity and conciseness; many spectroscopical discussions are richly illustrated with graphs and tables.

This is a useful reference book for anyone willing to keep abreast with advances in chemistry in general and phosphorus-carbon chemistry, in particular.

M. Gheorghiu

"Absorption Spectra in the Infrared Region", L. Lang Ed., S. Holly and P. Sohár, collaborators, Akadémiai Kiadó, Budapest, 1974, vol. 1, 320 p.

This is a collection of 300 spectra of familiar compounds and of other compounds recently synthesised by Hungarian workers, published between 1962—1970. The compounds were selected in keeping with research problems and developments in the chemical industry e.g. pharmaceutical, petrochemical, plastics and dyes.

Spectra are given in the range of 4000—400 cm^{-1}, mostly in KBr, few in CCl_4 or pure. Each spectrum is accompanied by structural and empirical formulae, molecular weight, melting point, n_D, sample, concentration, cell length, solvent and the equipment used, in this case a UR—10 spectrophotometer.

A subject index, formula and author indexes and bibliographic references are appended.

Excellent graphic presentation.

Prof. Lang was the Editor of the very successful "Absorption spectra in the ultraviolet and visible region". This new series dedicated to the IR spectra is welcomed by the community of chemists, therefore we recommend this book as a useful tool in any laboratory of organic chemistry.

We are looking foreward to the next volumes.

M. Gheorghiu

G. VARSÁNYI, "Assignments for Vibrational Spectra of 700 Benzene Derivatives", Vol. 1 and Vol. 2, Akadémiai Kiadó, Budapest, 1973, 668 p.

The present book is the result of a systematic study on vibrational spectra of benzene derivatives carried out by the author, professor of physical chemistry at the Technical University, Budapest. It has facilitated assignement of the vibrational spectra of several hundred benzene derivatives, eliminating the frequent errors occurring from analogies with aliphatic compounds spectra for aromatics.

The book is of great value to the practical analyses of vibrational spectra of aromatic compounds.

The principles of the general treatise are based on an earlier book of the author's "Vibrational Spectra of Benzene Derivatives", published by Akadémiai Kiadó, Budapest, and Academic Press, New York and London in 1969. Volume 1 begins with a brief theoretical discussion of the subject (25 pp), followed by vibrational assignment tables for all of the 700 compiled compounds. Volume 2 consists of a collection of infrared spectra of a great number of benzene derivatives.

In analysing normal vibrations of benzene derivatives, the author refers to tangential vibrations (C—C stretching, C—X and C—H in-plane bending), radial vibrations (radial skeletal, C—X and C—H stretching) for both light and heavy substituents, as well as out-of-plane vibrations (skeletal, C—X and C—H out-of-plane). The discussion is based on normal coordinate calculations performed by different authors for various benzene derivatives. A table listing the characteristic frequencies of the internal vibrations of substituents and the types of vibrations in chemical sequence (hydrogen, carbon, halogens, oxygen, nitrogen, sulfur, other heteroatoms) concludes the volume.

Tables containing the assigned vibrational spectra of various benzene derivatives make up the bulk of vol. 1 (approx. 400 pages). Seven hundred benzene derivatives are listed according to the increasing number of substituents. For derivatives having the same number of substituents, the order is defined by structural isomerism. These tables systematize unavailable information on the vibrational spectra of this large group of compounds, grouping them not only by the type of substitution but also by electron structure and mass of substituents.

The tables for each group of derivatives, designated by the same group number, are preceded by a Summarizing Table giving both possible frequency regions of the vibrations corresponding to the thirty normal modes of benzene and approximate vector diagrams of characteristic normal vibrations. The group number, defined on p. 33, is very useful for the reader to rapidly locate the spectrum of a compound. The specific designation of group numbers for all investigated compounds is listed on pp. 41—42.

Each table provides information on : *a*) vibrational frequencies (infrared bands and Raman lines), measured or calculated theoretically, in cm^{-1}, together with their serial numbers according to Wilson, *b*) characterization of infrared bands or Raman lines intensity as "strong", "medium", "weak", etc. *c*) polarization properties of Raman lines, if available, *d*) corresponding literature references and *e*) references to the spectra presented in vol. 2.

However, as the author himself remarks, "the assignments in the Tables are in many cases only tentative, [...] the main purpose of the present compilation being to help further research in this field."

Volume 2 consists of a collection of infrared spectra of benzene derivatives (transmission in % *vs.* cm^{-1}), recorded in Hungary on Perkin-Elmer 457, and Zeiss-Jena UR 10 and UR 20 spectrometers. The group number accompanying each spectrum establishes the connection with the detailed assignment tables in vol. 1.

An Index of substituents in which the compounds are arranged in the order established in vol. 1, concludes vol. 2, thus helping the reader in efficiently locating the spectra and vibrational assignments for a given compound.

The book may is a valuable tool for organic chemists and other workers investigating the structure of organic compounds or attempting to identify a certain benzene derivative when vibrational spectra are known.

Rodica Beldie

"Origins of Life Chemistry and Radioastronomy", Dr. Lynn Margulis Ed., Springer-Verlag Berlin, Heidelberg, New York, 1973

The book "Origins of Life-Chemistry and Radioastronomy" edited by Dr. L. Margulis, presents the dialogue between eminent scien tists in various research fields, on several aspects of the origin of life on Earth or in the Univers. It is, at the same time, the latest record of the series of conferences devoted to the "Origin of Life".

It is a record of the proceedings of the round table held on the occasion of the 1971 Conference organized by the "Interdisciplinary Communications Program", a NASA-sponsored foundation. Experimental results and the latest discoveries in the field of chemistry, biology, geology, genetics, astronomy, etc., are discussed and new hypotheses on the origins of life on Earth are postulated.

The first part dwells on some aspects regarding identification of amino acids, porphyrines as contamination products, and uptake of carbon oxide or dioxide into reduced organic matter under Martian conditions of high uv fluxes. Such contamination was experimentally attested by Hubbard's works.

Particular emphasis is placed on the energy sources that could largely contribute to the synthesis of organic combinations, starting from the early atmosphere. : the rôle of uv radiations, thunderstorms, shock waves, heat and the geothermal activity. The uv radiations are essential to the synthesis of formaldehyde from hydrogen and carbon oxide as well as to cyanide formation, both as precursors of the prebiotic synthesis. These reactions occurred in the aqueous medium of the seas and oceans or, more likely, in rain drops.

Although cyanide is presumably formed by electrical discharges, it could be synthesized with uv radiations using the hydrogen from H_2S photolysis. Another aspect of the efficiency of u.v. rays is their capacity for releasing almost completely their energy on a surface level, whether that of the ocean, or a solid-liquid or air-solid interface.

The intensity of electrical discharges depends on the evaporated water and quantity of water vapors transferred to the upper atmosphere liable to create appropriate conditions for a thunderstorm. Such conditions were created by the warmth of the early earth which could generate enough water vapors and moisture. An important contribution was made by solar energy and the geothermal activity.

These interdisciplinary confrontations afforded some conclusions on the apparition of organic macromolecular precursors (monomers). Yet, it is still difficult to ascert how these polymers or more complex combinations are being formed in prebiotic conditions. Unfortunately this problem was but little approached so far. An important question is the formation of L-amino acids i.e. of the optical activity of the matter have appeared.

Today's knowledge of the earth crust, applicability of "plate tectonic" discussed in the concluding part of this work enable the understanding of sedimentation processes of outgassing that have determined the particular evolution of the early atmosphere. The presence of ammonia in the early atmosphere, its capacity for absorbing infrared radiations at 10 microns, could prevent the ocean from freezing at the time when the sun radiation was reduced.

It is premature to say if the organic matter has an interstellar origin ; discussions revealed some evidence yielded by radioastronomical investigations whereby over 20 organic molecules have been identified in the interstellar space. The abiotical synthesis or the identification of precursors in meteorites is supported by experimental data, as summarized in 13 tables and 26 figures.

As the editor himself shows "those who are seeking in this book a sure, unequivocal and complete answer about the origin of life will be somewhat disappointed". However, this book remains a stimulus for new investigations in such an extremely complex field with so many unknowns.

The work edited by Dr. L. Margulis is addresed to all those engaged in elucidating the problem of the origins of life on earth : chemists, biologists, geochemists, astronomers etc. That is why we warmly recommend it to the readers.

Victor Bulacovschi

NOTE POUR LES AUTEURS

La *Revue Roumaine de Chimie* publie des articles en anglais, français, russe, allemand ou espagnol. Les auteurs sont priés d'envoyer des articles, notes, communications et comptes rendus inédits.

Les manuscrits seront dactylographiés à deux intervalles. Les tableaux seront dactylographiés sur feuilles séparées, de même que la légende des figures. Les diagrammes seront tracés à l'encre de Chine sur papier calque. Les tableaux et les figures seront numérotés par des chiffres arabes, en nombre strictement nécessaire. Prière de ne pas inscrire les mêmes données dans les tableaux et les figures. Les formules chimiques seront incluses dans le texte ; en outre, elles seront transcrites sur des feuilles séparés. Les auteurs sont priés d'indiquer les caractères italiques (en soulignant les lettres au crayon), ainsi que tout autre caractère spécial. L'ordre des références bibliographiques sera celui de leur mention dans le texte ; le nom de l'auteur sera précédé de l'initiale du prénom ; les publications périodiques seront présentées suivant les prescriptions internationales. Les références seront ajoutées à la fin de l'article ; elles paraîtront comme des notes, au bas de la page. Le texte sera précédé d'un résumé comprenant 15 lignes au maximum.

L'entière responsabilité du contenu des articles appartient aux auteurs. On publie des articles dus aux collaborateurs roumains ou étrangers.

XYLIDINE ISOMERS III[1]

ACID-BASIC PROPERTIES OF XYLIDINES IN THEIR EXCITED STATES

V. E. SAHINI, JOSETTE WEINBERG, C. BENDIC* and MARILENA MILESCU

Centre of Physical Chemistry, Str. Galaţi 31, Bucarest, Romania

*Laboratory of Physical Chemistry, University of Bucharest, Bd. Republicii 13, Bucharest, Romania

Received March 11, 1974

The pK_a values of xylidine isomers in the first excited singlet state are determined using Förster's cycle, the experimental values being compared with the theoretical ones obtained by a SCF – MO calculation. Basic properties of xylidines are also discussed in terms of π-electron densities, frontier electron densities and steric effects.

Acid-basic properties of the molecules in their excited states were the subject of many experimental and theoretical papers.

In connection with this topic, the influence of factors such as electronic structure, effects of donor and acceptor substituents, steric effects and others on pK_a values were investigated.[2-6]

These studies show an increase of the donor or acceptor character of the substituents in the first excited singlet state of the molecules and in this way the decrease or the increase of their basic properties, respectively.[7-9]

The aim of the present paper is to study, in comparison with the fundamental state, the change of the basic properties of xylidines in their first excited singlet state and to correlate it with different structural quantities such as π-electron densities on the nitrogen atom, frontier electron densities and steric effects of the methyl group.

1. EXPERIMENTAL

Xylidine isomers (Schuchardt) were purified by fractional distillation under low pressure.

The acid and basic forms were obtained according to Beale [10] using the aqueous solutions over the concentration range $10^{-3}-10^{-4}$M.

In order to determine the pKa values in the first excited singlet state ($pK_a(s_1)$), we used Förster's cycle [11] for the following reversible reactions

$$R - NH_3^+ \overset{Ka}{\rightleftharpoons} R - NH_2 + H^+ \qquad (1)$$

$$(R - NH_3^+)^* \overset{K_a^*}{\rightleftharpoons} (R - NH_2)^* + H^+ \qquad (2)$$

where R is xylil radical and reaction (2) refers to the lowest excited singlet state of xylidines.

The O–O transition was taken by averaging the frequencies of the first absorption and the respective fluorescence maxima, for both acid and basic forms.

Ultraviolet and fluorescence spectra were recorded by means of a UNICAM SP-800 spectrophotometer and a PERKIN-ELMER 204 spectrofluorimeter.

The results of the absorption and fluorescence measurements are given in table 1.

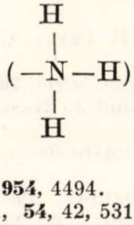
Table 1

Absorption and fluorescence maxima for xylidine isomers

Species		ν_{max} (cm^{-1})				
		2.3–	2.5–	2.6–	3.4–	3.5–
		xylidine				
Absorption Spectra	$R-NH_3^+$	38.168	37.583	37.951	37.951	38.400
	$R-NH_2$	35.524	35.250	35.778	34.904	35.148
Fluorescence Spectra	$R-NH_3^+$	34.843	34.483	34.821	35.142	34.602
	$R-NH_2$	29.658	29.554	30.120	28.736	29.325

2. THEORETICAL

The models generally used for the theoretical treatment of the protonated form, consider either the existence of a charge transfer from the nitrogen atom towards the proton, performed by the formation of a covalent bond



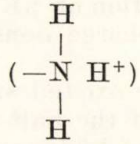
$$(-\overset{\displaystyle H}{\underset{\displaystyle H}{N}}-H)^+$$

---

[10] R. N. Beale, *J. Chem. Soc.*, **1954**, 4494.

[11] Th. Förster, *Z. Elektrochem.*, **54**, 42, 531 (1950).

or the localization of the proton near the nitrogen atom of the neutral molecule



$$(-\underset{\underset{H}{|}}{\overset{\overset{H}{|}}{N}}\ H^+)$$

The latter model gives the best agreement of the experimental data with the theoretical ones.[12]

This model in the SCF–MO method consists in the modification of the Hamiltonian operator due to the effective charge of the proton by a change of the nitrogen ionization potential only.

In order to calculate the O–O transition, for both acid and basic forms, necessary for evaluating the $pK_a(S_1)$ using Förster's cycle, the SCF–MO–PPP method has been used, considering for the protonated form an increase in the absolute magnitude of the nitrogen ionization potential from $W_{2p} = -27.53$ eV to $W_{2p} = -41.55$ eV.[8]

The SCF results were used to calculate the $pK_a(S_1)$ values, π-electron densities and frontier electron densities.

3. RESULTS AND DISCUSSION

The experimental and theoretical values of $pK_a(S_1)$, the π-electron densities on the nitrogen atom, in both the ground q_N and first excited singlet q_N^* states, the frontier electron densities in S_1 state f_N^*, as well as the experimental values of $pK_a(S_0)$[10,13] are presented in table 2.

Table 2

pK_a (S_1) values, π-electron densities and frontier electron densities for xylidine isomers

Isomer	pK_a (S_0) (exper.)	pK_a (S_1) (exper.)	pK_a (S_1) (theoret.)	q_N	q_N^*	f_N^*
2,3-xylidine	4.72	−3.46	−2.68	1.8570	1.6698	0.1910
2,4-xylidine	4.84	—	−7.73	1.8667	1.6824	0.1896
2,5-xylidine	4·53	−3.06	−2.54	1.8570	1.7002	0.2024
2,6-xylidine	3.95	−3.27	−4.50	1.8712	1.6728	0.1984
3,4-xylidine	5.17	−4.75	−6.21	1.8528	1.6786	0.1792
3,5-xylidine	4.91	−4.04	−4.55	1.8433	1.6642	0.1792

The decrease of the basic properties of all xylidine isomers in the excited (S_1) state, is evident for both the experimental and theoretical values of $pK_a(S_1)$ in a quite similar sequences.

---

[12] S. Mataga and N. Mataga, *Bull. Chem. Soc. Japan*, **32**, 511 (1959).

[13] B. M. Wepster, *Rec. Trav. chim.*, **76**, 357 (1957).

This fact was expected since the donor character of the $-NH_2$ group increases in the excited state, leading to a decrease in the value of q_N^*. However, no direct correlation of $pK_a(S_1)$ with q_N^* in xylidine series, is obtained, as not only the charge density accounts for a protonation reaction.

In such a reaction in the excited state, an important contribution arises from the perturbation of the half-occupied levels of the molecule by the unoccupied level of the hydrogen ion.

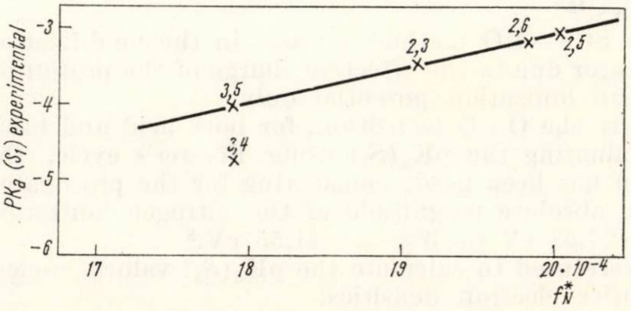


Fig. 1. — $pK_a(S_1)$ values of some xylidine isomers vs. the frontier electron densities f_N^* on the nitrogen atom.

This will be very important when the hydrogen ion level energy will be higher or nearly degenerate in comparison with the energy of the higher half-occupied level of the molecules. In this case the reaction will be a frontier electron density controlled one.[14,15]

In fig. 1 the $pK_a(S_1)$ values of xylidines were plotted against the corresponding frontier electron densities f_N^* on the nitrogen atom in the excited state S_1.

One may notice that for 3.5— ; 2.3— ; 2.6— and 2.5— xylidine, the decrease of $pK_a(S_1)$ is linear vs. f_N^*.

In the ground state, it was possible to divide xylidine isomers into classes according to the steric hindrance due to the methyl groups.

In the S_1 state, the higher frontier electron densities, the higher the π-stabilization energies due to the perturbation of the molecule by the proton.

As the isomers with the methyl group in the ortho and meta positions present the largest f_N^* values, the largest values for $pK_a(S_1)$ are found.

In the case of methyl group in the para position (3,4— and 2,4— xylidine), an appreciable decrease of the basicity in the S_1 state is observed according to the smallest frontier electron densities, as shown in table 2.

RADIOLYSIS OF THE COMPLEX OXALATES IN AQUEOUS SOLUTIONS. IV[1].

THE INFLUENCE OF SOME REDUCING FREE RADICALS SCAVENGERS ON THE POTASSIUM TRISOXALATOCOBALTATE RADIOLYSIS IN AQUEOUS SOLUTIONS

TATIANA MEMETEA and J. PĂUN

University of Bucharest, Radiation Chemistry Laboratory, Bd. Republicii 13, Bucharest Romania

Received December 6, 1973

The radiolysis of $[Co(C_2O_4)_3]^{3-}$ complex ion in aqueous solution in various conditions, the presence and the absence of air, neutral and acid medium and the presence of some reducing species scavengers such as NO_2^-, NO_3^-, N_3^- ions and acetone has been studied. At 2×10^{-3}M concentration the radiochemical yield $G(-[Co(C_2O_4)_3]^{3-}) = 4.96 \pm 0.05$ in the absence of air, and 3.19 ± 0.05 in the presence of air. At the same complex concentration, $G(-[Co(C_2O_4)_3]^{3-})_{pH=1} \doteq 5.62$. In the absence of air the reduction takes place by the reactions with hydrated electron and hydrogen atom. In the presence of air the complex ion is reduced by O_2^- ion.

In previous papers[1-3] we established that in various conditions of irradiation such as dose rate, L.E.T., pH, the concentration of the solution, the radiolysis of potasium trisoxalatocobaltate in aqueous solution obeys a zero order kinetic law. From the interpretation of the experimental data we proposed a general mechanism of the radiolysis.

For a better understanding of the radiolytic process we are reporting in the present paper some results concerning the influence of some reducing species scavengers on the kinetics of the radiation-chemical decomposition of $[Co(C_2O_4)_3]^{3-}$ ion.

EXPERIMENTAL

Potassium trisoxalatocobaltate was synthesized as described in literature.[4] In all the runs we used a constant complex concentration of 2×10^{-3}M. The solutions were prepared with triply distilled water. The substances used as scavengers were of analytical purity.

[4] S. P. L. Sörensen, *Z. anorg. Chem.*, **11**, 1 (1896).

The irradiations have been performed in a Co^{60} equipment of the mobile source type with telemanipulation having the initial activity of 500 Ci and specific activity of 20 Ci/g. The dosimetry was carried out by the chemical method using Fricke dosimeter. The dose rate was in the range from 6.73×10^{18} to 9.12×10^{19} eV/h/g.

The decomposition of the complex in aqueous solution during the irradiation was followed by spectrophotometrical method recording the diminution of the optical density at 420 nm.

The hydrogen peroxide produced during the irradiation was determined spectrophotometrically using the pertitanic acid method reagent and recording the optical density of the solution at $\lambda = 420$ nm ($k = 910\ M^{-1}\ cm^{-1}$).

RESULTS

a) The radiolysis of potassium trisoxalatocobaltate in neutral aqueous solution (natural pH) follows a zero order kinetic law in the presence as well as in the absence of air. In figure 1 is shown the decrease of the optical density of the 2×10^{-3}M complex in aqueous solution during the irradiation, in the presence and the absence of air. The rate of decomposition in the presence of air is lower than in its absence. The decomposition yields at this concentration are: $G(-[Co(C_2O_4)_3]^{3-})_{air} = 3.19 \pm 0.05$; $G(-[Co(C_2O_4)_3]^{3-})_{Ar} = 4.95 \pm 0.05$.

b) In the presence of 0.1N perchloric acid (pH = 1), the radiochemical decomposition of the complex also follows a zero order kinetic law, but the decomposition rate is lower, as shows in figure 1.

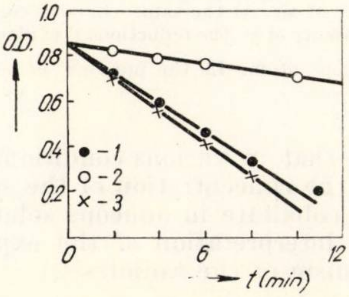

Fig. 1. — The influence of air and pH on the radiochemical decomposition of $K_3[Co(C_2O_4)_3]$ in aqueous solution. Dose rate: 9.12×10^{19} eV/h/g: *1*, absence of air; *2*, presence of air; *3*, absence of air, $HClO_4$ 0.1N.

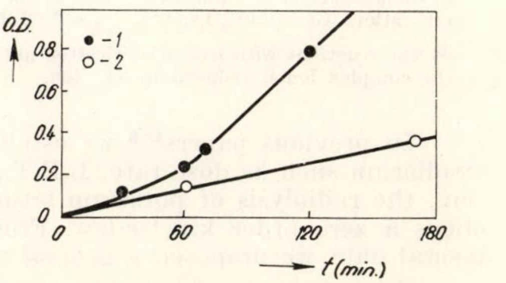

Fig. 2. — The accumulation of H_2O_2 in irradiated solution of 2×10^{-3}M $K_3[Co(C_2O_4)_3]$: *1*, presence of air; *2*, absence of air.

c) The hydrogen peroxide is building up continuously during the irradiation as shown in figure 2 where the optical density of the irradiated solution to which pertitanic acid reagent was added, is ploted against the irradiation time. The radiochemical yields of hydrogen peroxide, $G(H_2O_2)$, in the presence and in the absence of air are identical to those reported for the irradiation of pure water: 3.7 and 0.78 respectively.[5]

---

[5] Z. Draganič, I. Draganič and M. Kosanic, *J. Phys. Chem.*, **68**, 2085 (1964).

d) By adding some reducing species scavengers an appreciable decrease of the decomposition rate of the complex ion appears. We used acetone and NO_3^- ion as selective scavengers of hydrated electron, N_3^- as selective scavengers of H atoms and NO_2^- as scavenger of both reducing species. As the utility of the maleic and ithaconic acid in the radiochemical polymerisation is known some experiments were made in the presence of these acids.

The acetone has an effect of lowering to a great extent the rate of complex decomposition. Figure 3 shows the decrease of the optical density of the irradiated solution as a function of the irradiation time, in the presence of air, the acetone concentration ranging from 10^{-1} to 2M.

The NO_2^- and NO_3^- ions are strongly decreasing the decomposition rate of the complex in the presence as well as in the absence of air. Figure 4 shows the decrease of the decomposition yield of the complex ion as a function of scavenger concentration from 2×10^{-5} to 2×10^{-3}M, in the absence of air. It is noticeable that NO_2^- ions have a higher ability of reducing the rate of decomposition than NO_3^- ions; even at 10^{-4}M NO_2^- ions concentration, the radiochemical yield decreases with 42%, while in the presence of NO_3^- the decrease is 6% only.

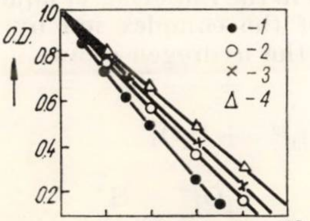

Fig. 3. — The influence of acetone on the radiochemical decomposition of aerated aqueous solution of $K_3[Co(C_2O_4)_3]$: *1*, without scavenger; *2*, acetone 10^{-1} M; *3*, acetone 1M; *4*, acetone 2M.

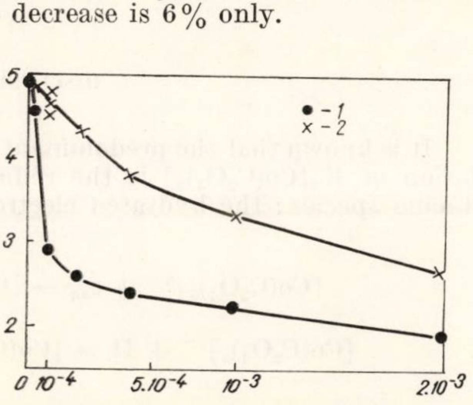

Fig. 4. — The decrease of $G(-[Co(C_2O_4)_3]^{-3})$ with the increasing concentration of (*1*), NO_2^-; *2*, NO_3^- ions

In the presence of N_3^- ions the decomposition rate of the complex diminishes by 40%. Figure 5 shows the optical density of the irradiated 2×10^{-3}M complex solution against time, to which 2×10^{-3} NaN_3, was added.

The effect of maleic and ithaconic acid results in a lowering of the decomposition rate of the complex (figure 6) indicating that these acids scavenge the reducing species.

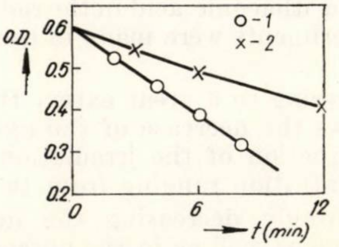

Fig. 5. – The influence of N_3^- ion on the radiochemical decomposition of the complex : *1*, without scavenger ; *2*, N_3^-.

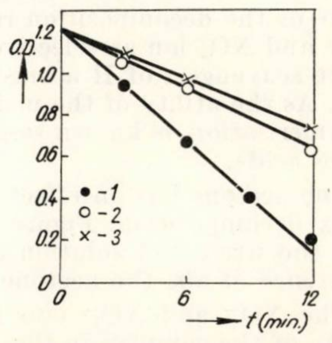

Fig. 6. – The influence of ithaconic and maleic acid on the radiochemical decomposition of $K_3[Co(C_2O_4)_3]$ aqueous solution : *1*, without scavenger ; *2*, maleic acid 10^{-1} M ; *3*, ithaconic acid 10^{-1}M.

DISCUSSION

It is known that the predominant process in the radiolysis of aqueous solution of $K_3[Co(C_2O_4)_3]$ is the reduction of the complex ion by the reducing species : the hydrated electron and the hydrogen atom

$$[Co(C_2O_4)_3]^{3-} + e_{aq}^- \rightarrow [Co(C_2O_4)_2]^{2-} + C_2O_4^{2-} \tag{1}$$

$$[Co(C_2O_4)_3]^{3-} + H \rightarrow [Co(C_2O_4)_2]^{2-} + C_2O_4^{2-} + H^+ \tag{2}$$

In the presence of air, these species are captured by O_2 as reactions (3) and (4) indicate

$$O_2 + e_{aq}^- \rightarrow O_2^- \tag{3}$$

$$O_2 + H \rightarrow HO_2 \rightleftharpoons H^+ + O_2^- \tag{4}$$

As is known, in neutral solution HO_2 radicals dissociate, the product of reaction (4) being the O_2^- ion too. The O_2^- concentration achieved corresponding to the solubility of air in water at room temperature ensures the reduction of the complex ion especially via reaction (5)

$$[Co(C_2O_4)_3]^{3-} + O_2^- \rightarrow [Co(C_2O_4)_2]^{2-} + C_2O_4^{2-} + O_2 \tag{5}$$

The lower value of $G(-[Co(C_2O_4)_3]^{3-})$ in the presence of air suggests that the rate constant of reaction (5) is lower than that of reaction (1).

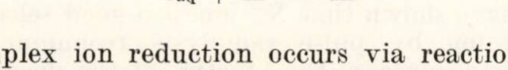
The continuous building up of H_2O_2 during irradiation demonstrates that hydrogen peroxide does not take place in the radiolytic process. The reason for this is that the H_2O_2 concentration is lower than that of $[Co(C_2O_4)_3]^{3-}$ ion, so that the former cannot compete for the reducing species. According to Wormser[6] H_2O_2 does not oxidize the $[Co(C_2O_4)_2]^{2-}$ ion in our conditions.

By irradiation at pH $= 1$ the hydrated electrons are quantitatively converted to hydrogen atoms.

$$e_{aq} + H^+ \rightarrow H \tag{6}$$

so that the complex ion reduction occurs via reaction (2) only. Since the Co^{3+} ion as well as the $C_2O_4^{2-}$ ion are feeble H atom scavengers, it is also expected that $[Co(C_2O_4)_3]^{3-}$ ion reacts with the H atom with a rate constant less than $10^7 M^{-1}s^{-1}$. Recently, Shagisultanova[7] reported for k_2 a value of $4.6 \times 10^6 M^{-1}s^{-1}$, which means that the $[Co(C_2O_4)_3]^{3-}$ ion is a feeble H scavenger. If the complex ions would scavenge quantitatively the hydrogen atoms it should be expected that $G(-[Co(C_2O_4)_3]^{3-}) \cong G_H \cong \cong 3.6$. The value of 5.62 obtained by us indicates that apart from reaction (2) at the reduction of the complex ion some other processes are also taking part from which the most probable seems to be excitation processes involving $[Co(C_2O_4)_3]^{3-*}$ or $[Co(C_2O_4)_2]^{2-*}$. The evidence for the formation of $(M^{II} L_2)^{2-*}$, where M $=$ Co, Ru and L $=$ bipyridyl, in the radiolysis of complex ions $(M^{III} L_3)^{3-}$, has already been given by Pearson[8] and Hart.[9]

In the presence of hydrated electron selective scavengers, besides reaction (1), reactions (7) and (8) are taking place



$$e_{aq}^- + H_3C\,COCH_3 \rightarrow H_3C-\underset{\displaystyle O^-}{\overset{\bullet}{C}}-CH_3 \tag{7}$$

respectively

$$e_{aq}^- + NO_3^- \rightarrow NO_3^{2-} \xrightarrow{H_2O} 2\,OH^- + NO_2 \tag{8}$$

where $k_7 = 5.9 \times 10^9 M^{-1} s^{-1}$ [10] $k_8 = 1.1 \times 10^{10} M^{-1} s^{-1}$.[10]

If the scavenger is the NO_2^- ion, reactions (9) and (10) occur in addition to reactions (1) and (2)

$$NO_2^- + e_{aq}^- \rightarrow NO_2^{2-} \xrightarrow{H_2O} NO + 2\,OH^- \tag{9}$$

$$\mathrm{NO_2^-} + \mathrm{H} \rightarrow \mathrm{NO_2^{2-}\cdot} + \mathrm{H^+} \qquad (10)$$

where $k_9 = 8.1 \times 10^{10}\ \mathrm{M^{-1}\,s^{-1}}$[10], $k_{10} = 1 \times 10^{9}\ \mathrm{M^{-1}\,s^{-1}}$[10].

The inhibition of the complex decomposition rate in the presence of the $\mathrm{N_3^-}$ ion is due to the competing action of this ion with the $[\mathrm{Co(C_2O_4)_3}]^{3-}$ ion for H atoms by reactions (2) and (11)

$$\mathrm{N_3^-} + \mathrm{H} \rightarrow \text{Products } (\neq \mathrm{H_2}) \qquad (11)$$

Czapski *et al.*,[11] have shown that $\mathrm{N_3^-}$ ion is a good selective H atom scavenger, determining by pulse radiolysis technique a k_1 value of $2.7 \times 10^{9}\ \mathrm{M^{-1}\,s^{-1}}$. In our case the kinetics of the decomposition process does not follow a zero order kinetic law, suggesting a more complicated process.

The attempt to make kinetic calculations using our results has been proved difficult, so new experimental data are in progress.

A THEORETICAL INVESTIGATION OF ZIEGLER-TYPE CATALYSIS. II.[1]

SPECIES RELATED TO SOLID TITANIUM TRICHLORIDE

D. R. ARMSTRONG, P. G. PERKINS and J. J. P. STEWART

Department of Pure and Applied Chemistry University of Strathclyde, Glasgow, C. 1

Received December 17, 1973

All-valence-electron self-consistent field calculations are presented for the $TiCl_3$ monomer and the $Ti_2Cl_{10}^{4-}$ anion. The ground-state geometry of the former species is planar and trigonal but the corresponding electronic state is ill-defined and may be either of $^2A_1'$ or $^2E''$ symmetry. The energy levels of $Ti_2Cl_{10}^{4-}$ form groups within which the levels are quite closely spaced. Those adjacent to the bonding-antibonding gap have predominantly 3*d* character and are formed from the "t_{2g}" sets of the individual titanium atoms. A multi-configuration interaction treatment shows the lowest state to be a triplet ($^3B_{3u}$) although a number of low-lying singly- and doubly-excited states do exist which involve the metal-metal interaction. The implications of the electronic structure of $Ti_2Cl_{10}^{4-}$ for that of the solid α $TiCl_3$ catalyst are discussed.

In Part 1[1] we presented a theoretical rationale of the Ziegler catalytic process, augmenting Cossee's scheme[2] and involving molecular catalysts. We now focus on the situation where a solid substance forms the basis of the catalyst system and here investigate theoretically two related species.

In the commercial production of stereoregular high polymers one catalyst in particular, titanium trichloride, together with the co-catalysts triethylaluminium and diethylaluminium chloride, has proved to be very efficient. This and related systems have been the subject of many previous papers.[3]

Single-crystal studies on titanium trichloride have shown that polymer growth occurs at the edges, cracks, and crushed areas of the medium,[4] and these are precisely those areas where exposed titanium atoms are expected to exist. Now the $TiCl_3$ monomer, which also has an "exposed" titanium atom, should be related electronically to isolated points on the catalyst surface. Hence we have carried out a series of calculations on this species to illuminate its electronic structure and formulate a more accurate description of the system.

[3] J. Boor, *Macromol. Revs.*, **2**, 115, (1967).

[4] W. R. Carradine and H. F. Rase, *J. Applied Polymer Sci.*, **15**, 889 (1971).

Titanium trichloride can be obtained by reduction of $TiCl_4$ with $EtAlCl_2$. It exists in three distinct crystalline forms which are well characterised by colour : the α and γ modifications are violet whilst the β is brown.

The α-form is used commercially as a Ziegler catalyst and X-ray structural analysis[5] indicates that in the crystal each titanium is surrounded by an octahedron of chlorine atoms. It would be helpful to be able to calculate directly the bulk solid and surface band structure of the material but its complexity precludes a detailed calculation of this at the present time. Hence as a model for solid α $TiCl_3$, we replaced the lattice by a block of the type $Ti_2Cl_{10}^{4-}$. We believe that the ground-state properties would only be slightly modified by using larger blocks and although the full Brillouin zone between point Γ and other symmetry points cannot be mapped, a reasonable estimate of the electronic band widths should be obtained.

Titanium (III) is a d^1 system and, on crystal field theory, the absorption band of the α form which appears in the visible region should be due to transitions involving the "d" orbitals on titanium. Dijkgraaf and Rousseau[6] have assigned the shoulder in the spectrum at 14,300 cm^{-1} to the Laporto-forbidden $^2T_{2g} \rightarrow {}^2E_g$ transition, whilst the absorption at 18,900 cm^{-1} was attributed to charge-transfer; the latter assignment was based solely on the observed high intensity of absorption. In the context of octahedral titanium, the electronic structure of the chromophoric group $TiCl_6^{3-}$ has also been described in terms of crystal-field theory.[7]

A set of unpaired d electrons, one on each Ti of $TiCl_3$, should show an e.s.r. signal. Solid $TiCl_3$ prepared by reduction of $TiCl_4$ with $EtAlCl_2$ is said to have no unpaired electrons[8], whereas the precipitate and supernatant liquor resulting from the reaction of $TiCl_4$ with $EtAlCl_2$ does show an e.s.r. signal. These results possibly indicate that, as the reaction proceeds, isolated molecules of $TiCl_3$ are formed which rapidly crystallise out as a α $TiCl_3$ and in the latter the "odd" electrons are in some way paired between the titanium atoms.

METHOD

Whereas in Part 1[1] all the molecules studied were of closed-shell type, in the present work we must deal with open-shell systems. Two systems, $TiCl_3$ and $Ti_2Cl_{10}^{4-}$, were examined in detail. The structure of molecular $TiCl_3$ is unknown but it can be assumed that the symmetry is either C_{3v} or D_{3h} and that the Ti—Cl bond length lies between 0.218 and 0.245 nm[5,9]. The structure of $Ti_2Cl_{10}^{4-}$ was related directly to that of the α $TiCl_3$ lattice, where representative bond lengths are Ti—Cl=0.246 nm and Ti—Ti=0.354 nm.[5] For the latter calculation, each Ti was assumed to be octahedrally surrounded by six chlorine atoms, the octahedra sharing an edge and giving an overall molecular symmetry of D_{2h}. From pilot calculations on $TiCl_3$ and from previous work [10] the effect of *d* orbitals on chlorine turned out to be negligible (the occupation of the chlorine 3*d* orbital was ∼ 0.2e), hence these orbitals were neglected in subsequent calculations : those included for titanium were the 4*s*, 4*p*, and 3*d* orbitals. The input parameters for Ti and Cl were identical to those of the previous paper.[1] A difference occurs since $TiCl_3$ has an odd number of electrons and we therefore studied it by the open-shell SCF methods of Pople and Nesbet [11] and of Dewar.[12] Similarly, although $Ti_2C_{10}^{4-}$ contains an even number of electrons and, in addition, its symmetry is that of an abelian point group, we investigated the possibility of a non-spin-paired ground state. For this a multi-electron configuration-interaction treatment [13] involving all singly and doubly excited states formed from a specified set of orbitals was used.

Since the results obtained in the present work here apply equally to both α and γ $TiCl_3$, no discussion of the relative merits of α and γ $TiCl_3$ as catalysts is possible and further illumination of this point must await a detailed SCF solid-state calculation.

RESULTS AND DISCUSSION

1. GEOMETRY

The geometry of $TiCl_3$ was elucidated by minimising the total energy for various conformations, all with constant Ti—Cl bond length. We do not detail the results here but the calculations unambiguously assign the geometry as D_{3h}, all other geometries, *e.g.*, C_{2v} and C_{3v}, affording higher energies. The calculational method does not predict bond lengths accurately, hence no attempt was made to determine the equilibrium Ti—Cl distance.

2. MOLECULAR ORBITALS AND GROUND STATE OF TITANIUM TRICHLORIDE MONOMER

Before proceeding to consideration of the model for the catalyst, we first present and assess the theoretical results on the ground-state and excited-state properties of the monomer. The calculated energy levels and composition of the molecular orbitals are given in tables 1 and 2. Viewed over all the calculations a change in Ti—Cl bond length of 0.027 nm produces only limited variation in the majority of the bonding energy levels the overall picture remaining essentially unaltered.

It is in the set of energy levels which border the bonding-antibonding gap where the most significant changes occur. The two M.O.'s of lowest

energy are mainly of chlorine $3s$ character and these are separated by *ca.* 2 eV from six sets of M.O.'s containing eighteen electrons and derived mainly from the $3p$ orbitals on chlorine. The M.O. of highest energy is partially occupied by the odd electron and has always chiefly titanium $3d$ character.

$1e'$	s on Cl
$1a_1'$	s on Cl

Using Pople-Nesbet theory and a Ti-Cl bond length of 0.245 nm, the symmetry of this M.O. (with β spin) is e'' in contrast to the calculation by Dewar's method, which assigns it as a_1'. It is also assigned as a_1' by both calculations with a Ti-Cl bond length equal to 0.218 nm. In order to follow up this point, the relative energies of the derived electronic states $^2E''$ and $^2A_1'$; were next calculated, including excited states and a multi-electron configuration interaction technique. In both cases (Ti—Cl = 0.245 nm and Ti—Cl = = 0.218 nm), the state of lower energy was $^2A_1'$. This is as expected, since a ground-state symmetry of $^2E''$ would violate the Jahn-Teller theorem. Since distortion to a pyramidal shape does not lower the degeneracy and C_{2v} systems are less stable, then we must conclude that the Pople Nesbet calculation at 0.245 nm is incorrect. However, the $^2A_1' - {}^2E''$ interstate energy gap in both cases was small (*e.g.* where Ti—Cl $= 0.245$ nm, it was only *ca.* 0.05 eV).

Of the virtual orbitals, the four of lowest energy are principally composed of $3d$ on titanium, followed at progressively higher energies by titanium $4p_z$, $4s$, and $4p_x + 4p_y$. Simple electrostatic crystal-field arguments assign energy level ordering of the titanium d orbitals in a D_{3h} field as $d_{z^2} < d_{xz} = d_{yz} < d_{x^2-y^2} = d_{xy}$. However, because of the form of the electron repulsion integrals, a CNDO-based theory cannot admit of any angular dependence of electrostatic repulsion for d orbitals, hence both splitting and ordering must be rationalised on the basis of covalent bonding. The bonding M.O.'s involving titanium are not easily recognisable, due to the swamping contributions from the s and p on chlorine but it is seen that titanium-to-chlorine bond orders are arranged in the order $d_{x^2-y^2} - \mathrm{Cl} > d_{xz} - \mathrm{Cl} > d_{z^2} - \mathrm{Cl}$. Thus, $d_{x^2-y^2}$ and d_{xy} are stabilised by bonding to chlorine more than d_{xz} and d_{yz}, and both pairs more than d_{z^2}. Hence, we would expect the opposite order for the corresponding anti-bonding orbital set. These latter M.O.'s, because they are almost pure $3d$ on titanium, are easily recognisable and are in the order $a_1' < e'' < e'$, as would be expected.

The effect of the symmetrical bond length increase is to expand the orbital energy scale. Only the a_2' orbital contains no contribution from titanium and, hence, is expected to be relatively insensitive to changes in the Ti—Cl bond length. This is indeed what is found: whereas the orbitals immediately higher and lower than it in energy change by *ca.* 0.4 eV, the a_2' orbital changes by only 0.08 eV.

3. GENERAL PROPERTIES OF TITANIUM TRICHLORIDE

Table 3 lists the charges and valencies calculated for $TiCl_3$. The overall charges on titanium and chlorine are in general agreement with those expected for a transition-metal complex. The charge separation increases with increasing interatomic distance and this is rationalised by the fact that the extent of covalent bonding must decrease to zero as the interatomic distance increases indefinitely and as the bond length increases, the molecular orbitals will become increasingly localised on either the titanium or the chlorine.

The concept of valency[14] is poorly defined when applied to open-shell systems such as the one under consideration. Thus, the calculated valency for Ti is *ca.* 1.0 and 1.5 more than the sum of all bond indices to Ti for the $^2A_1'$ and $^2E'$ states, respectively. Nevertheless, the results indicate a covalency of titanium in $TiCl_3$ as 3.1 ± 0.1 and a free valency, due to the unpaired electron, as 0.99 ± 0.01 for the $^2A_1'$ states and 1.47 for the $^2E'$ state. (In a simple model of $TiCl_3$ the covalency of Ti is exactly

---

[14] D. R. Armstrong, P. G. Perkins, and J. J. P. Stewart, *J. Chem. Soc., Dalton*, **1973**, 838.

3.0 and the free valencies are exactly 1.0 and 1.5 for the $^2A_1'$ and $^2E'$ states respectively).

4. OPEN-SHELL RESULTS

A comparison of the results of Pople-Nesbet and Dewar's "half-electron" methods is valid because both methods use a common set of parameters. Both methods yield very similar results, for example, the majority of the orbital energies resulting from Dewar's method are within 0.01 eV of the average of α and β orbital energies resulting from using the Pople-Nesbet method.

The expectation value of $<S^2>$, calculated using programme MECI,[13] is 0.75. Most of the unpaired spin density is, as expected from energy considerations, in the *d* orbitals of titanium. Some negative spin density exists but is nowhere greater than 0.004. The positive spin density is greater than unity and, when positive and negative spin densities are summed, the total spin density is precisely unity.

5. ENERGY LEVELS IN $Ti_2C_{10}^{4-}$.

The formal symmetry of $Ti_2Cl_{10}^{4-}$ is D_{2h} and we first assumed a simple closed-shell ground-state. For the initial purposes of the work this is quite adequate. The energy levels of the anion are presented in figure 1, where, for brevity, only the limiting levels at the top and bottom of each group are given. The four "extra" electrons in this anion exert a repulsive effect which raises all the orbitals linearly in the energy scale. This "reverse-crystal-field effect" has been discussed previously[15] and could be removed by the superimposition of the appropriate number of cations situated around the ion if the basic geometry were known. It does not affect any conclusions drawn from the relative positions of orbitals in the scale.

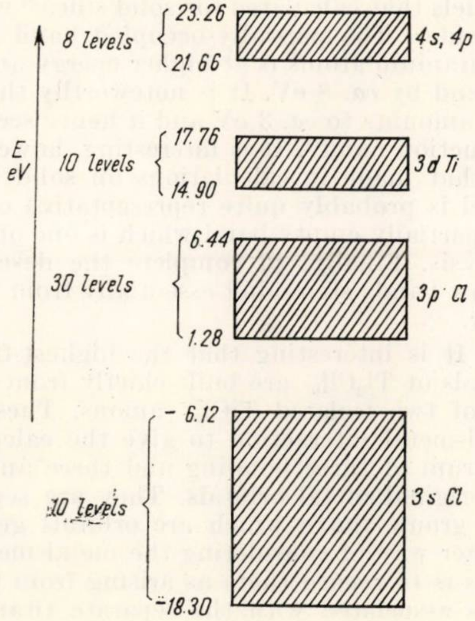

Fig. 1. — Energy levels for $Ti_2Cl_{10}^{4-}$.

---

[15] P. G. Perkins, *Rev. Roumaine Chim.*, **17**, 773 (1972).

In crystalline α $TiCl_3$ the energy levels will form a banded structure in which there will be a different energy band shape in different symmetry directions in the Brillouin Zone. The present calculation, which is essentially a cluster model, unfortunately cannot reproduce the band curvature or yield a density-of-states plot which would typify the crystal better. However, effective band widths are obtained from the cluster model and from the orbital energies we can obtain a relevant description which should carry over to the band structure.

We assume that the core orbitals on chlorine and titanium are completely occupied and, due to weak delocalisation, form very narrow bands at low energies : these can, therefore, be ignored in our description of crystalline $TiCl_3$. The atomic orbitals on chlorine give rise to two bands, namely, a band *ca.* 12 eV wide due to 3*s* and a band *ca.* 5 eV wide stemming from the 3*p* orbitals. The widths of these bands qualitatively reflects the degree of lateral interaction, the 3*s* chlorine orbitals bonding to Ti more strongly than the 3*p*. It is noteworthy that this behaviour parallels that calculated for solid silica[16] where also bands with *s* character are wider. The partially-occupied band formed from the 3*d* orbitals on the titanium atoms is at higher energy and is separated from the chlorine 3*p* band by *ca.* 8 eV. It is noteworthy that the total span of this *d* band only amounts to *ca.* 3 eV and it hence seems rather narrow for a "metalic conduction band". It is interesting, however, that this observation parallels that made in calculations on solid TiO and TiN[17] and, hence, our model is probably quite representative of the solid in this respect. It is this partially empty band which is one of the important factors in Ziegler catalysis. Finally, to complete the description, at still higher energies narrow bands stemming essentially from the 4*s* and 4*p* levels on titanium occur.

It is interesting that the highest-filled and lowest-five-unoccupied orbitals of $Ti_2Cl_{10}^{4-}$ are built chiefly from the two triply-degenerate "t_{2g}" sets of two isolated $TiCl_6^{3-}$ anions. These six orbitals are split by the metal-metal interaction to give the calculated closely-spaced eigenvalue spectrum of three bonding and three antibonding levels with respect to the original metal orbitals. They are separated by *ca.* 1.5 eV from the next group above which are orbitals generated by the e_g sets. Hence, another way of considering the metal-metal interaction and the resulting states is to regard them as arising from the interaction of a pair of $^2T_{2g}$ terms associated with the separate titanium atoms.

6. GROUND AND EXCITED STATES OF $Ti_2Cl_{10}^{2-}$

The closed-shell calculation pairs the highest energy electrons in the lowest of the above six levels. Clearly, however, electronic states will exist which may well be lower in energy than the singlet since the levels are closely spaced. Hence a multi-electron configuration-interaction calculation including all singlet and triplet states arising [from electronic configurations involving the three highest occupied M.O.'s and the two lowest unfilled M.O.'s was undertaken.

---

[16] A. Breeze and P. G. Perkins, *J. Chem. Soc., Faraday II*, **69**, 1237 (1973).

[17] A. Breeze and P. G. Perkins, to be published.

This involved a considerable number of doubly-excited states. The outcome of this calculation is that a triplet state exists which is slightly more stable than the simple closed-shell system. Table 4 lists the energies of the singly-excited states generated from the possible configurations.

The lowest two states have symmetries $^3B_{3u}$ and ^1A_g respectively. The first involves a configuration where the highest and lowest orbitals of the group are singly occupied by electrons with the same spin whilst the second is the lowest closed-shell configuration. These lowest two states are very similar in energy and this situation, together with the other singlets and triplets lying close to the ground-state will give rise to temperature-dependent magnetic effects as heavy thermal population of the states will occur. Because some of the thermally accessible states are singlets then a reduction in paramagnetism on increasing temperature is predicted.

Table 4

Singly excited states of $Ti_2Cl_{10}^{4-}$ arising from the pseudo-configurations t_{2g}^2 and t_{2g}^1 t_{2g}^1

Energy *	1Γ	3Γ

	0.18	0.19
	0.19	16.90
	19.10	19.11
	23.69	33.90
	38.07	38.26
	38.26	
	47.42	
	55.80	

* the energies are relative to the ground state arbitrarily set to zero energy.

The nature of the configurations giving rise to these states means that even if experiment indicated that the electronic state is a singlet, effective bonding between the two titanium atoms does not necessarily exist since several of the sigglets involve pairing of electrons in which one resides in each set of three orbitals.

Because of the uncertainty of the lowest electronic state at ordinary temperatures it is not particularly meaningful to analyse the selection rules for the electronic spectra. However, the true symmetry (D_{2h}) is sufficiently low that certain transitions will be formally allowed and will appear in the visible region *e.g.* the two triplet-triplet transitions $^3B_{2g} \leftarrow \leftarrow {}^3A_u$ which involve promotions from the state lying at 0.2 kK to those at 16.9 and 19.1 kK. These transitions could account for the observed bands in α $TiCl_3$. Most of the doubly-excited states are fairly high in energy and so are of little importance to the magnetic properties. Moreover, optical transitions to them are two-photon processes and hence very weak. For these reasons we do not include them in table 4.

With regard to solid α $TiCl_3$ we expect that the "t_{2g}— t_{2g}" interaction between all pairs of titanium atoms, each in octahedral site symmetry, will result in a basically similar situation to that described above for $Ti_2Cl_{10}^{4-}$ the main difference being that the "bonding t_{2g}" and "antibonding t_{2g}" levels of the anion will form narrow bands in the solid. These are not expected to be much wider than the energy the levels span in the $Ti_2Cl_{10}^{4-}$ ion itself. With regard to the excited states of the solid these should only be modified in a minor way by the extension of the Ti-Ti interaction and should essentially form a set of weakly-delocalised excition states. This means that we would expect the predicted experimental optical spectrum to be closely similar to that for $Ti_2Cl_{10}^{4-}$.

7. CALCULATED GROUND STATE PROPERTIES OF $Ti_2Cl_{10}^{4-}$

These are presented in table 5. The properties in this table refer, of course, to the ^1A_g state which will be heavily thermally populated at ordinary temperatures. In this state both electrons reside in the lowest orbital of the "t_{2g}" set. Only the Ti-Ti bond is of particular interest, the other results being essentially similar to those obtained for the $TiCl_3$ monomer. There is a Ti-Ti bonding component which assumes some importance in this anion and the Ti-Ti bond interaction stems almost entirely from the contribution of the highest filled M.O. From the multi-electron C.I. results we know that the "true" ground state is built from configurations with one bonding and one antibonding electron. This antibonding component renders the overall Ti-Ti bond weak.

Table 5

Properties calculated for $Ti_2Cl_{10}^{4-}$

	Formal charge	Configuration	Valencies	Bond indices

8. ACTIVATION OF THE CATALYST SURFACE

Since we now know the general structure of the ground and excited states of a system related to α $TiCl_3$ we now attempt to say how our calculations apply to the catalytic activity of the crystal. We first consider therefore the activation of the catalyst surface. At the surfaces of α $TiCl_3$ there must be some chlorine vacancies in order that electroneutrality can be preserved. We would also expect that there are also labile chlorine atoms which can readily be alkylated by co-catalyst to form active sites for polymerisation. Arlman[18] has shown that the energy required to abstract one of these or to form a chlorine vacancy is far less when the atom is at an edge rather than in the middle of an α $TiCl_3$ sheet *i.e.* the (0001 face). We would expect these labile chlorine atoms to project somewhat out of the catalyst surface and so predispose them to replacement to give alkylated catalyst. The alkyl group attached to the catalyst would then be available for insertion of ethylene molecules to give the incipient polymer. Cossee[19] has presented a convincing rationalisation of the tacticity and reaction mechanism problems for simple polymerisations on $TiCl_3$ using geometrical arguments. We now consider how our results can add to his picture of the process. We also consider what is the function of the co-catalyst $AlCl_3$.

---

[18] E. H. Arlman, *J. Catalysis*, **3**, 89 (1964).

The level scheme of figure 1 is derived from the $Ti_2Cl_{10}^{4-}$ anion and is expected to apply to the volume band structure of α $TiCl_3$. At the surface of the crystal there will clearly exist surface states and, of these the most important will be dominated by the *3d* levels of titanium. Because of the weak Ti-Ti interactions in the crystal these surface bands will also be narrow and we would expect them to fall in the same energy region as the volume states. A difference here is that because of the discontinuity of potential and C_{4v} point symmetry at the surface titanium sites the "t_{2g}" levels would be split into e and b_2 at the Γ point of the Brillouin zone. This splitting will however not be large and we estimate it to be *ca.* 0.1 eV from comparison with data given for the molecular complex with a vacant site studied in ref.[1]. Overall we believe that the surface states will probably be submerged in the volume states of the crystal and hence figure 1 is a reasonable overall energy band picture.

Alkylation of the catalyst surface by removal of chlorine in the way suggested by Cossee[19] seems reasonable and we must next consider the modification this will bring about in the energy level diagram. From previous work on the methyltitanium chlorides[20] we know that the electrons in a Ti-C bond are strongly localised in one highly energetic bonding orbital. We may reasonably assume that this situation will obtain when Ti$-$C bands are formed on the surface of α $TiCl_3$.

With respect to the band structure of the solid these bonds constitute localised impurities and we must consider where they lie with respect to the main band structure : (the chlorine atoms which they replace are, of course, also impurities but are expected to yield levels lying submerged within the main bands). The Ti$-$C bonds should be localised because the separation of neighbouring Ti atoms, to which the alkyl is bound at the surface, is large enough to bring about localisation. Again the calculations on the series Me_xTiCl_{4-x} throw light on the situation. Taking the cases of $TiCl_4$ and $MeTiCl_3$, the Ti C σ bond is localised in the highest bonding orbital of $MeTiCl_3$ and this is *ca.* 2 eV less stable than the highest bonding orbital of $TiCl_4$. We conclude from this that, in the case of alkylated α $TiCl_3$ the Ti$-$C σ bonds on the surface will form accidentally-degenerate isolated energy levels lying above the Ti$-$Cl valence bands. Figure 1 shows that there is a substantial gap (*ca.* 8 eV) between the *3p* Cl valence bands and the bottom of the Ti *3d* band. The Ti$-$C σ levels are expected to be situated in this gap leaving the d band to be still only partly occupied by the "t_{2g}" electrons. Moreover, the Ti$-$C σ levels should lie rather close to the d band since it is the latter which are strongly involved in Ti—C bonds.[1,20] By analogy with $MeTiCl_3$ we expect the Ti—C σ^* orbitals also to be localised and to lie either in or slightly above the *d* band of Ti.

---

[19] P. Cossee, in "The Stereochemistry of Macromolecules", Vol. 1, (Ed. A. D. Ketley), Marcel Dekker, N. Y., 1967, Chapter 3. p. 145.

[20] D. R. Armstrong, P. G. Perkins, and J. J. P. Stewart, *Theor. chim. Acta*, submitted for publication.

We expect, overall, that the spectral properties of the system will still be dominated by the two "t_{2g}" electrons and the excited states generated by the *d* band, just as in $Ti_2Cl_{10}^{4-}$. However, the Ti—C σ bond will be energetically labile since electrons will be readily thermally excited to the *d* band and the Ti—C σ^* orbital; in fact rather more so than they are in the soluble catalyst where the orbital gap between bonding and antibonding sets is much larger[1]. For the rest, the electronic situation is closely analogous to that of the "soluble" catalyst and hence we expect that the mechanism shown to be operative for the *cis* insertion of ethylene in the latter case will be equally applicable to the present instance.

9. ROLE OF ALUMINIUM TRICHLORIDE IN THE CATALYST

Aluminium trichloride, in combination with α $TiCl_3$, is a more effective catalyst for the polymerisation of olefins than is $TiCl_3$ alone. It is believed to react with solid $TiCl_3$ to form a solid solution in which there are layers of $AlCl_3$ and $TiCl_3$.[21]

The best catalysts appear to be those which contain octahedrally-coordinated titanium, and clearly the ease of attaining this geometry together with steric control are important factors in the process. In α $TiCl_3$ the titanium atoms are maintained in octahedral site symmetry by chlorine bridging to other acceptor atoms and hence certain of the halogens are removed from the site of polymerisation. Because of its smaller radius, aluminium can remove the chlorine atoms from the region of the reaction site more effectively than can another titanium in the crystal and we postulate that this is one of the properties of aluminium which makes it so effective as a co-catalyst. This implies that any group or atom which is more effective than Ti in "tying-back" the chlorine atoms and producing octahedral site symmetry around titanium should enhance the activity of the catalyst.

In the uniform site theory of Ziegler catalysis,[21] $AlCl_3$ is assumed to be in solid solution in the $TiCl_3$ lattice so that Ti_8Cl_{24} clusters are isolated by layers of $AlCl_3$; it is this solid phase which is the catalyst. Accepting this, and the results of Carradine and Rase,[4] then some aspects of the catalysis can now be explained.

The activity of $TiCl_3$—$AlCl_3$ catalyst is greater than that expected for simple surface catalysis, based on the surface area of the crystals in the reaction. As the polymerisation proceeds, the growing polymer chain causes mechanical damage to occur,[22] with consequent fragmentation of the crystal. The $AlCl_3$ in solid solution presumably induces planes of weakness which can aid fragmentation of the catalyst crystal, at the

[21] V. W. Buls and T. L. Higgins, *J. Polymer Sci.*, A—1, **8**, 1025 (1970).

[22] L. A. M. Rodriguez and J. A. Gabant, *J. Polymer Sci. C.*, 125 (1963).

same time exposing active sites with Ti in a favourable steric environment, *i.e.*, assuming that, at the $AlCl_3-TiCl_3$ crystal interfaces, the bonding of Al to Ti *via* chlorine bridges occurs. Ultimately the particles of catalyst would become so small that isolated $AlCl_3-Ti_8Cl_{24}$ units would exist and the catalyst would become virtually homogeneous. Before this stage was reached a considerable degree of inhomogeneity in the solid phase would be manifest because of the quasi-random nature of the mechanical breakdown of the crystal : such inhomogeneity would be expected to produce different catalyst sites having modified activities. This latter suggestion helps to rationalise, to some extent, the wide range of molecular weights of the high polymer found when using aluminium-doped $TiCl_3$.

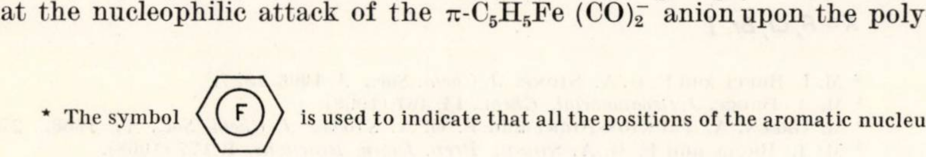
[b]University of Georgia, Athens, Ga. (U.S.A.) and
[c]Iowa State University, Ames, Ia. (U.S.A.)

Received March 2, 1974

The π-cyclopentadienyliron dicarbonyl anion, π-$C_5H_5Fe(CO)_2^-$ reacts with some pentafluorophenyl-silicon derivatives, including $C_6F_5SiMe_3$, $(C_6F_5)_2SiPh_2$, $(C_6F_5SiMe_2)_2O$ and $C_6F_5SiMe_2(CH_2)_3SiMe_3$ by replacing a fluorine atom in the *para*- position to silicon, to give σ-organoiron derivatives of the general type π-$C_5H_5Fe(CO)_2-\sigma-C_6F_4-SiRR'_2$-*p*.

INTRODUCTION

The π-cyclopentadienyliron dicarbonyl anion, π-$C_5H_5Fe(Co)_2^-$ which can be readily generated by treating the π-cyclopentadienyliron dicarbonyl dimer [π-$C_5H_5Fe(CO)_2]_2$ with sodium amalgam in tetrahydrofuran,[1] reacts with hexafluorobenzene to give π-cyclopentadienyl-σ-pentafluorophenyliron dicarbonyl*



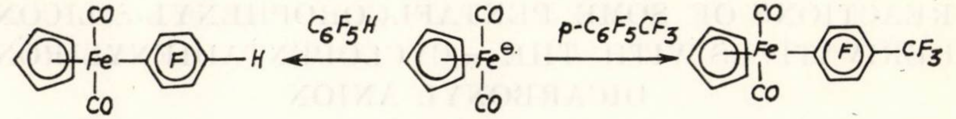
When substituents other than fluorine were also present on the aromatic nucleus, e.g. hydrogen, trifluoromethyl and other groups, it was found that the nucleophilic attack of the π-$C_5H_5Fe(CO)_2^-$ anion upon the poly-

---

* The symbol is used to indicate that all the positions of the aromatic nucleus which are not occupied by other groups are substituted with fluorine atoms.

[1] R. B. KING and M. B. BISNETTE, *J. Organometal. Chem.*, **2**, 38 (1964).

fluoroaromatic ring occurs in the *para*-position in respect with the substituent[1].



When the π-cyclopentadienyliron dicarbonyl anion reacted with halogenopentafluorobenzenes, $C_6F_5X (X = Cl, Br, I)$ two different reactions occurred. The major one was the replacement of a halogen atom, other than fluorine, to give the same product as the reaction with hexafluorobenzene $(X = F)$, namely π-$C_5H_5Fe(CO)_2C_6F_5$[2]; a secondary reaction was the formation of products like π-$C_5H_5Fe(CO)_2C_6F_4H$-p.[2,3]

Similar reactions were found with other polyfluorinated aromatic derivatives,[4,5] e.g. pentafluoropyridine,[4] and even with perfluoroolefins and perfluoroacetylenes; these reactions were reviewed.[5,6,7]

The mechanism of the reaction between metal carbonyl anions and polyfluorinated hydrocarbons was discussed in the literature[6,8] in terms of a nucleophilic attack of the anion upon the fluorocarbon, with the formation of an intermediate fluorinated carbanion, which further eliminates an F^- anion or (if present) a halide ion (X^-) or (in some instances) adds a proton. The possible pathways explaining all the product isolated from the reactions of metal carbonyl anions with polyfluoroaromatics are summarized in the following scheme[2,6] Since the reaction of the π-cyclo-

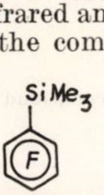
pentadienyliron dicarbonyl anion with substituted pentafluoroaromatics can take various courses, we have investigated such reactions with pentafluorophenyl-silicon derivatives. The reactions considered as possible were : nucleophilic substitution of fluorine (in *para* or other position to silicon) or cleavage of the Si—C_6F_5 bond. It was found that the substitution of fluorine *para* to silicon occurs in all cases.

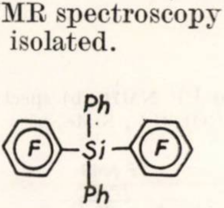
RESULTS AND DISCUSSION

We have investigated the reactions of π-cyclopentadienyliron dicarbonyl anion with the following four pentafluorophenyl-substituted organosilicon derivatives : pentafluorophenyltrimethyl-silane (I) ; bis (pentafluorophenyl) diphenylsilane (II) ; 1,3-bis (pentafluorophenyl) tetramethyldisiloxane (III) and pentafluorophenl-γ-trimethylsilylpropyldimethylsilane (IV).

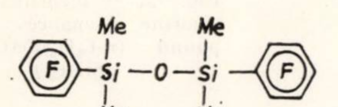
The reactions were carried out in tetrahydrofuran, by adding the pentafluorophenyl-silicon compound to the solution containing the anion π-$C_5H_5Fe\ (CO)_2^-$, generated *in situ*, as described in the experimental part. Infrared and ^{19}F NMR spectroscopy were used to establish the structure of the compounds isolated.



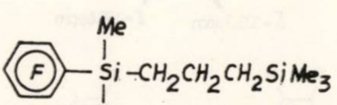
I



II

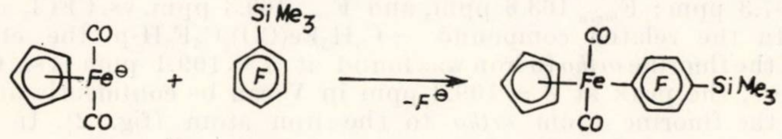


III



IV

The reaction of pentafluorophenyltrimethylsilane (I) with the π-cyclopentadienyliron dicarbonyl anion gave a pale yellow crystalline compound, m.p. 141°, identified as π-cyclopentadienyl-σ-(*p*-trimethylsilyltetrafluorophenyl)iron dicarbonyl (V) :



I V

The infrared spectrum of V contains in the carbonyl stretching (ν_{CO}) region two intense, sharp bands, at 2050 and 2001 cm^{-1}, showing a pattern characteristic of compounds of the π-$C_5H_5Fe(CO)_2R$ type (fig. 1a). The ^{19}F NMR spectrum shows and A_2X_2-type pattern and consists of only two pairs of doublets (fig. 1b), centered at $\delta = 109.3$ ppm and $\delta = 130.6$ ppm. vs. $CFCl_3$ as internal standard, thus indicating the presence of only two types of structurally non-equivalent fluorine atoms.

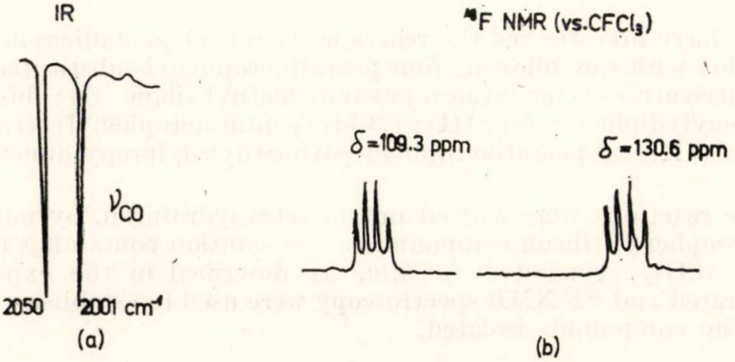


Fig. 1. — IR spectrum (a) and ^{19}F NMR (b) spectrum of compound $(\pi\text{-}C_5H_5)Fe(CO)_2\text{-}C_6F_4\text{-}SiMe_3\text{-}p$.

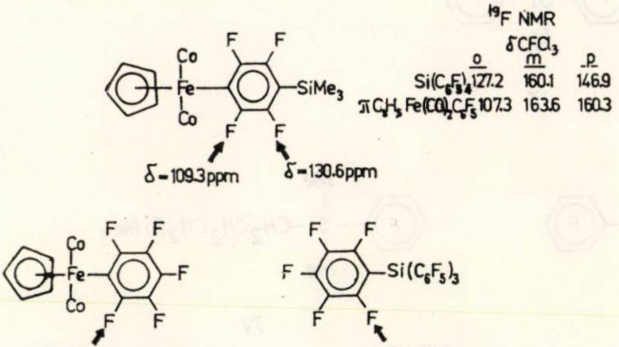

Fig. 2. — Identification of fluorine resonances in compound $(\pi\text{-}C_5H_5)Fe(CO)_2C_6F_4\text{-}SiMe_3\text{-}p$

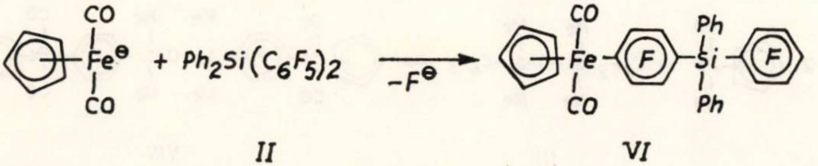
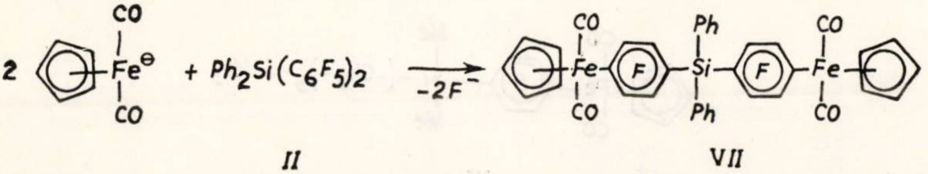
A comparison of the ^{19}F NMR spectrum of V with the ^{19}F NMR spectra of π-$C_5H_5Fe(CO)_2C_6F_5$ [1] and Si $(C_6F_5)_4$ [9] allows an unequivocal assignment. Thus, in π-$C_5H_5Fe(CO)_2C_6F_5$ the ^{19}F chemical shifts are as follows: F_{ortho} 107.3 ppm; F_{meta} 163.6 ppm, and F_{para} 160.3 ppm. vs. $CFCl_3$ as standard. In the related compound π-$C_5H_5Fe(CO)_2C_6F_5H$-p the chemical shift of the fluorine *ortho* to iron was found at $\delta = 109.1$ ppm vs. $CFCl_3$.[2] Therefore, the peak at $\delta = 109.3$ ppm in V can be confidently attributed to the fluorine atom *ortho* to the iron atom (fig. 2). In the ^{19}F NMR spectrum of Si $(C_6F_5)_4$ the chemical shifts are : F_{ortho} 127.2 ppm ; F_{meta} 160.1 ppm, and F_{para} 146.9 ppm, vs. $CFCl_3$ as standard.[9]. Therefore, the peak at $\delta = 130.6$ ppm in the spectrum of V can be assigned to the fluorine atom *ortho to the silicon* atom (fig. 2). Since there are only two kinds of fluorine atoms in the molecule of V, with 1 : 1 ratio (from integrated peak area ratio), in *ortho* positions to either fluorine or silicon, it follows that compound V is the *para*-substituted compound. Other isomers (*ortho* or *meta*) would have an entirely different ^{19}F NMR spectrum.

The reaction of π-$C_5H_5Fe(CO)_2^-$ with bis (pentafluorophenyl (diphenylsilane) (II) in 1 : 1 molar ratio gave a yellow solid, m.p. 2°5−10° (dec.), identified as π-cyclopentadienyl-σ-[(*p*-pentafluorophenyldiphenylsilyl) tetrafluorophenyl] iron dicarbonyl (VI).



The infrared spectrum of VI contained two sharp, intense absorption bands in the ν_{CO} region, at 2050 and 2004 cm^{-1}, as expected for structure VI.

A 2 : 1 ratio of the same reagents, gave a yellow solid, m.p. 237°C, identified as the product of nucleophilic attack on both C_6F_5 groups in II, with the structure VII



The structure VII, which contains only two kinds of fluorine atoms, in positions *ortho* to either silicon or iron, is confirmed by the ^{19}F NMR spectrum (fig. 3), which is of A_2X_2 type and contains only two pairs of

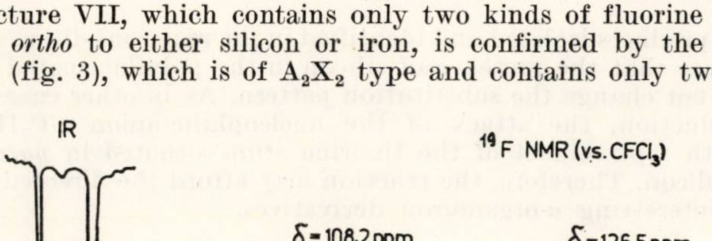


Fig. 3. — IR spectrum (a) and ^{19}F NMR spectrum (b) of compound $Ph_2Si[C_6F_4$-$Fe(CO)_2(\pi$-$C_5H_5)]_2$.

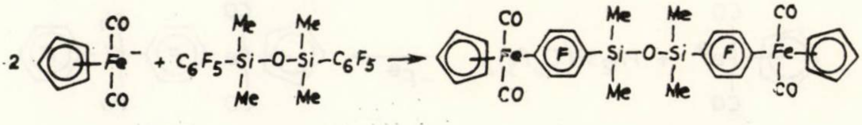
---

[9] K. W. Jolly and L. H. Sutcliffe, *Spectrochim. Acta*, A, **24**, 1191 (1968).

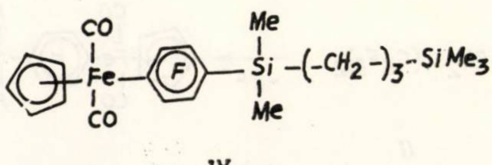
doublets, centered at $\delta = 108.2$ ppm and $\delta = 126.5$ ppm. The infrared spectrum of VII exhibits two sharp, intense absorption bands in the ν_{CO} region, at 2050 and 2004 cm^{-1}. The ^1H NMR spectrum exhibits peaks at $\tau = 4.98$ ppm (π-C_5H_5) and $\tau = 2.7-2.8$ ppm (C_6H_5), with the integrated area ratio, expected for structure VII.

From $[\pi\text{-}C_5H_5Fe(CO)_2]^{\theta}$ and the pentafluorophenyl-substituted disiloxane (III) a waxy yellow solid was obtained showing strong IR absorption bands at 2048 and 2001 cm^{-1}, characteristic of the carbonyl ligands of the π-$C_5H_5Fe(CO)_2$ groups, in accordance with structure VIII



III VIII

The reaction of $\pi\text{-}C_5H_5Fe(CO)_2^-$ with IV, gave a yellow-orange oil, with strong absorption bands in the ν_{CO} region at 2051 and 2002 cm^{-1}, which was not investigated further. The infrared spectrum indicates the presence of π-$C_5H_5Fe(CO)_2$ groups in the molecule, thus suggesting structure IX, but the compound could not be purified satisfactorily for analysis.



IX

The products isolated and identified in the reactions discussed above, demonstrate that the presence of silicon in the polyfluorinated aromatic ring does not change the substitution pattern. As in other cases, cited in the introduction, the attack of the nucleophilic anion $\pi\text{-}C_5H_5Fe(CO)_2^-$ occurs with replacement of the fluorine atom situated in *para* position towards silicon. Therefore, the reaction may afford the directed synthesis of some interesting σ-organoiron derivatives.

EXPERIMENTAL PART

The reaction described here were routinely conducted in an atmosphere of oxygen-free dry nitrogen. Anhydrous solvents were used throughout. Tetrahydrofuran was distilled over sodium-benzophenone ketyl, prior to use. The ^{19}F NMR spectra were recorded on a Varian HA—100 instrument in benzene solution and the IR spectra on a Perkin Elmer 621 A instrument, in n-hexane, at the University of Georgia.

Reaction of $\pi\text{-}C_5H_5Fe(CO)_2^-$ with I

The sodium salt of the $\pi\text{-}C_5H_5Fe(CO)_2^-$ anion was prepared by stirring 0.88 g (2.5 mmole) of $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ with excess sodium amalgam (1%) in 100 ml. tetrahydrofuran, during 3—4 hrs. After removing the excess of sodium amalgam the orange yellow solution obtained was treated with 1.2 g (5 mmole) pentafluorophenyltrimethylsilane, introduced with a syringe through a rubber serum cap adapted to the neck of the three-neck reaction flask, and the mixture was stirred overnight at room temperature. The solution was evaporated, extracted with hexane, concentrated, chromatographed on Florisil ^{R} (a mixture of MgO and SiO_2) and the yellow band eluted with hexane and evaporated to give 0.95 g (47.7% yield) of a pale-yellow solid, m.p. 141°C, identified as π-cyclopentadienyl-σ-(*p*-trimethylsilyltetrafluorophenyl)iron dicarbonyl (V).

$C_{16}H_{14}F_4FeO_2Si$	*Calcd.* :	C 48.24%	H 3.52%	Fe 14.02%
	Found :	C 48.53%	H 3.34%	Fe 14.37%

Reaction of π-$C_5H_5Fe(CO)_2^-$ with II (1 : 1 ratio)

A sodium salt of π-$C_5H_5Fe(CO)_2^-$ prepared as above from 0.354 g (1 mmole) $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ and excess sodium amalgam in 75 ml tetrahydrofuran, was treated with a solution containing 1.03 g (2 mmole) $Ph_2Si(C_6F_5)_2$ in 10 ml THF and stirred overnight. The reaction mixture was worked up as above and chromatography on Florisil on elution with acetone, gave after evaporation 0.59 g (59% yield) of a yellow solid, m.p. 205—210°C (dec.), identified as π-cyclopentadienyl-σ-[*p*-(pentafluorophenyldiphenylsilyl)tetrafluorophenyl]iron dicarbonyl (VI).

$C_{31}H_{15}F_9FeO_2Si$	*Calcd.* :	C 73.96%	H 3.00%
	Found :	C 73.45%	H 3.18%

Reaction of π-$C_5H_5Fe(CO)_2^-$ with II (2 : 1 ratio)

A sodium salt of π-$C_5H_5Fe(CO)_2^-$ anion prepared as above from 0.354 g (1 mmole) of $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ and excess sodium amalgam in 100 ml THF was treated with a solution containing 0.516 g (1 mmole) $Ph_2Si(C_6F_5)_2$ dissolved in 10 ml. THF and stirred overnight. The mixture was worked up as above and chromatographed over Florisil ; elution with acetone gave a solution which on concentration deposited 0.45 g (51.6%) of a yellow solid, m.p. 237°, identified as bis [*p*-(π-cyclopentadienylirondicarbonyl)tetrafluorophenyl]diphenylsilane (VII).

$C_{38}H_{20}F_8Fe_2O_4Si$	*Calcd.* :	C 54.81%	H 2.42%	Fe 13.42%
	Found :	C 55.13%	H 2.74%	Fe 13.85%

Reaction of π-$C_5H_5Fe(CO)_2^-$ with III

The reaction was carried out as above, with 1.55 g (3.3 mmole) of $C_6F_5SiMe_2OSiMe_2C_6F_5$, to give after chromatography on Florisil and elution with hexane, a waxy yellow solid. A hexane solution of this material shows only two strong bands in the ν region, which can be assigned to compound VIII.

Reaction of π-$C_5H_5Fe(CO)_2^-$ with IV

The reaction was carried out as above, with 1.70 g (5 mmole) of $C_6F_5SiMe_2(CH_2)_3SiMe_3$, to give after chromatography on Florisil and elution with hexane and evaporation, a yellow orange oil. The infrared spectrum of this oil in hexane, showed peaks at 2051 and 2002 cm^{-1}, consistent with compound IX.

One of us (I.H.) is grateful to the Babeş-Bolyai University of Cluj (Romania) for two leaves of absence spent at Iowa State University and University of Georgia (U.S.A.) and expresses his appreciation for the hospitality enjoyed there.

*Department of Chemistry,
University of Bucharest, Spl. Independenţei 89, Romania.
**Department of Chemistry and Physics,
Institute of Petroleum and Geology, Str. Traian Vuia 6,
Bucharest, Romania

Received October 17, 1973

In order to elucidate some problems related to the thermal stabilities of complex combinations we provide in this paper data obtained from the thermal analysis applied to ferrate (VI) ion salts with Ni(II) and Co(II) tetrapyridine and tetrapicoline complex compounds.

1. INTRODUCTION

In recent decades, in the area of solid reaction, thermal analysis methods have gained increased acceptance as research methods of great practical importance. [1-2]

In a previous work [3] the synthesis of ferrate (VI) ion salts with Ni(II) and Co(II) complex ammines, has been presented.

This paper is concerned with the study of salts prepared by means of thermal analysis.

In the literature, referring to the thermal behaviour of ferrates (VI), only the study made by Scholder and his coworkers [4] on thermal behaviour of potassium ferrate (VI) in oxygen stream may be cited. Comparing the thermal behaviour of potassium ferrate (VI) and potassium permanganate in oxygen stream, it was possible to draw conclusion on the intermediate stages that may appear at decomposition.

2. EXPERIMENTAL METHODS

Two series of compounds belonging to Ni(II) and Co(II) complex compounds with pyridine and picoline, containing ferrate (VI) ion, have been prepared.

[4] R. SCHOLDER, H. V. BUNSEN and F. KINDERVATER, *Z. anorg. Chem.*, **282**, 268 (1955).

These salts are the following:

$NiPy_4[FeO_4]$; $Ni(\alpha\text{-pic})_4[FeO_4]$; $Ni(\beta\text{-pic})_4[FeO_4]$;
$Ni(\gamma\text{-pic})_4[FeO_4]$; respectively $CoPy_4$ $[FeO_4]$;
$Co(\alpha\text{-pic})_4[FeO_4]$; $Co(\beta\text{-pic})_4$ $[FeO_4]$; $Co(\gamma\text{-pic})_4$ $[FeO_4]$.

These substances have been studied by means of thermogravimetric analysis (A.T.G.) using a M.O.M. Budapest Paulik Paulik, Erdey apparatus.[5]

Tests were heated in the furnace atmosphere at a heating rate of 8 deg./min.

$NiPy_4[FeO_4]$. The test was heated in the presence of furnace air to 800°. An endothermal process at 120°, an exothermal process at 250° and another endothermal process at 620°, have been recorded.

$CoPy_4[FeO_4]$. The test is heated in the furnace atmosphere to 800°. Decomposition of the compound begins at 140°.

This fact corresponds to an endothermal process.

An endothermal process is recorded at 245°. Two exothermal processes are observed at 220° and 310°.

The same endothermal process found for Ni(II) compound previously presented was reproduced at 620°.

$Ni(\alpha\text{-pic})_4[FeO_4]$. An endothermal process at 90°, an exothermal process at 225° and another endothermal process at 620° have been recorded.

$Co(\alpha\text{-pic})_4$ $[FeO_4]$. An endothermal process at 125°, an exothermal process at 230° and another endothermal process at 620° have been recorded.

$Ni(\beta\text{-pic})_4$ $[FeO_4]$. An endothermal process at 105°, an exothermal at 235° and another endothermal process have been recorded.

$Co(\beta\text{-pic})_4[FeO_4]$. In this case an endothermal process at 130°, an exothermal at 250° and another endothermal process at 620° have been recorded.

$Ni(\gamma\text{-pic})_4[FeO_4]$. An endothermal process at 110°, an exothermal process at 240° and another endothermal process at 620° have been observed.

$Co(\gamma\text{-pic})_4$ $[FeO_4]$. An endothermal process at 150°, an exothermal process at 265° and another endothermal process at 645° have been observed.

3. DISCUSSION

Drawing a comparison between thermal behaviour of ferrate (VI) ion salts and thiocyanates of Ni(II) and Co(II) pyridine and picoline complexes, it is possible to conclude that for the compounds containing ferrate (VI) ion, the ligand elimination during heating time takes place in a single stage evidenced by an endothermal process.

For thiocyanates of Ni(II) and Co(II) complex ammines, ligand elimination takes place in two stages corresponding to the two endothermal peaks of A.T.D. curves as well as to losses in weight recorded by the A.T.S. curves.[6]

Thus, in the case of $NiPy_4$ $[FeO_4]$ at 120°, en endothermal process characterized by a 36.6% loss of weight is recorded. This corresponds to a loss of two pyridine molecules.

It is possible to suppose that $NiPy_4$ $[FeO_4]$ compound looses two pyridine molecules at room temperature, in fact, $NiPy_2$ $[FeO_4]$ is considered as initial compound.

An endothermal peak due to a phase transformation of resulting oxide is recorded at 620° on A.T.D. curve.

Following the thermal behaviour of $NiPy_4\,(SCN)_2$[6] a two-stage ligand elimination is observed.

---

[5] F. Paulik, J. Paulik and L. Erdey, *Talanta*, **13**, 1405 (1966).

[6] I. G. Murgulescu, E. Segal and D. Fătu, *J. Inorg. Nuclear Chem.*, **1965**, 27.

Two thermal effects at 188° and 275° connected with two endothermal peaks of A.T.D. are recorded.

These two effects correspond to those stages of ligand elimination.

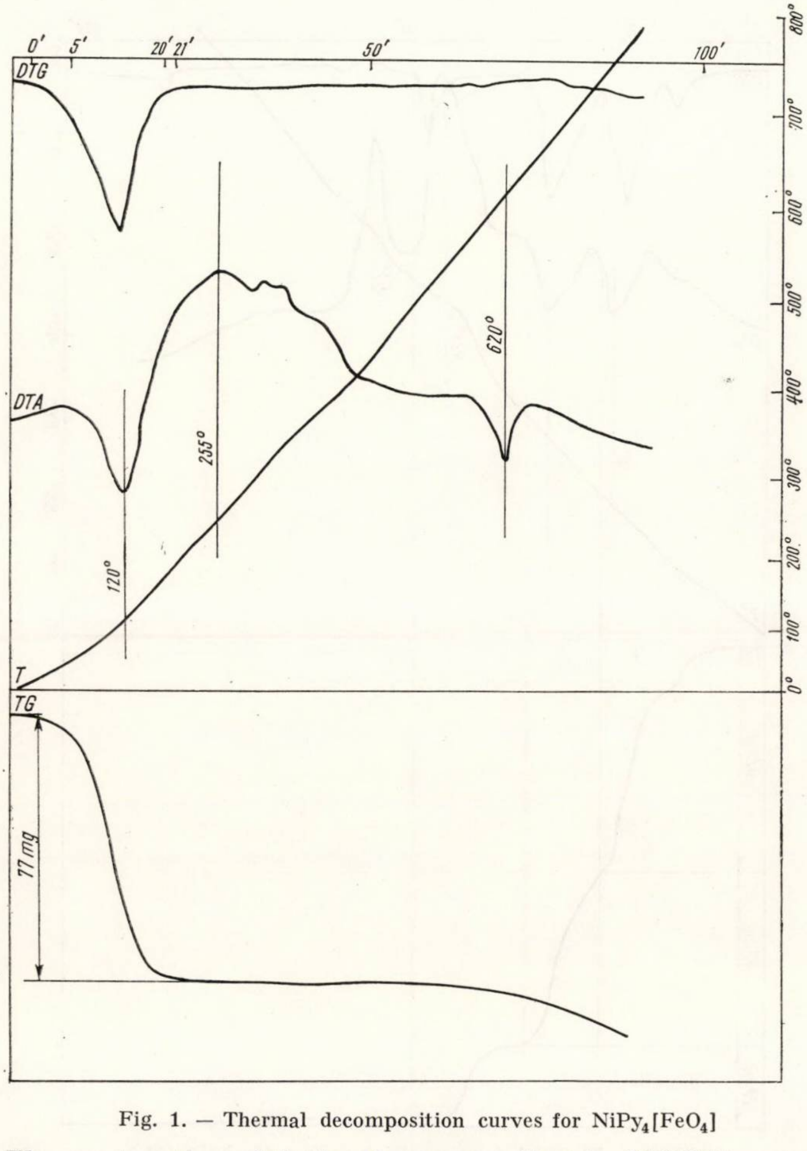

Fig. 1. — Thermal decomposition curves for $NiPy_4[FeO_4]$

The next section of the level corresponding to $Ni(SCN)_2$ compound is followed by decomposition associated with an oxidizing process of $Ni(SCN)_2$, decomposition of the resulting NiO and by recrystallization.

An analogous behaviour of the other thiocyanates of Co(II) and Ni(II) complex ammines has been established.

In the case of $CoPy_4$ $[FeO_4]$ the exothermal peak at 310° is connected with a crystallization process of the resulting compound. This corresponds to an exothermal process.

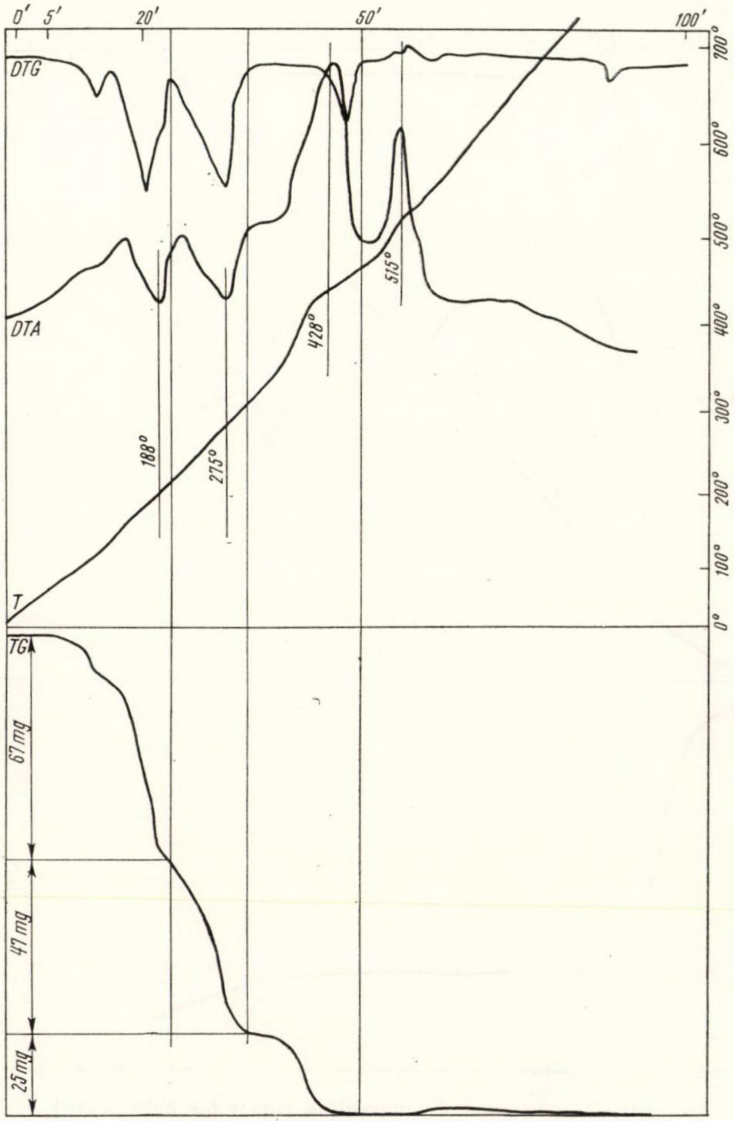

Fig. 2. — Thermal decomposition curves for $NiPy_4(SCN)_2$

An endothermal process connected with phase transformations of the compound is recorded at 620°.

Analysing the thermal behaviour of $Co(\gamma\text{-pic})_4[FeO_4]$, the existence of an endothermal process at 150° corresponding to ligand elimination and formation of metal oxides is established.

The temperature of 265°C, characterized by the existence of an exothermal peak of A.T.D. – corresponds to a recrystallization process of resulting oxides.

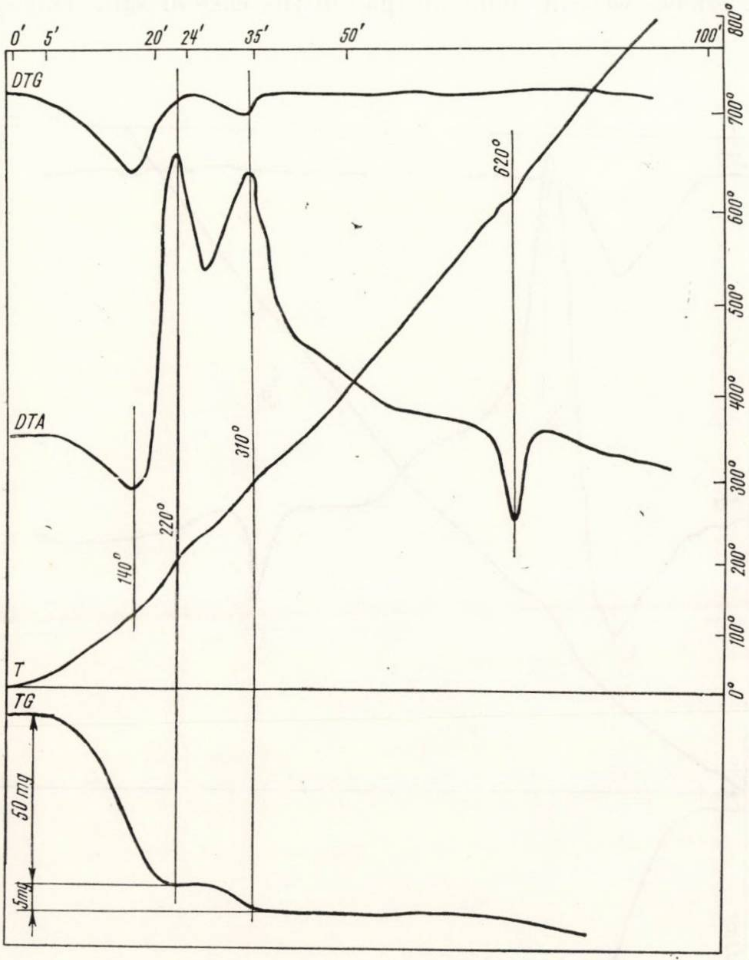

Fig. 3. – Thermal decomposition curves for $CoPy_4[FeO_4]$

An edothermal effect due to a crystalline transition or to a reaction between the resulting oxides is recorded at 645°.

Examining the aspect of the A.T.D. curve corresponding to $Ni(\gamma\text{-pic})_4[FeO_4]$ compound, an endothermal process is established at 110° marking the beginning of decomposition by ligand elimination and oxides formation. The exothermal process at 245° may be assigned to the recrystallisation of resulting oxides. An endothermal effect assigned to phase transformation or to reaction of resulting oxides is recorded at 620°.

We have focused here on γ-picoline compounds (the most stable ones), the behaviour of corresponding α and β compounds being analogous).

Examining the characteristic temperatures of endothermal and exothermal effects we can conclude that in the case of salts containing the

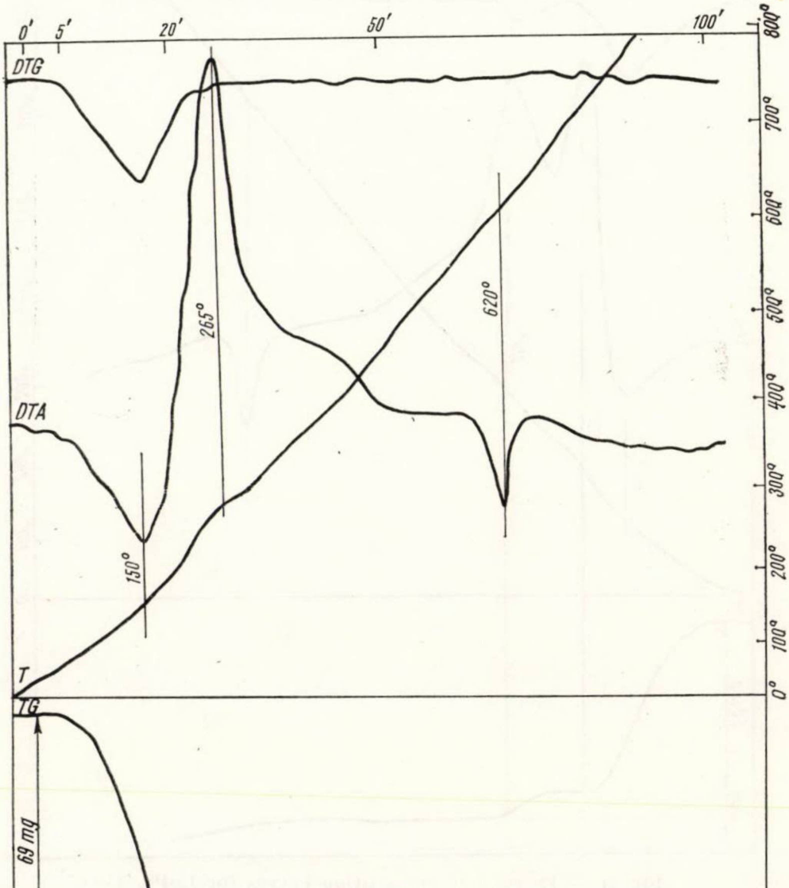

Fig. 4. — Thermal decomposition curves for $Co(\gamma pic)_4[FeO_4]$

ferrate (VI) ion the temperature of decomposition "tm" (and thermal stabilities of these compounds, too) are diminished when ferrate (VI) ion is introduced in their molecule.

The problem of the thermal behaviour of Ni(II) and Co(II) tetrapyridine and tetrapicoline complex compounds is well known in the literature.[6-9]

Table 1

Temperatures corresponding to endothermal and exothermal processes

Compound	Characteristic temperature "tm" (°)	Exothermal process temperature (°)	Endothermal process temperature (°)
$NiPy_4[FeO_4]$	120	255	620
$CoPy_4[FeO_4]$	140	220	620
$Ni(\alpha\text{-pic})_4[FeO_4]$	90	225	620
$Co(\alpha\text{-pic})_4[FeO_4]$	125	230	620
$Ni(\beta\text{-pic})_4[FeO_4]$	105	235	620
$Co(\beta\text{-pic})_4[FeO_4]$	130	250	620
$Ni(\gamma\text{-pic})_4[FeO_4]$	110	245	620
$Co(\gamma\text{-pic})_4[FeO_4]$	150	265	645

Obtaining some compounds that are thermally less stable while the ferrate (VI) ion is introduced, can be explained in terms of a π strong bond (metal-oxygen) that appears in the presence of $[FeO_4]^{2-}$ion.[10]

This leads to its great polarizability and to a strong field formation (in the case of salts containing it), greatly diminishing the positive charge of the central metal ion Ni(II), Co(II).

Thus, the sphere of action of the central metal ion decreases; having a diminished effective charge, this ion presents a smaller attraction power for polar ligand molecules.

In conclusion, a destabilization of compounds containing $[FeO_4]^{2-}$ with Ni(II) and Co(II) complex ammines is produced. This fact is also observed by ligand elimination in a single stage, corresponding to a single endothermal process.

In the case of thiocyanates of complex ammines the following intermediate complexes are formed[11]:

$$NiPy_4\ (SCN)_2(s) \longrightarrow NiPy_2(SCN)_2\ (s) + 2Py\ (g)$$

$$NiPy_2\ (SCN)_2\ (s) \longrightarrow Ni(SCN)_{2(s)} + 2\ Py(g)$$

The chemical analysis of compounds containing ferate (VI) ion after previous heating at various temperatures (200°, 400°, 600°) leads to the conclusion that in these stages, intermediate compounds do not form. We suppose only the formation of metal oxides. Among ferrate (VI) ion salts with picoline a greater stability of γ picoline compounds

[11] I. G. MURGULESCU, E. SEGAL and D. FĂTU, *Rev. Roumaine Chim.*, **11**, 291 (1966).

is observed. A lower stability of α and β picoline compounds is evident due to a metal ligand bond weakening.

This is explained with the help of a steric hindrance existing in these cases. The endothermal process that appears and is reproduced for all compounds containing ferrate (VI) ion at about 620° reveals the existence of a common phenomenon for these compounds. (This temperature is not characteristic of Ni(II) and Co(II) tetrapyridine—tetrapicoline thiocyanates).

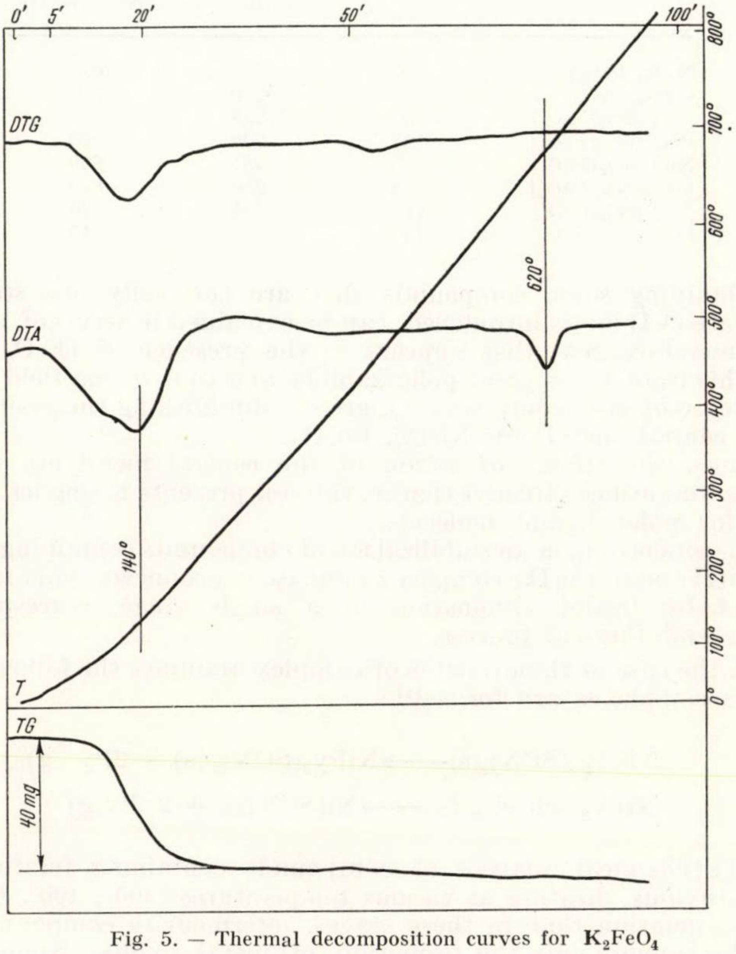

Fig. 5. — Thermal decomposition curves for K_2FeO_4

This phenomenon may be correlated with a phase modification of Fe_2O_3 formed in a previous stage.

The equilibrium between the two existing forms of Fe_2O_3 is known.[12] Thus $\gamma Fe_2O_3 \rightarrow \alpha Fe_2O_3$ (at about 600°).

---

[12] A. F. Wells, "Structural Inorganic Chemistry", 2nd ed. Oxford, University Press, 1962, p. 545.

Another explanation of the endothermal effect at 620° consists in the possible formation of some ferrites with the general formula $Fe_2O_3 . MO$ (M represents Co(II) or Ni (II)). These ferrites[13] belong to spinels groups. Examining the thermal behaviour of K_2FeO_4 (a study made in a separate note) an endothermal peak appears at 620° on A.T.D. curve).

The reproducibility of this phenomenon in the case of potassium ferrate (VI) leads to the conclusion of the existence of a phase transformation. The possibility for a spinel compound formation is not admitted.

This explanation is valid for all the studied compounds containing $(FeO_4)^{2-}$; the same endothermal process at 620° exists in all these cases.[7]

Correlating this endothermal process at 620° with changes in the magnetic properties of Fe_2O_3, the results were found to agree with the experimental data.[14]

Changes in the magnetic properties of Fe_2O_3 are produced by a single endothermal process (found in all the cases studied during phase transformation $\gamma Fe_2O_3 \rightarrow \alpha Fe_2O_3$ corresponding to an exothermal process).

4. CONCLUSIONS

The thermal behaviour of two series of salts containing ferrate (VI) ion with Ni(II) and Co(II) tetrapyridine and tetrapicoline compounds has been studied.

The influence of $[FeO_4]^{2-}$ ion is evidenced by the formation of compounds with relative lower thermal stabilities.

For compounds containing ferrate (VI) ion, ligand elimination takes place in a single stage due to a lower stability.

In all the cases studied, reproducibility of the same endothermal process at 620° (common for K_2FeO_4, too) suggests the existence of a change in Fe_2O_3 magnetic properties.

CHELATES AND POLYCHELATES OF AMINO ACIDS. II[1]

COMPLEXES IN COPPER SOLUTION (II) WITH N(R)-ANTHRANILIC ACIDS

I. GABE, ANICA TOLEA and A. AIRINEI
"P. Poni" Institute of Macromolecular Chemistry
Aleea Grigore Ghica Vodă, 41A, Jassy

Received May 25, 1973

The complexes in solution of N-substituted anthranilic acids with copper (II) have been studied. Their formation constants have been calculated using the McConnell and Davidson's graphical method and some conclusions concerning the substituent influence of nitrogen atom of amino group on the formation ability of chelates have been drawn.

It is well known that many compounds appear in the formation reactions of complexes of some metal ions with α- and *o*-amino acids. The great attention paid to such complexes is caused by the fact that amino acids occupy an important place in the organic structure of the organisms of the animal kingdom. Connected with this, it is interesting to point out the studies underlain by the idea of blocking the viral carcinogenic functions by introducing some chelates into the affected cell, which may link the active amino- and carboxyl groups of the virus structure during metabolism.[2-19]

In a previous paper,[1] we showed that bis-difunctional amino acids can react with transitional metal salts giving chelate polymers, insoluble in water and in usual organic solvents. This fact proves that the metal ion substitutes hydrogen in the carboxylic group and is linked through a donor-acceptor bond to the nitrogen atom of the amino group through the agency of the lone-pair electrons of this atom.

Experimental data[1] enabled the calculation of force constants and valence angles relative to the metal ion radius. Other series of our determinations refer to the copper complexes in solution. Our measurements show that the complexes in solution may have a molar ratio 2 : 1 and 1 : 1, the latter will not precipitate at room temperature, if sufficiently diluted solutions are used.

The complexes having a molar ratio 2 : 1 formed the object of many studies,[20] chelates being precipitated from water solutions and analysed in solid state (by infrared spectra and elemental analysis).

The complexes having a molar ratio 1 : 1 were less studied. In the case of anthranilic acid, for instance, there are such complexes used in the spectrophotometrical determinations of some cations.[21]

We studied the N(R)-anthranilic acids (R = methyl, ethyl, allyl, phenyl) prepared according to the literature.[22-25]

The complexes in solution were studied by McConnell and Davidson's method[26] and by Job's continuous variation method. [27,28] Concentrations between 6.25×10^{-4} M and 1.25×10^{-2} M for N-substituted acid and concentration of 1.25×10^{-2} M for copper perchlorate were used in both series of determinations.

The ionic strength of the solution was kept constant at 0.4, using sodium perchlorate.

We studied spectrophotometrically the variation of molar absorptivity at wavelengths of 664 nm and 650—680 nm, using the position of the absorption maxima of copper complexes with N-methyl and N-ethyl anthranilic acid, respectively.

The experimental data are shown in figures 1 and 2. We calculated from the curves of figure 1 the formation constants of complexes and obtained the values given in table 1.

The results of the studies of the systems discussed by Job's method are shown in figure 2. The shape of these curves reveals that the 2 : 1 complex forms first, and the 1 : 1 complex thereafter and that the two complexes coexist in different amounts at a given moment depending on the mixing ratios. The characteristic absorption maxima and their intensities do not change with time, as results from kinetic determinations. Substituting the amino nitrogen by a radical influences but very little the

Table 1

Formation constant values for copper complexes

Ligand	$K_1 \times 10^4$ Complex 2 : 1	$K_2 \times 10^4$ Complex 1 : 1
N-methylanthranilic acid	0.85	0.26
N-ethylanthranilic acid	0.78	0.18

ionization constant values of the 1 : 1 water-dioxane solutions; thus pK_a is 6.53 for the anthranilic acid and 6.58 for N-methylanthranilic acid.[29]

The substituent has a greater influence on formation constant values of the metal complexes of the respective acids, because the formation constant for the copper complex of N-methylanthranilic acid is 3.7×10^{-4} compared to 1.4×10^{-3} for anthranilic acid.[29]

---

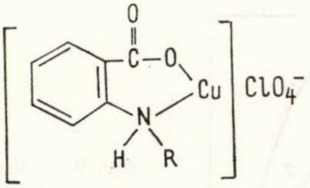
[29] W. F. Harris and T. R. Sweet, *J. Phys. Chem.*, **60**, 509 (1956).

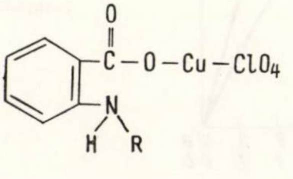
The substitution of methyl by ethyl in the nitrogen atom of the amino group also causes a slight decrease in the formation constant. It is interesting to notice that the substitution of hydrogen in the amino group of the ligand by methyl or ethyl causes some steric hindrances that yield complexes in solution only for those metals which can give plane-square symmetry complexes.

That is why our attempts to obtain complexes in solution with Mn, Ni, Fe, Co, Zn were not satisfactory.

The volume of the nitrogen substituent produces greater steric hindrance; formation constant values of substituted acids are lower than those of unsubstituted acids. The increase in the radical volume (allyl, phenyl) hinders the formation of 1 : 1 complexes and the solubility product of 2 : 1 complexes is so small, that these complexes precipitate immediately in the solution.

Two structures can be supposed for the complexes in solution at a molar ratio 1 : 1.





We take into account the first structure, i.e. the complex structure, because the IR absorption maximum of the amino group which is placed at about 3400 cm^{-1}, in sodium N-methylanthranilate,[20] is shifted to lower frequencies at about 3320 cm^{-1} due to complexation with copper ions. In this way, Decker's results,[20] concluded from the elemental analysis, that copper N-methylanthranilate would be a salt are invalidated.

IR spectral analysis proves the existence of a complex.

When discussing amino nitrogen donor ability we must have in view the influence of the substitution of hydrogen by electron repelling groups and strength modifications in the hydrogen bridge between the amino nitrogen and the carbonylic group of the acid function.

MOLECULAR COMPLEXES WITH AROMATIC CATIONS AS ELECTRON ACCEPTORS. II*

CHARGE-TRANSFER SPECTRUM OF 2,4,6-TRIPHENYLPYRYLIUM THIOCYANATE

ALEXANDRU T. BALABAN and MARIA PARASCHIV
Institute of Atomic Physics, P.O.B. 35, Bucharest

Received June 7, 1974

The orange-red colour of 2,4,6-triphenylpyrylium thiocyanate is due to a charge-transfer band at 488 nm (in dichloromethane).

The deeper colours of iodides of organic aromatic cations as compared to the corresponding perchlorates or tetrafluoroborates are due to charge transfer bands [1,2] involving transitions to less polar electronically excited states. In a crude approximation the ground and excited states can be represented by structures I and II, respectively

$$\underset{\text{I}}{R^{\oplus}\,X^{\ominus}} \overset{h\nu}{\rightleftharpoons} \underset{\text{II}}{R\cdot\ X\cdot} \rightleftharpoons \underset{\text{III}}{R - X}$$

Thus tropylium [3], pyrylium [4,5], and pyridinium iodides [6–8] present absorption bands in the visible range at frequencies decreasing in this order. In a previous paper,[5] we investigated in detail various pyrylium iodides. Nothing is known about charge transfer involving pseudohalide anions and the same cations. In the present paper we report a study of 2,4,6-triphenylpyrylium thiocyanate.

EXPERIMENTAL PART

PREPARATION OF 2,4,6-TRIPHENYLPYRYLIUM THIOCYANATE

2,4,6-Triphenylpyrylium perchlorate was converted into its pseudobase (1,3,5-triphenyl-2-penten-1-one) with sodium acetate in aqueous-ethanolic solution.[9] The pseudobase, m.p. 120°, was dissolved in ethanol and treated with excess 1 N sulphuric acid and a concentrated aqueous solution of ammonium thiocyanate. The brick-red precipitate was filtered off and recrystallized from acetic acid.

An alternative method, involving the treatment of a diluted acetic acid solution of triphenylpyrylium perchlorate with a concentrated aqueous solution of ammonium thiocyanate, must be repeated three to four times in order to afford a perchlorate-free product (as evidenced by the absence of IR absorption at 625 and 1100 cm^{-1}). Better results are obtained by preparing 2,4,6-triphenylpyrylium chloride (introducing gaseous hydrogen chloride into a benzene solution of the pseudobase), dissolving it in dil. ethanol, and treating the solution with aqueous ammonium or potassium thiocyanate.

A third method, which is rather cumbersome, involves the preparation of anhydrous thiocyanic acid from potassium thiocyanate and phosphoric acid at −70° in vacuum,[10] then treating it with the triphenylpyrylium pseudobase in benzene solution.

M.p. 192°. *Found*: N,3.81 ; $C_{23}H_{17}O^{\oplus}SCN^{\ominus}$ requires N, 3.82%.

Electronic absorption spectra were recorded with a CF−4 Optica (Milan) spectrophotometer.

RESULTS AND DISCUSSION

The structure of the brick-red product is ionic, as evidenced by the infrared absorption spectrum (KBr pellet) which contains all bands of the 2,4,6-triphenylpyrylium cation[11] and, in addition, the intense band at 2052 cm^{-1} of the thiocyanate anion.

The ultraviolet absorption spectrum of 2,4,6-triphenylpyrylium thiocyanate in ethanol is closely similar to that of the fluoroborate, chloride, or perchlorate, presenting bands at 264(sh), 280, 325(sh), 360, and 410 nm.[3] However, a dichloromethane solution of the thiocyanate has a deeper colour than the ethanolic solution, and its spectrum (fig. 1) presents the bands displayed in table 1.

For the bands designated as *x*-, *y*- and *x*-band [12,13] the agreement with the absorption spectrum of the 2,4,6-triphenylpyrylium iodide [5] is very good.

The transition at 488 nm in CH_2Cl_2, which is absent in 2,4,6-triphenylpyrylium salts with non-intereacting anions such as ClO_4 or BF_4, must be ascribed to a charge-transfer similar to that of the iodide. 2,4,6-Triphenylpyrylium iodide has the charge transfer band at 551 nm in methylene chloride. The difference is to be ascribed to the smaller donor ability of the thiocyanate anion as compared to the iodide anion. A comparison between the acceptor abilities of thiocyanogen and iodine in charge-transfer spectra with aromatic donors was made by Vântu and coworkers.[14]

Table 1

[14] W. Scholz, A. Truţia and V. Vântu, *Tetrahedron Letters*, **1965**, 57.

A direct equilibrium in solution between ionic and covalent tropylium isocyanate was evidenced by NMR,[15] and this will necessitate a revision of earlier data.[16] However, on the time-scale of the electronic excitation, process II—III is too slow to affect the charge transfer I—II.

The NMR spectrum of triphenylpyrylium thiocyanate (I) in deuterochloroform containing 10% acetonitrile presents at —40° a broadening of signals, but fails to reveal the appearance of new bands due to a covalent form (III).

The elemental analysis was performed by Mrs. C. Popescu, and the NMR spectrum was recorded by Mrs. A. Vasilescu.

STUDIES IN THE *s*-TRIAZINE FIELD (NEW SERIES). XVI.[1]

ACIDIC AND TAUTOMERIC EQUILIBRIUM CONSTANTS OF THE CONJUGATED ACIDS OF SOME E-1,3-DIMETHYL-6-(*p*-DIALKYLAMINO-β-STYRYL)-2,4-DIOXO-1H, 3H-1,3,5-TRIAZINES

M. SAFTA and G. OSTROGOVICH

Laboratory of Organic Chemistry, Polytechnic Institute "Traian Vuia"
Timişoara, str. Bocşa 6, Romania

Received December 21, 1973

The tautomerism constant K_T = [Ammonium ion] / [Triazinium ion] = K''_{a_1} (triaz.)/K'_{a_1} of first step conjugated acids of the title compounds, as well as the apparent acidity constant $Ka_1 = (K'_{a_1} . K''_{a_1})/(K'_{a_1} + K''_{a_1})$, have been determined by the spectrophotometric method. The Si Jung Yeh's [12b] and the Gerson's[14] modes of applying this method were discussed. It is presented another way to use the spectrophotometric data for the same purpose. The effective acidity constants K'_{a_1} and K''_{a_2} have been calculated. The substitution of Me by Et in the dialkylamino-compound determines an increase of both constants but much more of the K'_{a_1} one. This is fully analogous to the observations of the Japanese authors [22] by *p*-dialkylaminoazo-derivatives. It corresponds to the known anomalous high basicity of diethyl- in comparison with dimethylaniline.[24b] It has obviously the same explanation through the intervention of a solvation inhibiting steric effect in the base molecule, which surpasses the spectral manifested increase of the +M-effect.

A previous paper including a spectrophotometric study which led to semiquantitative results [2] allowed us to prove that the protonation in the first step of the 6-(*p*-dimethylamino-β-styryl)-2,4-dioxo-1H,3H-1,3,5-triazine, a yellow coloured base, is giving rise to an ammonium-triazinium tautomery entirely similar to the ammonium-azonium tautomery exhibited by the salts of *p*-amino-azo-derivatives with an acid equivalent.

Discovered by J. Thiele on the *p*-amino-azobenzenes hydrochlorides [3] and categorically elucidated for the first time, as is known, by Hantzsch *et al.*,[4] this particular type (which, besides others, belongs to the large enough and multiform genus of "benzoido-chinoido" tautomery) has become, from the beginning till nowadays, including some controversies,[5-10] the subject of extensive studies concerning a series of various amino-azoderivatives.

Especially in the last time these studies have been carefully performed, leading to the determination of the acidity constants of the conjugated acid pairs, respectively constants of the tautomeric equilibria established between those species in solution.[11-20]

For our compounds the tautomeric equilibrium (and the protolytic equilibrium involved) has been determined in 50 % vol. aqueous-ethanolic solution in the presence of sulphuric acid.

The tautomeric equilibrium for the 1,3-dimethylated compounds, which constitutes the object of this study, is described in the following scheme (1).

In contrast to many cases in which it was possible to isolate in crystalline form, as "chromoisomeric" species, both monoprotonated tautomeric compounds of some aminoazo-derivatives,[4] the product which crystallized from the aqueous or aqueous-ethanolic solutions employed is in our cases only the coloured tautomer of II″ type (obtained as the bisulphate $BH^{\oplus}HSO_4^{\ominus}$).[2,21]

Besides — as it was not seldom achieved with aminoazo-derivatives — we could also obtain the type III product, which arises by double protonation of the base I and which is, as expected, colourless.

In our first paper on this matter,[2] a preconceived opinion concerning the doubtless —M effect of the dioxo-*s*-triazinic nucleus, which causes the yellow colour of the type I base and the halochromism of the monoprotonated species II″ — i.e. this effect should be very strong — as

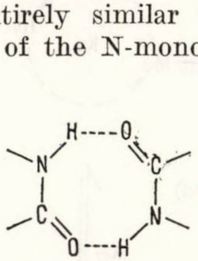
well as the fact that the coloured tautomer is the one which separates from the solution at crystallization, have induced us to assume in advance as very probable that in the equilibrium between the two monoprotonated species II′ and II″, the latter is the prevailing one, in other words that from the two basic centres of the molecule — the N atom at the 5 position of the triazine nucleus and that belonging to the dialkylamino group, the first one exhibits a higher basicity than the second. This misleaded us in interpreting the modifications of the solution spectrum as function of the medium acidity, of course complicated by the subsequent intervention of the second protonation step, which call forth to the colourless species of type III.

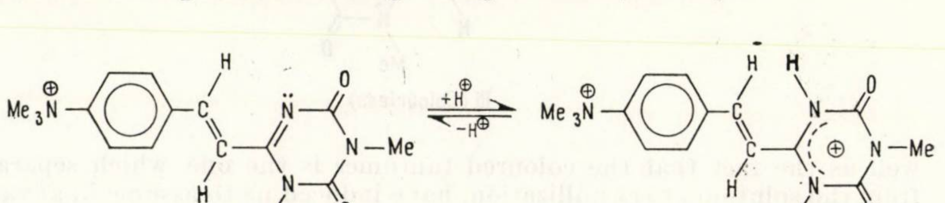
The results of the present paper showed that actually the N-atom of the dialkylaminogroup is more basic than the one in position 5 of the *s*-triazine and, consequently, the colourless type II′ tautomer is prevailing in solution as compared to the type II″ coloured one. Consequently, the fact that the tautomer leaving the system at crystallization is however the last one, should be due to its much smaller solubility compared to that of the first one, at least in aqueous and ethanolic-aqueous media, but probably in any other medium which could be a solvent of the base and of its conjugated acids.

A very plausible explanation of this finding is based on the observation that the coloured form possesses a higher constitutional symmetry in comparison with that of the colourless one, in other words that it should be capable of a stronger molecular association. Indeed one can immediately recognize that such an asssociation should establish itself through a lattice of hydrogen bonds entirely similar to those of the carboxylic acids dimers and especially of the N-monosubstituted carboxyl-amides, according to the scheme :



In the present paper we determined spectrophotometrically the tautomeric constant K_T and the overall acidity constant K_{a_1} from which the individual acidity constants K'_{a_1} and K''_{a_1} were calculated.

As far as the protonation in the second step is concerned, the value of K'_{a_2} constant is known from our previous paper in which we studied spectrophotometrically the protonation equilibrium of the quaternary ammonium compound IV corresponding to base I, namely :

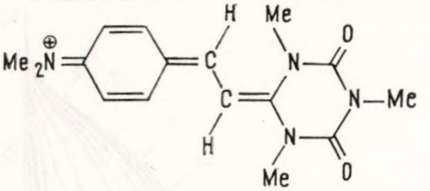


IV

V

The evaluation of the equilibrium constants of the monoprotonation process becomes possible from the moment at which we recorded the spectra of the *p*-dimethylamino-β-styryl-hemicyanine cation VI. The latter is metamer with IV — as II′ is tautomer with II″ — and has been synthetized by condensation of *p*-dimethylaminobenzaldehyde with the

1,3,5,6-tetramethyl-2,4-dioxo-1H,3H-1,3,5-triazinium iodide :



VI

The key of the problem was given by comparing this spectrum with that of the I + H_2SO_4 system, in the same medium.

Before the presentation of the results, it is necessary to refer to a very recent study performed by the Japanese authors Yamamoto *et al.*[22] which found that the K_T value belonging to the conjugated acids of *p*-dialkylaminoazobenzenes is considerably influenced by the volume of the alkyl group. They revealed that this influence is due to the abnormally basicity increase of the Et_2N-group compared to the Me_2N- one. In agreement with former studies concerning a N,N-dialkyl-aniline series,[23-25] this is due to the fact that in the molecule of the N,N-diethylamino base, besides the general conjugation effect, a steric effect is also present. The solvation of this base by proton bonds with the solvent molecules (a still very important solvation of the Me_2N-group) undergoes a practically complete inhibition by the steric effect, so that the free energy of the protonation process is adequately decreasing in this case compared to the Me_2N-group, determining thus a much higher basicity than that of the first one (i.e. a very important lowering of the conjugated acidity constant, K_a). These observations determined us to extend the present study from compound I, in which Alc = Me, to the one with Alc = Et.

RESULTS AND DISCUSSION

a) THE SPECTROSCOPIC BEHAVIOUR OF THE PROTONATION PROCESS

Figs 1 and 2 clearly show that in 50% vol aqueous-ethanolic solution and in the presence of H_2SO_4 up to a concentration $C_{H_2SO_4} \approx 0.4N$, the E-1,3-dimethyl-6-(*p*-dimethylamino-β-styryl)-2,4-dioxo-1H,3H-*s*-triazine (I, Alc = Me) exists in equilibrium with the two protonated tautomeric species II′ and II″ (Alc = Me). The species II'_{Me} exhibits a band in the ultraviolet range ($\lambda = 300$ nm, see fig. 1, curves *6* ÷ *11* and fig. 2, curve *1*) while II''_{Me} has a less intense band in the visible region ($\lambda = 523$ nm, see fig. 1, curve *10*).

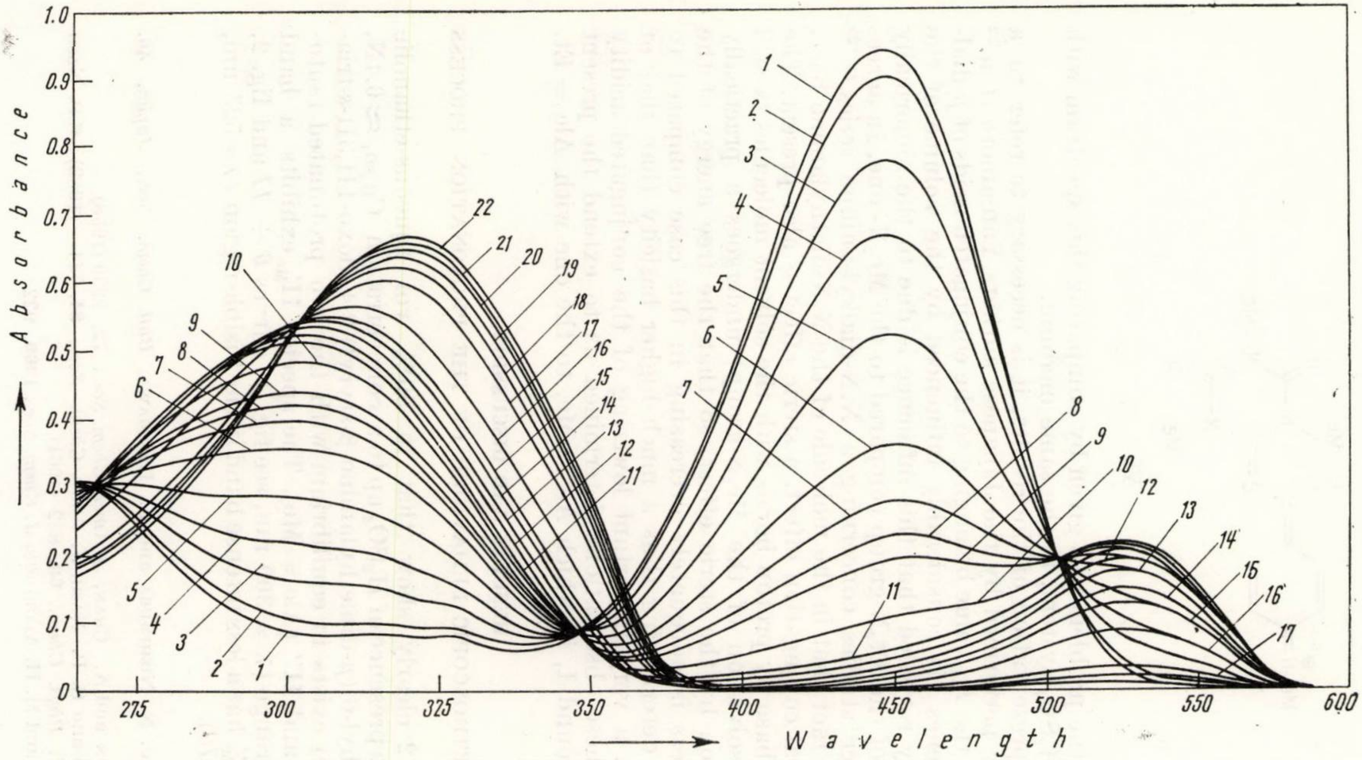

Fig. 1. — Influence of medium acidity (expressed as $C_{H_2SO_4}$ normality) on the absorption of the system initially formed from base I ($C = 2.5 \cdot 10^{-5}$ mol·l^{-1}; Alc = Me) and H_2SO_4 in 50 vol. % aqueous-ethanolic solution :

Curve Nº	1	2	3	4	5	6	7	8	9	10	11
$C_{H_2SO_4}$ (val/1)	0	10^{-3}	$5 \cdot 10^{-3}$	10^{-2}	$2 \cdot 10^{-2}$	$4 \cdot 10^{-2}$	$6 \cdot 10^{-2}$	$8 \cdot 10^{-2}$	10^{-1}	$2 \cdot 10^{-1}$	$4 \cdot 10^{-1}$

Curve Nº	12	13	14	15	16	17	18	19	20	21	22
$C_{H_2SO_4}$ (val/1)	$6 \cdot 10^{-1}$	$8 \cdot 10^{-1}$	1	1.5	3.0	5.0	6.0	7.0	8.0	9.0	10

The gradual acidity increase up to the above mentioned limit is expressed by the appearance and intensity increase of these two bands, together with the intensity decrease of the characteristic band of base I_{Me}, at 447 nm (fig. 1, curve *1*). The concentration of the last becomes negligible just when $C_{H_2SO_4}$ reaches the 0.4 N value (fig. 1, curve *11*). In the acidity range 0.4 N $\leqslant C_{H_2SO^4} \leqslant$ 1.5 N (fig. 1, curves *12—15*) only the monoprotonated species II′ and II″ are practically present in the system, afterwhich the second protonation is continuing in a rate increasing with acidity, the following equilibrium $(II' + II'') \rightleftharpoons III$ being established (fig. 1, curves *16 ÷ 22* and fig. 2). It is thus seen that the

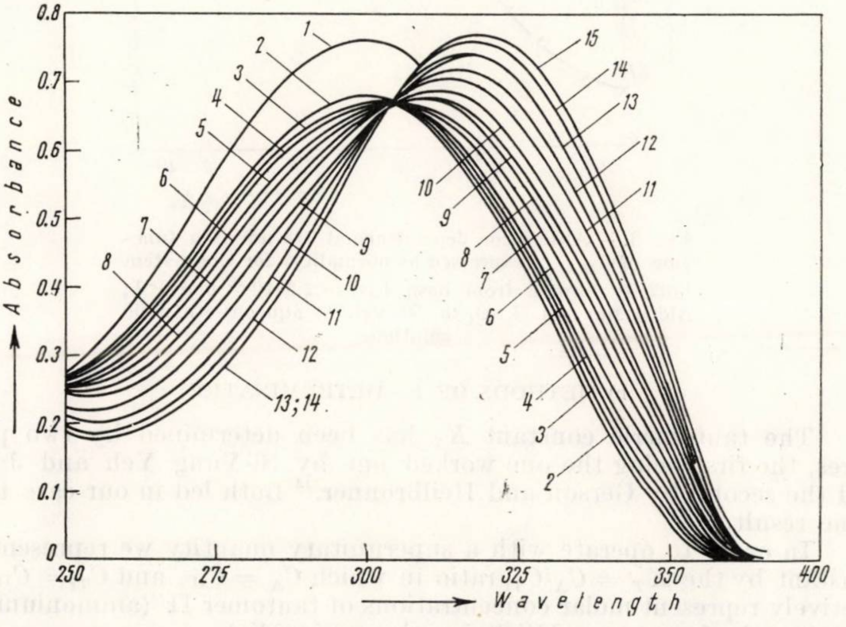

Fig. 2. — Spectral manifestation of the shifting of protolytic equilibrium system IV $\rightleftharpoons$ V with the H_2SO_4—normality increase, in 50 vol % aqueous-ethanolic solution ($C_{IV} = 2.5 \cdot 10^{-5}$ mol $\cdot l^{-1}$):

colourless, diprotonated species (III_{Me}) is characterized by a band with maximum at about 320 nm (321 nm fig. 1, curve *22*, respectively 318, fig. 2, curve *15*). The two successive protonation steps clearly appear as individual stages in fig. 3.

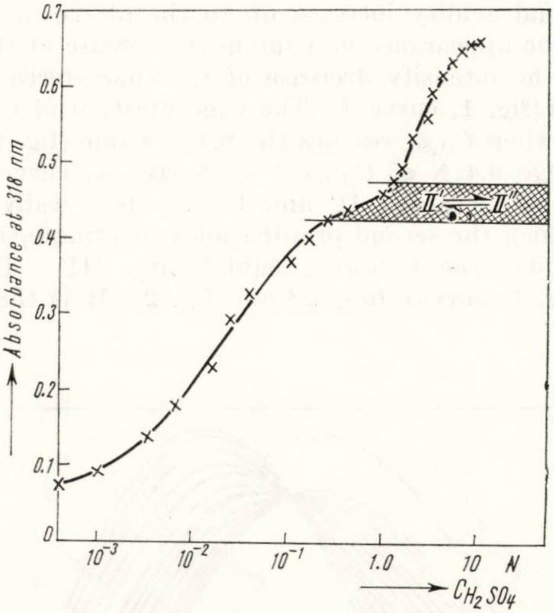

Fig. 3. — Absorption dependence at 318 nm as a function of $C_{H_2SO_4}$ (expressed as normality) for the system initially formed from base I ($C = 2.5 \cdot 10^{-5}$ mol $\cdot$ l^{-1}; Alc = Me) and H_2SO_4 in 50 vol. % aqueous-ethanolic solution.

b) METHODS OF K_T DETERMINATION

The tautomeric constant K_T has been determined by two procedures, the first being the one worked out by Si-Yung Yeh and Jaffe[12b] and the second by Gerson and Heilbronner.[14] Both led in our case to the same result.

In order to operate with a superunitary quantity we represent this constant by the $K_T = C_A/C_{Tr}$ ratio in which $C_A = C_{II'}$, and $C_{Tr} = C_{II''}$ respectively represent molar concentrations of tautomer II′ (ammonium-benzoido) and of tautomer II″ (triazinium-chinoidic).

1. — In agreement with the above mentioned authors [7b] it is reasonable to consider that the longest wavelength band at 300 nm is characterized by the same molar extinction coefficient value for both the pure compound II′ and for compound IV, which differs from the first one only by the substitution of one hydrogen atom by a methyl group in the ammonium group which is attached to the β-styryl system in the *para* position. In fact this premise is theoretically justified by the fact that the two groups $Me_2\overset{\oplus}{N}H$- and $Me_3\overset{\oplus}{N}$- must exhibit practically the same electronic effect, as it is also shown by the identical values of the substituent constants which were determined for the MeHN- and Me_2N-groups ($\sigma_{p-NHMe} = -0.83$ and $\sigma_{p-NMe_2} = -0.84$).[26]

---

[26] D. H. McDaniel and H. C. Brown, *J. Org. Chem.*, **23**, 420 (1958).

It is thus possible to determine, for each acidity value $C_{H_2SO_4}$, the concentrations C_A and C_{Tr} of species II′ and II″ by measuring the difference between the two molar extinction coefficients $\varepsilon_{IV}^{\lambda_A}$ and $\varepsilon_{VI}^{\lambda_A}$ of compounds IV and VI (at the same acidity value for the species IV) at the analytical wavelength ($\lambda_A = 300$ nm in our case) as compared with the apparent molar extinction ε^{λ_A} observed for the equilibrium mixture II′ ⇌ II″. This leads to :

$$K_T = \frac{C_A}{C_{Tr}} = \frac{\varepsilon^{\lambda_A} - \varepsilon_{Tr}^{\lambda_A}}{\varepsilon_A^{\lambda_A} - \varepsilon^{\lambda_A}} \tag{3}$$

Due to the fact that species VI (corresponding to tautomer II″) exhibits no absorbance at this wavelength ($\varepsilon_{VI}^{\lambda_A} = 0$), it results that in the entire acidity range, in which the system practically contains only the two tautomers, we have $\varepsilon_{Tr}^{\lambda_A} = 0$, so that equation (3) simplifies and becomes :

$$K_T = \frac{\varepsilon^{\lambda_A}}{\varepsilon_A^{\lambda_A} - \varepsilon^{\lambda_A}} \tag{4}$$

2. — The second procedure [14] is based on the extinction additivity both at the wavelength of the frontal band maximum of one tautomer and of that of the frontal band maximum of the other one. The additivity is expressed by the following equations :

$$\varepsilon^{\lambda_A} = \varepsilon_A^{\lambda_A} \cdot C'_A + \varepsilon_{Tr}^{\lambda_A} \cdot C'_{Tr} \tag{5}$$

$$\varepsilon^{\lambda_{Tr}} = \varepsilon_{Tr}^{\lambda_{Tr}} \cdot C'_{Tr} + \varepsilon_A^{\lambda_{Tr}} \cdot C'_A \tag{6}$$

in which C'_A and C'_{Tr} represent the molar fractions of each tautomer so that instead of relation $C_A + C_{Tr} = C_I$ (where C_I is the initial molar concentration of base I) the following equation may be written :

$$C'_A + C'_{Tr} = 1 \tag{7}$$

Deducing from eq (6) the expression for C'_{Tr} and substituting it in (5) one reaches the following equation :

$$K_T = \frac{C'_A}{C'_{Tr}} = \frac{(\varepsilon_{Tr}^{\lambda_A} \cdot \varepsilon^{\lambda_{Tr}} - \varepsilon_{Tr}^{\lambda_{Tr}} \cdot \varepsilon^{\lambda_A}) \cdot \varepsilon_{Tr}^{\lambda_{Tr}}}{(\varepsilon_A^{\lambda_{Tr}} \cdot \varepsilon_{Tr}^{\lambda_A} - \varepsilon_A^{\lambda_A} \cdot \varepsilon_{Tr}^{\lambda_{Tr}})(\varepsilon^{\lambda_{Tr}} - \varepsilon_A^{\lambda_{Tr}} \cdot C'_A)} \tag{8}$$

Due to the fact that none of the tautomer species II′ = A and II″ = Tr is not absorbing in the frontal band maximum range of the other one (just as the conjugated acids of the *p*-amino-azoderivatives),

($\varepsilon_{\mathrm{Tr}}^{\lambda_{\mathrm{A}}} = 0$ and $\varepsilon_{\mathrm{A}}^{\lambda_{\mathrm{Tr}}} = 0$), the second member of equation (8) is very much simplified. The expression of the K_T constant is thus given by the equation :

$$K_T = \frac{\varepsilon_{\mathrm{Tr}}^{\lambda_{\mathrm{Tr}}} \cdot \varepsilon^{\lambda_{\mathrm{A}}}}{\varepsilon^{\lambda_{\mathrm{Tr}}} \cdot \varepsilon_{\mathrm{A}}^{\lambda_{\mathrm{A}}}} \tag{9}$$

Besides the $\varepsilon^{\lambda_{\mathrm{A}}}$ and $\varepsilon^{\lambda_{\mathrm{Tr}}}$ values which can be directly obtained from the extinction curves of the tautomeric mixtures solutions, only $\varepsilon_{\mathrm{A}}^{\lambda_{\mathrm{A}}}$ is known from the spectrum of species IV. The value of the $\varepsilon_{\mathrm{Tr}}^{\lambda_{\mathrm{Tr}}}/\varepsilon^{\lambda_{\mathrm{Tr}}}$ ratio can be determined indirectly by means of equation (7′) which is equivalent to (7) :

$$\frac{\varepsilon^{\lambda_{\mathrm{Tr}}}}{\varepsilon_{\mathrm{Tr}}^{\lambda_{\mathrm{Tr}}}} = 1 - \frac{\varepsilon^{\lambda_{\mathrm{A}}}}{\varepsilon_{\mathrm{A}}^{\lambda_{\mathrm{A}}}} \tag{7′}$$

It may be clearly seen that when the above simplifications are justified, this procedure must lead to a K_{T} value practically identical to the one determined by Jaffé's *et al.* procedure, because by substituting the reverse value of the expression from the second member of eq. (7′) in equation (9) we reach exactly equation (4).

It has to be pointed out that the graphical method proposed by Kaminski *et al.* [18a,b,c] for the molar extinction coefficient determination of the two tautomers, based on the experimentally obtained straight line extrapolation up to the intersection with the coordinate axes – a method which was also successfully applied by the Japanese authors, for the *p*-amino-azoderivatives[22] – cannot be applied in our case because the acidity range in which the straight line, $\varepsilon^{\lambda_{\mathrm{Tr}}} = a \cdot \varepsilon^{\lambda_{\mathrm{A}}}$, can be obtained is too small, so that the extrapolation becomes inaccurate.

3. – We found that in the present case the spectrophotometric measurements can be also extended over the lower acidity range in which the protolytic equilibrium I ⇌ (II′ + II″) is established (and thus the system contains also base I, besides the two conjugated acids). This can be done, as we have $\varepsilon_{\mathrm{I}}^{\lambda_{\mathrm{A}}} \ll \varepsilon_{\mathrm{A}}^{\lambda_{\mathrm{A}}}$ and $\varepsilon_{\mathrm{I}}^{\lambda_{\mathrm{Tr}}} \ll \varepsilon_{\mathrm{Tr}}^{\lambda_{\mathrm{Tr}}}$ (practically $\varepsilon_{\mathrm{I}}^{\lambda_{\mathrm{Tr}}} = 0$).

Writing relation (10) which applies in these conditions

$$C'_{\mathrm{A}} + C'_{\mathrm{Tr}} + C'_{\mathrm{I}} = 1 \tag{10}$$

in which $C'_{\mathrm{I}} = \dfrac{\varepsilon^{\lambda_{\mathrm{I}}}}{\varepsilon_{\mathrm{I}}^{\lambda_{\mathrm{I}}}}$ and $C'_{\mathrm{A}} = \dfrac{\varepsilon^{\lambda_{\mathrm{A}}}}{\varepsilon_{\mathrm{A}}^{\lambda_{\mathrm{A}}}}$

follows that

$$C'_{\mathrm{Tr}} = \frac{\varepsilon^{\lambda_{\mathrm{Tr}}}}{\varepsilon_{\mathrm{Tr}}^{\lambda_{\mathrm{Tr}}}} = 1 - \left(\frac{\varepsilon^{\lambda_{\mathrm{I}}}}{\varepsilon_{\mathrm{I}}^{\lambda_{\mathrm{I}}}} + \frac{\varepsilon^{\lambda_{\mathrm{A}}}}{\varepsilon_{\mathrm{A}}^{\lambda_{\mathrm{A}}}} \right)$$

from which

$$K_T = \frac{C'_{\mathrm{A}}}{C'_{\mathrm{Tr}}} = \frac{\varepsilon^{\lambda_{\mathrm{A}}} \cdot \varepsilon_{\mathrm{I}}^{\lambda_{\mathrm{I}}}}{\varepsilon_{\mathrm{I}}^{\lambda_{\mathrm{I}}} (\varepsilon_{\mathrm{A}}^{\lambda_{\mathrm{A}}} - \varepsilon^{\lambda_{\mathrm{A}}}) - \varepsilon_{\mathrm{A}}^{\lambda_{\mathrm{A}}} \cdot \varepsilon^{\lambda_{\mathrm{I}}}} \tag{11}$$

As is seen, in the K_T expression there are four values which can be directly recorded, namely : ε^{λ_A}, $\varepsilon_A^{\lambda_A}$, ε^{λ_I} and $\varepsilon_I^{\lambda_I}$. As $\varepsilon_I^{\lambda_A} \neq 0$ (see fig. 1) the ε^{λ_A} values for various acidities have been corrected. Therefore, it was taken into account that $\varepsilon_I^{\lambda_A}$ is decreasing proportionally with the increase of sulphuric acid concentration, thus with the increase of the protonated II′ species concentration. The corrections thus calculated and the $\varepsilon_{cor}^{\lambda_A}$ values which allowed the computation of C'_A and C'_B values, and also of C' values, are given in table 2.

c) THE DETERMINATION OF THE TAUTOMERIC EQUILIBRIUM CONSTANTS AND THE INFLUENCE OF THE ALKYL GROUPS NATURE

As the tautomeric equilibrium constant K_T is a measure of the difference between the basicity of the amino nitrogen (pK'_{a_1}) and that of the *s*-triazine nitrogen (pK''_{a_1}) (eq. (12)) the examination of the effects of the N-alkyl groups on the pK'_{a_1} and pK'_{a_2} values is needed for the interpretation of these effects on the K_T values, because :

$$K_T = \frac{K''_{a_1}}{K'_{a_1}} \tag{12}$$

On the other hand, from the tautomeric equilibrium relations for the first protonation step, it can be shown that[27] :

$$\frac{1}{K_{a_1}} = \frac{1}{K'_{a_1}} + \frac{1}{K''_{a_1}} \tag{13}$$

and

$$K'_{a_1} = K_{a_1}(1 + K_T) \tag{14}$$

in which K_{a_1} is the apparent dissociation constant of the first protonation step.

From eqs. (14) and (12) it follows that if K_T and K_{a_1} are known values, the first dissociation constants K'_{a_1} and K''_{a_1} can be computed.

The K_{a_1} value for the two compounds (Alc $= -CH_3$ and $-C_2H_5$) has been determined directly by the graphical method [28,29] by means of fig. 4, in which $pK_{a_1} = \text{tg}\alpha$.

Concerning K_T, it was determined by means of equation (4) or (7′) and of equation (11) and the results obtained are given in tables 1 and 2 for Alc $= CH_3$, and in table 3 for Alc $= C_2H_5$.

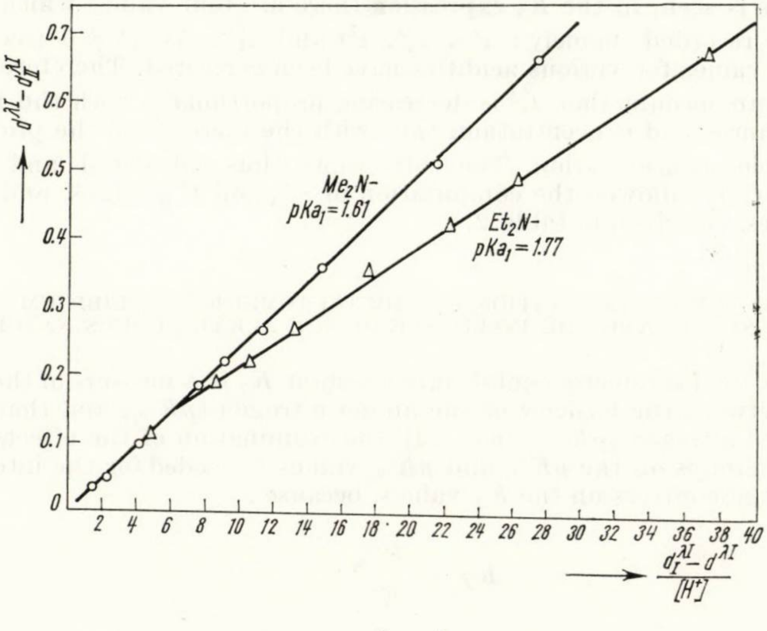

Fig. 4. — Plot of $d^{\lambda}I - d_{II}^{\lambda}I$ *versus* $\frac{d_I^{\lambda}I - d^{\lambda}I}{[H+]}$ for the determination of the $pKa_1 = \text{tg}\ \alpha$ values.

According to the data in table 2 the mean K_T value ($=3.66$) obtained by us, (eq. 11) is in very good agreement with the one based on equation (4) or (7′) ($K_T = 3.59$, table 1).

Knowing the value of pK_{a_2} (from the previous paper [1]) and of K_T, we calculated (for Alc $= CH_3$) the second ionization constants, K'_{a_2} and K''_{a_2}, by means of the following equations [27]:

$$K_{a_2} = K''_{a_2}\,(K_T + 1)$$

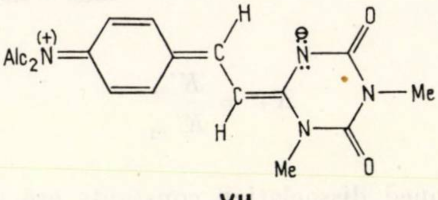
IV	—	—	300	26 ,800	—	—
VI*	—	—	—	—	520	16,800

* in H_2SO_4 0.1 N

It is seen that the N,N-diethylamino base absorbs at longer wavelength than its N,N-dimethylamino analogue. This fact is proving that the degree of resonance interaction between the lone pair electrons of the amin nitrogen and the π-electrons is greater for the former compound. In other words the contribution of the mesomeric form VII to the real state of the molecule is greater when Alc $= -C_2H_5$.



VII

For the same reason the pK''_{a_1} values increase in the order : dimethylamino < diethylamino (see table 4). The pK'_{a_1} values should therefore increase in the opposite order, namely diethylamino < dimethylamino, but actually they increase in the same order : diethylamino > dimethylamino as that for the N,N-dialkyl-aniline derivatives [23-25] and dialkylaminoazobenzenes.[22] This is due to the inhibition of the hydrogen bonding between the hydroxylic solvent and the aminonitrogen atom for base I, where Alc $= C_2H_5$. The decrease of solvation energy increases the free energy of this base and, consequently, reduces the energy gap between I (Alc $= -C_2H_5$) and its corresponding conjugated acid II′, thus increasing the basicity of this compound compared to its dimethylamino analogue. Obviously, this also finds its expression in the higher K_T value of the diethylamino-compound than that of the dimethyl-analogous ones.

EXPERIMENTAL

PREPARATION OF THE COMPOUNDS

The E-1,3-dimethyl-6-(p-*dimethylamino-β-styryl*)*-2,4-dioxo-1H,3H-1,3,5-triazine* and the corresponding *hemicyanine VI* were prepared following ref.[21] The compound IV was prepared following ref.[30]

The E-1,3-dimethyl-6-(p-*diethylamino-β-styryl*)*-2,4-dioxo-1H,3H-1,3,5-triazine* was prepared using piperidine catalysis as in the case of their *p*-dimethylamino-analogues. The same solvents for purification were used.

PREPARATION OF THE SOLUTIONS

The solutions were prepared as it was described in the previous paper (Part XV).[1] The spectra of these having the initial concentration of the base I equal to $2.5 \cdot 10^{-5}$ mol$\cdot$l^{-1} were recorded using an UNICAM SP-8000 instrument and a 1 cm cell.

SYNTHESES OF NAPHTH[2,3-c]ACRIDAN-5,8,14-TRIONIC DYES

F. URSEANU, C. DRĂGHICI and V. OLTEANU
Laboratory of Chemistry and Technology of Aromatic Intermediates and Dyes, Polytechnic Institute, Bucharest, Calea Victoriei, 149

Received December 12, 1973

New syntheses for the preparation of dyes with 6-methyl-aminonapht[2,3-c]acridan-5,8,14-trione structure are described.

1. INTRODUCTION

The use of sythetic fibres on a large scale is conditioned by the output of various typical dyes. Thus, a special importance acquire disperse dyes, which can dye all categories of synthetic fibres (polyester, polyamide, polyacrylonitrile fibres) and cationic dyes used only for dyeing polyacrylonitrile fibres.

Numerous syntheses of these dyes showing various structures have been performed in recent years; among them are those with naphth[2,3-c]-acridan-5,8,14-trione structure,[1-9] which have remarkable tinctorial properties.

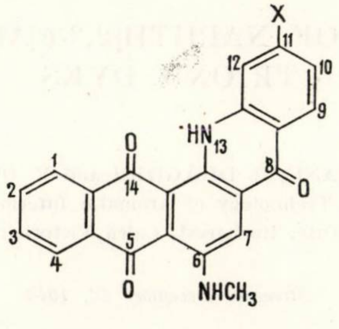
In the present work we discuss the synthesis of three 6-methylaminonaphth[2,3-c]acridan-5,8,14-trione derivatives with the following general formula :

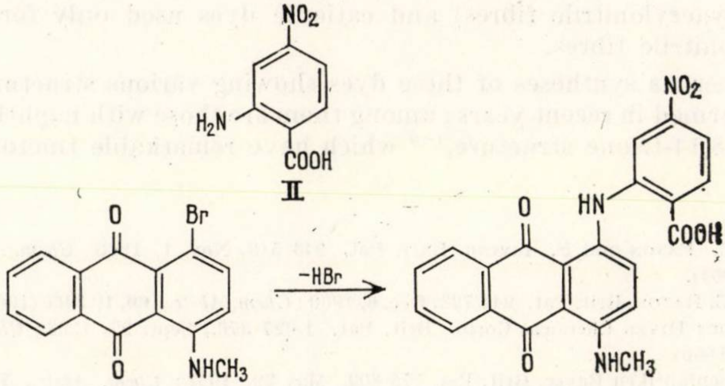


in which $X = NO_2,\ NH_2,\ NHCOCH_2\overset{+}{N}C_5H_5]Cl^-$

2. SYNTHESIS OF 6-METHYLAMINONAPTH[2,3-C]ACRIDAN-5,8,14-TRIONE DERIVATIVES

From the starting material 1-methylamino-4-bromoanthraquinone I, 6-methylaminonaphth [2,3-c]acridan-5,8,14-trione derivatives were obtained based on the reaction schemes given below.

2.1. CONDENSATION OF 1-METHYLAMINO-4-BROMOANTHRAQUINONE WITH 4-NITROANTHRANILIC ACID



Condensation was performed by the Ullmann reaction,[10-12] by heating the reagents I and II in nitrobenzene at 180° for 10 hours, in the

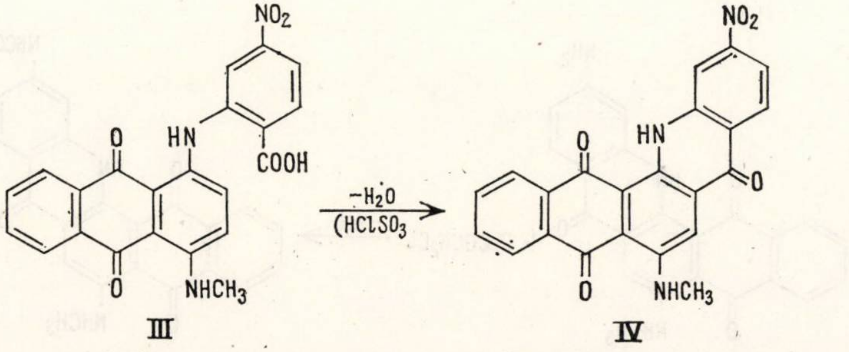
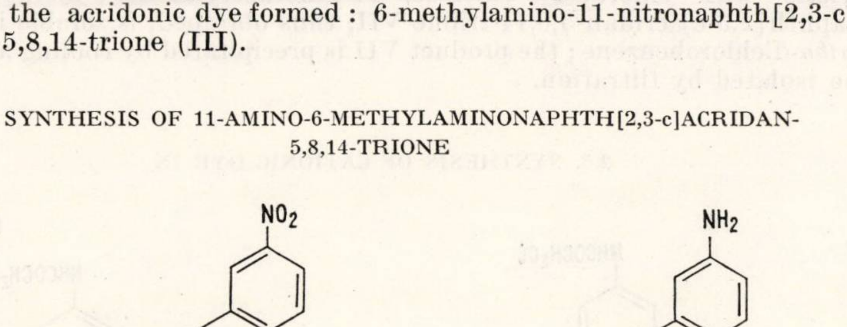
presence of copper powder and copper sulphate as catalysts and anhydrous sodium acetate, necessary to neutralize the hydrobromic acid formed during the reaction; 4-methylamino-1-anilinoanthraquinone-5′-nitro-2′-carboxylic acid III are thus obtained.

2.2. ACRIDONIC RING CLOSURE IN 4-METHYLAMINO-1-ANILINOANTHRAQUINONE-5′-NITRO-2′-CARBOXYLIC ACID



Acridonic ring closure was achieved in $HClSO_3$, at a temperature between 65—70°, at a relative short reaction time (15 minutes), according to literature procedures.[5,6,8,13] At the end the mixture was poured on ice in order to decompose the excess of chlorosulphonic acid and to precipitate the acridonic dye formed: 6-methylamino-11-nitronaphth[2,3-c]acridan-5,8,14-trione (III).

2.3. SYNTHESIS OF 11-AMINO-6-METHYLAMINONAPHTH[2,3-c]ACRIDAN-5,8,14-TRIONE



---

[13] B. S. Ioshi, B. D. Tilak and K. Venkataraman, *Proc. Indian Acad. Sci.*, **32A**, 201 (1950).

11-Amino-6-methylaminonaphth [2,3-c]acridan-5,8,14-trione dye V has been obtained by reduction with aqueous solution of natrium sulphide in N.N-dimethylformamide of the corresponding 6-methylamino-11-nitronaphth[2,3-c]acridan-5,8,14-trione derivative IV; reduction was performed by a three hours at 90°.

2.4. SYNTHESIS OF 11-CHLORACETYLAMINO-6-METHYLAMINONAPHTH[2,3-c] ACRIDAN-5,8,14-TRIONE (VII)

Acylation was carried out by heating at 160° for 2 hours in *ortho*-dichlorobenzene of 11-amino-6-methylaminonaphth[2,3-c] acridan-5,8,14-trione with chloracetyl chloride. 11-Chloracetylamino-6-methylaminonaphth[2,3-c]acridan-5,8,14-trione VII, thus obtained, is soluble in warm *ortho*-dichlorobenzene; the product VII is precipitated by cooling and may be isolated by filtration.

The solution of 11-chloracetylamino-6-methylaminonaphth [2,3-c] acridan-5,8,14-trione in *ortho*-dichlorobenzene was treated with calculated quantities of pyridine, at 130–140° for 15–20 minutes; cationic dye IX, thus formed by quaternization, is insoluble in *ortho*-dichlorobenzene.

3. EXPERIMENTAL

3.1. A mixture of 3.16 g (10 mmol) 1-methylamino-4-bromo-anthraquinone (I), 9.1 g (50 mmol) 4-nitroanthranilic acid (II), 1 g CH_3COONa, 0.1 g copper powder and 0.06 g $CuSO_4$ in 4 0 ml nitrobenzene is heated at 180° for 10 hours; the colour of the reaction mixture turns gradually from reddish-violet to bluish-violet. The conversion of 1-methylamino-4-bromoanthraquinone to product III is followed by means of paper-chromatography (eluent CH_3COOH 80%).

Finally, when the reaction is over, the mixture is cooled to 20°, filtered and the precipitate washed with benzene until the filtrate is colourless, dried at 80–85°, affording 10 g product (III + excess of II).

3.2. The 10 g of previously obtained mixture from the compounds III and II are dissolved in 80 ml $HClSO_3$ and the resulted solution is heated at 65–70° for 15 minutes. (A drop from the mixture, decomposed with water, forms a blue-green precipitate). The mixture is cooled at 20°, poured over 250 g crushed ice and the precipitate washed with water until the filtrate is neutral and colourless and dried at 75–80°. 3.5 g dye IV are obtained (87.7 yield from I).

Note: Since a quantity of the excess of compound II is dissolved in the aqueous acid filtrate, it may be recovered by precipitation with 25% ammonia solution at pH =4–4.5, filtered and dried 4.6 g compound II is thus recovered.

3.3. 1.999 g (5 mmol) compound IV are dissolved in 50 ml N.N-dimethylformamide at 80°; in the solution thus resulted a warm solutions of 0.45 g Na_2S in 10 ml water is droped for 15 min. The reaction is completed by heating at 90° for 3 hours; the mass colour turns from light green to dark green. The formation of the amino group by reducing the nitro group is determined by a characteristic colour reaction with the help of the Erlich reagent. Then, 50 ml water is added, the mixture cooled at 5–10°, neutralized with concentrated HCl at pH = = 7, the precipitate formed is filtered, washed with 50 ml water and dried at 70–80°, yielding 1.51 g dye V (81.9% yield).

3.4. 1.476 g(4 mmol) compound V are dissolved in 20 ml *ortho*-dichlorobenzene at 150–160°, then 0.37 ml (0.551 g; 4.88 mmol) chloracetyl chloride VI is added. The reaction is completed by heating at 160° for 2 hours; the mass colour turns from green to violet.

3.5. The warm solution of compound VII in *ortho*-dichlorobenzene is treated with 0.4ml (0.386 g; 4.88 mmol) pyridine VIII, at 130–140° for 15–20 minutes, the precipitate formed is filtered, washed with 10 ml benzene and dried at 30–40° and p = 10 mm Hg; 1.46 g dye IX are obtained (86% yield from V).

4. ANALYSES

The analyzed compounds * were previously purified by recrystallization from an appropriate solvent: ethanol, nitro-benzene (see table 1). The purified compounds were subjected to elemental, chromatographic, spectral and tinctorial analyses.

---

* Analyses were also made for the I and II compounds used as starting materials in this work and synthesized in laboratory according to literature procedures.[14–17]

DMF = N.N-dimethylformamide

In the case of eluents CH_3 COOH 80% and HCOOH, the chromatographic paper was impregnated with a 10% solution of 1-bromonaphthalene in ethanol.

4.3. SPECTRAL ANALYSIS

Infrared, ultraviolet and visible absorption spectra of the products were recorded.

IR spectra were recorded using a UR–10 spectrophotometer, in pellet KBr.

Characteristic vibration frequencies ν [cm^{-1}] :

Compound I : 720 v.s. ; 731 s. ; 998 s ; 1118 v.s. ; 1270 v.s. ; 1515 v.s. ; 1597 v.s. ; 1630 v.s. ; 1667 v.s. ; 2955 w. ; 3075 w. ; 3276 m.

Compound II : 731 v.s. ; 821 v.s. ; 1258 v.s. ; 1358 v.s. ; 1430 v.s. ; 1531 v.s. ; 1571 v.s. ; 1681 v.s. ; 2200–3300 ; 3395 v.s. ; 3512 v.s.

Compound IV : 731 s. ; 745 s. ; 1019 s. ; 1245 v.s. ; 1270 v.s. ; 1290 v.s. ; 1349 v.s. ; 1530 v.s. ; 1581 v.s. ; 1607 v.s. ; 1640 v.s. ; 3320 s. ; 3439 s.

Compound V : 731 m. ; 785 m ; 1021 s ; 1275 v.s. ; 1496 s. ; 1578 v.s. ; 1611 s. ; 3310 w. ; 3430 w.

Compound VII : 741 w. ; 789 w. ; 1026 m. ; 1050 m. ; 1247 m. ; 1270 s. ; 1590 s. ; 1620 m. ; 1699 m.

(w = weak ; m = medium ; s = strong ; v.s. = very strong).

Ultraviolet and visible spectra were determined with a Specord apparatus. Determinations were made in N.N.-dimethylformamide (for compounds IV and V) and water (for compound IX), also the extinction coefficients ε_{max} were calculated.

The characteristic absorption maxima λ_{max} and $\lg \varepsilon_{max}$ are presented in table 3.

Table 3

Maxima absorption in ultraviolet and visible

DMF = N.N-dimethylformamide.

5. UTILIZATION OF THE PRODUCTS

The IV and V compounds synthesized were used as disperse dyes for "Terom" polyester fibres, while IX compound was used as cationic dye for polyacrylonitrile fibres.

Results of determinations are presented in table 4. The colours were defined according to C.I. Hue Chart.[18] A good agreement is observed between the colours seen on the dyed fibres and the values of absorption maxima.[19]

Table 4

Determinations with dyed fibres

Compound	Dyed fibres	Colour	Fastness					
			Light	Cold water	Washing at 40°	Perspiration		Rubbing
						acid pH = 5.5	alkaline pH = 8.4	
IV	PE	bluish green 40	5−6	5/5/5	5/5/5	4−5/5/4−5	4−5/5/4−5	5
V	PE	green (bright) 17	5	5/5/5	5/5/5	4−5/5/4−5	4−5/5/4−5	5
IX	PNA	bluish violet 37−13	4−5	5/5/5	5/5/5	5/5/5	5/5/5	4−5

PE = polyester fibres
PNA = polyacrylonitrile fibres

NEW DIRECTION OF SUBSTITUTED 4-HYDROXY ACIDS DEHYDRATION LEADING TO 2,3-DISUBSTITUTED 1-ACETOXY-NAPHTHALENES

DIANA M. MONDESHKA and I. G. ANGELOVA
Department of Organic Chemistry, Higher Institute of Chemical Technology
Sofia 56, Bulgaria

Received November 23, 1973

The dehydration reaction of several substituted 4-phenyl-3-hydroxy acids under the action of different agents has been investigated. It has been shown that the reaction discovered with 2,4-diphenyl-3-methyl-3-hydroxybutanoic acid, namely, its conversion on dehydration in acetic anhydride in the presence of anhydrous zinc chloride into 2-phenyl-3-methyl-1-acetoxy-naphthalene has a general validity and the dehydration of the above mentioned hydroxy acids leads also to the corresponding 1-acetoxy-naphthalenes. It has been found that in the presence of $AlCl_3$ a retro-aldol type decomposition of the hydroxy acids took place first, instead of cyclization to acetoxy-naphthalenes. It has been established that under the action of concentrated sulphuric acid mainly γ-lactones or indene-1-ones are formed. The structures of the obtained compounds are proved by UV, IR and NMR spectra.

Previous papers reported that in the attempts to obtain α, β-unsaturated methyl ketones from 2,4-diphenyl-3-methyl-3-hydroxybutanoic acid **(1a)** according to a previously proposed method (dehydration in acetic anhydride in the presence of anhydrous zinc chloride),[1,2] only trace amounts of unsaturated ketones were formed whereas, instead, the main product was a 2,3-disubstituted 1-naphthol which was acetylated under reaction conditions.[3]

Pertinent literature data, though comparatively scarce, offer some information as to the 2,4- and 3,4-diaryl- or alkyl-aryl-substituted 1-naphthols (or acetoxy naphthalenes). Several compounds were obtained but in relatively low yields and in a rather complicated manner.[4-6] Contrary to this there are almost no data concerning the preparation of the more difficult to be obtained 2,3-disubstituted isomers. Only one of the latter compounds has been quite recently reported.[7] On the other hand,

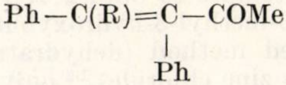
when trying to cyclize some 1,3-diaryl-2-arylmethyl-2-hydroxyglutaric acids to substituted benz- and dibenzanthrols by means of concentrared sulphuric acid it has been observed that on attempting to isolate from the reaction mixture the above compounds, they easily tautomerized to corresponding anthrones and, therefore, were not obtained in pure form.[8]

The purpose of the present investigations was to study the dehydration reaction of the substituted 4-phenyl-3-hydroxy acids **(1b—d)**, some of which may cyclize to indene-1-ones as well **(1d)** and to check whether under the above conditions the main direction of the reaction would lead to the formation of 2,3-disubstituted 1-acetoxy-naphthalenes. We also aimed to see whether a cyclization reaction would take place in a higher degree under the action of stronger cyclizing agents such as $AlCl_3$. Finally, we set ourselves the task to check if the dehydration of **1a-d** by means of concentrated sulphuric acid would bring about the formation of the corresponding 1-naphthols and whether the latter, if formed, would tautomerize during their isolation similarly to polynuclear phenols.

The present paper reports the result of a study on the dehydration of 2,4-diphenyl-3-methyl-3-hydroxybutanoic acid **1a**, 2,4-diphenyl-3-ethyl-3-hydroxybutanoic acid **1b**, 2,4-diphenyl-3-benzyl-3-hydroxybutanoic acid **1c** and 2,3,4-triphenyl-3-hydroxybutanoic acid **1d**.

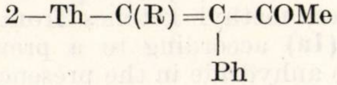
The acids **1a-d** were prepared from magnesosodium phenylacetate and benzyl ketones.[9] The main isomer was purified by recrystallization. As the dehydration reaction of substituted β-hydroxy acids does not proceed stereospecifically,[2,10-14] some of the experiments were carried out with a treo-eritro acids mixture.

The dehydration of **1b-d** was carried out after[15] as well as after modified,[2] the latter leading mainly to the formation of α,β-unsaturated methyl ketones **3a-e** or **3'a-f**, on dehydration



$$Ph-C(R)=\underset{Ph}{\underset{|}{C}}-COMe$$

3a-e



$$2-Th-C(R)=\underset{Ph}{\underset{|}{C}}-COMe$$

3'a-f

3a	R = Me	3d	R = Ph		3'a,B	R = Me
3b	R = Et	3e	R = Naphth		3'c,d	R = Et
3c	R = CH_2Ph				3'e	R = Ph
					3'f	R = 2 — Th

of 3-arylsubstituted-3-hydroxy acids.[1-3] The reaction mixture was treated as described,[1-3] i.e. hydrolysis with water, extraction of the organic products with ether and isolation of the neutral compounds. The composition of the neutral products was measured by TLC and IR-spectroscopy, the presence of absorption bands at about 1770, 1370 and 1200 cm^{-1} being an indication of the formation of acetylated 1-naphthols. It was observed that the yields of the acetoxy-naphthalenes formed, arose with the increase of the quantity of zinc chloride, optimal results being 0.6 — 0.7 g $ZnCl_2$ for 1 g hydroxy acid. At the same time a retroaldol type decomposition of **1b-d** into the initial ketones and phenyl-acetic acid took place as well,[2,3,16] though in a small degree. On dehydration after both methods[2,15] only traces of unsaturated ketones of type **3** were formed, as revealed by TLC and IR-spectra.

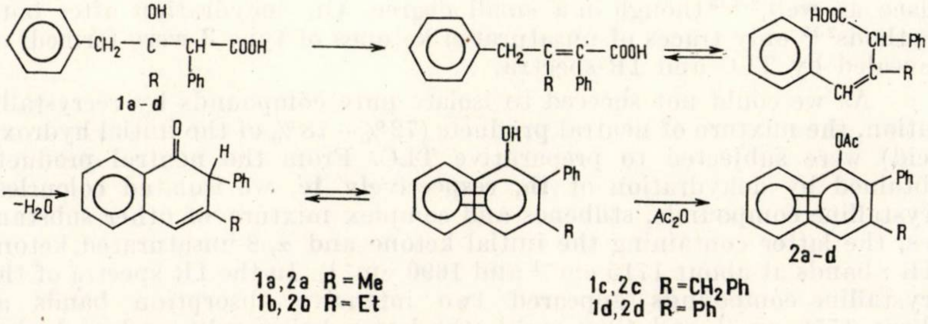
As we could not succeed to isolate pure compounds by recrystallization, the mixture of neutral products (72%—78% of the initial hydroxy acid) were subjected to preparative TLC. From the neutral products obtained by dehydration of **1b**, respectively **1c**, we isolated colourless crystalline compounds, stilbenes and complex mixture of other substances, the latter containing the initial ketone and α, β-unsaturated ketone (IR : bands at about 1715 cm^{-1} and 1690 cm^{-1}). In the IR spectra of the crystalline compounds appeared two intensive absorption bands at about 1770 cm^{-1} and 1200 cm^{-1} (the latter being split and of higher intensity) as well as a medium intensive band at about 1370 cm^{-1}. The UV spectra showed the multiplet structure, characteristic of naphthalene derivatives, the longest-wave maxima being positioned at about 322 nm. The NMR spectra of the above compounds confirmed their structures of 2-phenyl-3-ethyl-1-acetoxy-naphthalene **(2b)** and 2-phenyl-3-benzyl-1-acetoxy-naphthalene **(2c)**.

The dehydration of **(1d)** was carried out in the same way. The isolated mixture of neutral products, unlike to the above-mentioned experiments, was orange in colour. Its IR-spectrum revealed 3 bands in the region of carbonyl absorption, the most intensive one being positioned at 1776 cm^{-1}. The second one, of smaller intensity, was at 1721 cm^{-1}, i.e. in the range of carbonyl absorption of the five-membered conjugated ketones. From the mixture of neutral compounds besides stilbenes and small quantity of phenyl-benzyl ketone, an orange crystalline compound and a colourless one were isolated by preparative TLC. The orange compound was identified, by its m.p., IR spectrum and specific staining with concentrated sulphuric acid as the already known 2-phenyl-3-benzyl-indene-1-one, formed by intramolecular cyclization of the carboxyl group with the phenyl substituent at β-position in the hydroxy acid. On the basis of IR, UV and NMR spectra the colourless crystalline compound was assigned the structure of 2,3-diphenyl-1-acetoxy-naphthalene **(2d)**, obtained by intramolecular cyclization of the carboxyl group with the phenyl substituent at γ-position, followed by acetylation of the phenolic hydroxyl group. These results show that the formation of a naphthalene system from 4-phenyl-substituted-3-hydroxy acids has general validity and represents the main direction of the dehydration reaction of these acids under the above-stated conditions. Due to the comparatively good yields in which the described compounds were obtained, this new route of dehydration could be successfully used as a method of preparation of different 2,3-disubstituted 1-naphthols. From the above results it follows also that the formation of the naphthalene system is preferred here in comparison with the indene-1-one system, as shown by experiments with **1d**.

Formation of naphthalene derivatives could be explained by the following scheme:



Whether the α, β-unsaturated acid is isomerized previously to the corresponding β, γ-unsaturated acid or first a cyclization to dihydro-ketonaphthalene takes place with the subsequent isomerization of the C=C bond, could not be affirmed with certainty. We assume, as more probable, a previous isomerization to β, γ-unsaturated acid having in view that the formation of α, β-unsaturated methyl ketones is evidently impeded. According to the proposed mechanism these ketones are formed through decarboxylation of the mixed anhydride of the corresponding α, β-unsaturated acid with the acetic acid.[1,2]

Further experiments for cyclization of **1a-d** were carried out in acetic anhydride in the presence of $AlCl_3$. Because of its greater catalyst ability, a higher degree of cyclization could be expected. Nevertheless all experiments proved that $AlCl_3$ favoured mainly the retro-aldol-type decomposition of **1a-d**; the cyclization reaction to substituted acetoxynaphthalenes proceeded at a much smaller rate. Such type of decomposition took place especially in the case of acids containing an aryl-substituent at the carbon atom connected with the tertiary hydroxyl group. These results are in agreement with the preliminary data obtained on dehydrating 3-aryl-substituted-3-hydroxy acids to indene-1-ones,[17] and show that $AlCl_3$ is not a very suitable cyclizing agent for substituted hydroxy acids.

Dehydration of **1a-d** by concentrated sulphuric acid was studied in order to check the possibility for their cyclization to free 1-naphthols as well as to establish the conditions under which they could be isolated having in view their tautomerism. Dehydration was carried out with 97% sulphuric acid within 5–15 min. The reaction mixtures were treated after the already known method [18] including consecutively isolation of sulphonic acids (extraction with water), of carboxylic acids (with Na_2CO_3 aq), of phenols (extraction with 2% NaOH aq) and of neutral compounds. Under the action of sulphuric acid, diarylsubstituted acids **1a, b**, especially **1a**, gave a high yield of substituted γ-lactones **4a, b**. The corresponding substituted 1-naphthols were formed in small quantities and mainly as the tautomeric dihydro-keto-naphthalenes as shown by the IR spectra (medium to intensive bands at about 1668 cm^{-1} and a very weak absorption at about 3550 cm^{-1}). From **1b** a mixture of two isomeric γ-lactones was obtained, one of which, **4b**, could be isolated. The second one, formed in small quantity, has probably structure **5**, on the basis of its IR and NMR spectra (the latter taken as a mixture with **4b**). The formation of **4a, b** could be explained by the rapid isomerization of α, β-unsaturated acids to the corresponding β, γ-ones with subsequent cyclization of the latter according to the scheme:

5.

Dehydration of **1d** led to a complex mixture of products: stilbenes, phenyl-benzyl ketone, 2-phenyl-3-benzyl-indene-1-one as well as to small quantities of γ-lactone and of the corresponding 1-naphthol, as seen from TLC and the IR-spectrum.

We did not succeed to isolate 1-naphthol, as in the experiments with **1a, b** evidently because of its fully conversion during isolation into the corresponding tautomeric dihydro-ketonaphthalene, as evidenced by the IR-spectrum : the absorption band at 3550 cm^{-1} disappeared and only an intensive one at 1665 cm^{-1} was observed. Dehydration of **1c**, contrary to that of **1a, b, d** proceeded at a lower rate with lactonization. Instead, the quantity of 1-naphthol, 2-phenyl-3-benzyl-1-hydroxy-naphthalene(**6**), increased and we succeeded in isolating part of it. The primary formation of a naphthol, in this case only, is difficult to be explained at the present stage.

---

[18] Ch. P. Ivanov and L. Mladenova-Orlinova, "Yearbook of the Higher Institute of Chemical Technology-Sofia", **10**, 257 (1963).

Nevertheless, the above results show that the products obtained under the action of sulphuric acid are strongly dependent on the initial hydroxy acid. The main directions of the dehydration reaction lead here to the formation of either substituted γ-lactones or indene-1-ones. A cyclization to the naphthalene system proceeds at an insignificant rate (with the exception of **1c**) and this method can be used for the preparation of substituted 1-naphthols only in limited cases.

EXPERIMENTAL

The IR-spectra were recorded on a IR-10 Zeiss (1958) spectrometer. Solutions of the substances in CCl_4 (1 % w/v) in a 1 mm NaCl cell were used.

The UV-spectra were recorded on a Perkin-Elmer, UV-137 Model selfrecording spectrophotometer. Solutions of the samples (2×10^{-5} g in EtOH) were used.

The NMR-spectra were recorded on a JNM-MH-100, JEOL spectrometer, operating at a frequency of 100 MHz., at room temperature. Solutions of the substances (8—10 % w/v) in $CDCl_3$, containing 1 % TMS as internal standard were used. The chemical shift values are given in ppm (δ — units).

1. Dehydration in acetic anhydride in the presence of anhydrous zinc chloride.

A. Dehydration of 2,4-diphenyl-3-ethyl-3-hydroxybutanoic acid 1b.

a. The hydroxy acid (1.022 g) was heated in 15 ml acetic anhydride for 5 hrs at 60—65°. Then 0.62 g anhydrous zinc chloride was added, and the temperature was increased up to the b.p. of the reaction mixture. After cooling water was added and the organic products were extracted with ether. The ether solution was treated with Na_2CO_3 aq (to extract the carboxylic acids), washed with water and dried (Na_2SO_4). After distillation of the ether, 0.83 g mixture of neutral products was obtained, which when subjected to preparative TLC* (solvent system, light petroleum : benzene : acetone = 45 : 15 : 1) yielded : 0.186 g stilbenes, 0.297 g (28.5 % of the initial acid) of a colourless crystalline product with m.p. 95—96° **(from ethanole) 2b, 0.035 g of light yellow noncrystalline substance 3b and 0.145 g of a complex mixture of neutral products.

Non-crystalline substance. IR-spectrum : $\nu C{=}O$, 1689 cm^{-1} (s) ; $\nu C{=}C$, 1640 cm^{-1} (vw) and $\delta_s CH_3CO$, 1363 cm^{-1} (m).

Substance with m.p. 95—96°.

IR-spectrum : —O.Ac : $\nu C{=}O$, 1771 cm^{-1} (vs) ; ν_s, $\nu_{as}{=}C{-}O{-}C$, 1190, 1215 cm^{-1} (vs. split) and 1040 cm^{-1} (m) ; δ_s CH_3CO, 1370 cm^{-1} (s).

UV-spectrum : λ_{max} at 252,287 and 325 nm.

NMR-spectrum: C_2H_5: 1.10 ppm (tr, 3H; $J=7.4$c/s) and 2.54 ppm (q,2H; $J=7.4$ c/s) ; O.Ac : 1.94 ppm (s,3H) ;

IR-spectrum : –O.Ac : νC=0,1775 cm^{-1}(vs) ; ν_s,ν_{as}=C–O–C, 1208,1180 cm^{-1} (vs, split) and 1035 cm^{-1}(m) ; δ_sCH$_3$CO, 1370 cm^{-1}(s).

UV-spectrum : λ_{max} at 251,287 and 321 nm.

NMR-spectrum : O.Ac : 1.96 ppm(s,3H) ; CH$_2$Ph : 3.88 ppm (s,2H) ; Ph : 7.08 ppm(s,5H) and 7.12 ppm(s,5H) ; Naphth : 6.98–7.78 ppm (m,5H).

Found : C, 85.10 ; H, 5.90
Calcd. for $C_{25}H_{20}O_2$: C, 85.22 ; H, 5.72

b. According to procedure 1Ab, from 0.531 g hydroxy acid, a mixture of 0.40 g neutral products was subjected to preparative TLC at the above conditions. The isolated products were : 0.108 g stilbenes, 0.194 g (36.5%) crystals with m.p. 98–99° 2c and a complex mixture of other products.

C. Dehydration of 2,3,4-triphenyl-3-hydroxybutanoic acid 1d.

a. According to procedure 1Aa, 0.998 g hydroxy acid gave 0.830 g mixture of neutral products. Preparative TLC (light petroleum : benzene : acetone=45 : 5 : 1) yielded 0.310 g stilbenes, 0.105 g phenyl-benzyl ketone, 0.080 g orange coloured crystals, 0.220 g almost colourless crystals and 0.090 g mixture of other products. After rechromatography (light petroleum : benzene : acetone=50 : 15 : 0.5) the crystalline fractions gave 0.057 g(7%) orange crystals with m.p. 135° (ethanol) (2-phenyl-3-benzyl-indene-1-one) and 0.239 g (24%) colourless needlelike crystals with m.p. 161–162° (from ethanol), 2d.

IR-spectrum : –O.Ac : νC=O, 1776 cm^{-1} (vs) ; ν_s,ν_{as}=C–O–C, 1205, 1178 cm^{-1}(vs, split) and 1035 cm^{-1} (m) ; δ_sCH$_3$CO, 1370 cm^{-1} (s).

UV-spectrum : λ_{max} 265,286 and 337 nm.

NMR-spectrum : O.Ac : 2.01 ppm(s,3H) ; Ph : 6.98 ppm(s,5H) and 7.02 ppm (s,3H) ; Naphth: 7.28–7.82 ppm(m, 5H).

Found : C, 85.32 ; H, 5.48
Calcd. for $C_{24}H_{18}O_2$: C, 85.35 ; H, 5.36

b. According to 1Ab, from 0.501 g hydroxy acid, the reaction yielded 0.36 g neutral products. Preparative TLC at above conditions gave stilbenes, phenyl-benzyl ketone, 0.061 g (15%) 2-phenyl-3-benzyl-indene-1-one and 0.105 g (21%) of 2d.

2. Dehydration by means of concentrated sulphuric acid.

A. Dehydration of 2,4-diphenyl-3-methyl-3-hydroxybutanoic acid 1a.

10 ml of concentrated sulphuric acid (97%) were added to 1.03 g of hydroxy acid, the mixture was vigourously shaken for 10 min, poured into 150 ml water and extracted with ether. The ether solution was washed with water (to extract monosulphonic acids, if formed) with Na$_2$CO$_3$ aq (to complete extraction of carboxylic acids), with 2.5% NaOH aq (to extract naphthols), with water to neutral reaction and dried (Na$_2$SO$_4$). After ether distillation a mixture of 0.62 g neutral products was obtained from which by recrystallization (ethanol) 0.515 g (56.8% of the initial acid) colourless crystals with m.p. 80–81°, soluble in warm alkali, 4a, were isolated.

IR-spectrum : νC=O, 1786cm^{-1}(vs) ; ν_s, ν_{as}=C–O–C, 1158cm^{-1} (s) and 1018 cm^{-1}(m).

NMR-spectrum : CH$_3$: 1.08 ppm(d,3H ; J = 6.5c/s) ; H$_A$: 2.44 ppm(m, 1H) ; H$_B$: 3.44 ppm(d,1H ; J = 6.3 c/s) ; H$_C$: 4.88 ppm (d,1H ; J = 5.0 c/s) ; Ph : 7.04 – 7.34 ppm (m, 10 H).

Found : C, 80.79 ; H, 6.43
Calcd. for $C_{17}H_{16}O_2$: C, 80.92 ; H, 6.31

The alkaline solution was acidified to pH 1, extracted with ether and the ether solution dried (Na$_2$SO$_4$). After distillation of ether a mixture of 0.045 g benzyl-methyl ketone (IR : ν C=O, 1717 cm^{-1}) and a carbonyl compound (IR : νC=O, 1667 cm^{-1}) was obtained.

B. Dehydration of 2,4-diphenyl-3-ethyl-3-hydroxybutanoic acid 1b.

According to 2A, 1.002 g hydroxy acid gave 0.42 g mixture of neutral products and 0.053 g products isolated from the alkaline solution.

From the neutral products was isolated after several recrystallizations (ethanol) 0.208 g (21 %) of colourless compound with m.p. 92–93°, soluble in warm alkali, 4b and 0.090 g mixture of this compound and another colourless one, 5.

Compound with m.p. 92–93°.

IR-spectrum : $\nu C = O$, 1782 cm^{-1}(vs) ; ν_s, $\nu_{as} = C-O-C$, 1160 cm^{-1} (s) and 1020 cm^{-1} (m).

NMR-spectrum : CH_3 : 0.99 ppm (tr, 3H ; J = 7.2 c/s) ; CH_2 : 2.30 ppm (qd, 2H ; J = 7.2 c/s and 6.3 c/s) ; H_A : 2.52 ppm(m,1H) ; H_B : 3.40 ppm(d,1H ; J = 6.1 c/s) ; H_C : 4.76 ppm(d,1H ; J = 4.9c/s) ; Ph : 7.01 – 7.22(m,1OH)

Received June 8, 1973

The validity of the effect of the aryl group on the anomeric proton at C_1 is discussed with various model substances especially as to the effect of nitrogen bridge on the anomeric carbon in the case of β-D-glucopyranoside; the magnetic field of the aromatic ring is cancelled by the lone pair electrons of the nitrogen atom, enabling the signals of H_1 to appear as a doublet at $\tau = 3.05 - 4.84$, which depends on the nature of the substituents attached to the nitrogen atom.

It has been reported [1] that the signal of H_1 in β-aryl glucopyranosides was not assigned, because the signal is overlapped with those of the protons H_2, H_3 and H_4.

In this study we extended these observations with different, nitrogenous model substances with or without the aryl group to find the degree of shielding or deshielding on the anomeric proton at C_1, and also to reveal the effect of aryl substituent at C_6 on the anomeric proton.

RESULTS AND DISCUSSION

Table 1 and fig. 1 show the degree of shielding on the anomeric protons found with various glucopyranosylamines. The nitrogen atom with β-configuration at the anomeric carbon atom exhibits no effect on the chemical shift of the anomeric proton as in the case of β-aryl glucopyranosides. When the nitrogen atom forms a bridge with other aryl substituents, the chemical shifts of anomeric proton appeared in the range of $\tau = 3.05$ to 4.84 having a spacing of $J = ca.$ 4 to 9 Hz.

It may, therefore, be regarded, that the effect of the lone pair electrons is compensated by the effect of the magnetic field of the aromatic

ring. The compounds exhibiting coupling constants $J_{1,2} = 2.0$ to 4.0 Hz are regarded to be of the 1C conformation with more or less deformation.

The value, τ, of H_1 depends on the nature of the substituents attached to the nitrogen atom as shown in table 1. Decrease of the lone paired electron on the nitrogen atom may increase the polarizability of H_1 so that the signal of the anomeric proton was found to appear in a relatively lower field, not overlapping with the signals of other ring protons. It was shown,[2] that the conformation of the acetoxyl groups seemed to affect only the chemical shifts of the protons attached to C_2, C_3 and C_6, but has little influence on the chemical shift of H_1 and H_4. Hence, we neglect the effect of the acetoxyl groups on H_1, except a small influence on the protonation effect.

This importance of the pairs of electrons of the glycosidic oxygen atom in determining the chemical shift of some ring protons has been pointed out [2] taking into consideration those of H_3 and H_5 of α-D-glucopyranose. It has not been reported for such nitrogenous sugar derivatives listed in table 2 to discuss the effect of the lone paired electrons of the nitrogen atom on the chemical shift of anomeric proton.

For some glucopyranosylamine derivatives the signal of the anomeric proton appears below $\tau = 5.0$, and really at $\tau H_1 = 4.30 - 4.15$ for β-anomer and at *ca.* 3.60 for α-anomer, respectively. On the other hand, for N-(tetra-O-acetyl-D-glucopyranosyl)-4-methyl pyridinium bro-

mide the signal appears at $\tau_{H_1} = 3.76$ for β-anomer and at $\tau_{H_1} = 3.20$ for α-anomer.[3] The signal of anomeric proton appeared below $\tau = 5.0$ as shown in table 1 is quite in accord with the results of Lemieux *et al.*[4]

For proof the validity of the idea of the nitrogen bridge, which is attributed to the lone pair of electrons on the nitrogen atom, the lone paired electrons of nitrogen atom can be blocked even with a drop of hydrochloric acid i.e. by protonating (XXIII) with HCl into its hydrochloride. The doublet signal of H_1 was shifted from $\tau = 4.80$ to 4.48, when (XXIII) was converted into its hydrochloride. It is interesting to note, that the signals of the acetoxyl protons attached to C_2 in the glucopyranosylamine derivatives show $\tau = 8.0 \pm 0.07$, since the acetoxyl group is not influenced by the anisotropic effect of benzene ring due to the effect of nitrogen bridge. By the way it may be mentioned, that the presence of the grouping $-O-CO-CH_2-Ar$ at C_1 places the aromatic ring in a position, which allows an easy and simultaneous approach of all of the protons of the C_2-acetoxyl group to the plane of the ring, so that the effect of an aromatic ring caused the signal of C_2-acetoxyl group to upfield shift.[5]

EXPERIMENTAL

The compounds examined were prepared by published procedures. Each substance was crystallized from a suitable solvent until further crystallization caused no change in either melting point or specific rotation. Thin layer chromatography was carried out on silicagel G (Merck) with the suitable solvent system and detection was made with 10% sulfuric acid. The characteristic constants of the materials are listed in table 2. The NMR spectra were measured at 35° with a Varian A–60 spectrometer. Tetramethylsilane was used as internal standard. All the measurements were carried out in 15% (W/V) deuteriochloroform solution.

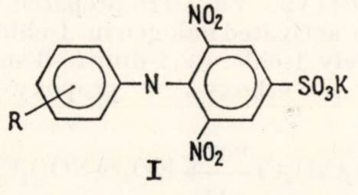
FORMATION OF NEW NITROGEN FREE RADICALS FROM DINITRO-SULPHO-PHENYL-N-ALKOXYAMINES

MARIA FRANGOPOL, P. T. FRANGOPOL and N. NEGOIȚĂ
Institute of Atomic Physics, P.O.B. 35, Bucharest, Romania

Received December 15, 1973

Oxidation with lead tetraacetate of 2,6-dinitro-4-sulpho- (IV) and 2,4-dinitro-6-sulpho-phenyl-N-alkoxyamines (V) led to the corresponding stable dinitro-sulpho-phenyl-N-alkoxyaminyl free radicals, whose ESR spectra are presented and discussed. Watersoluble, new stable free radicals were also obtained by treatment of IV and V with alkali. Infrared and ultraviolet-visible spectra of the new secondary amines IV and V are reported.

We have previously reported [1] the formation of long-lived diarylamino free radicals I possessing one of the phenyl rings substituted with donor groups R = *o*-, *m*-, *p*- Me; *o*-, *m*-, *p*-OMe; *p*-NMe_2, *p*-NPh_2; 3,4-$(OMe)_2$ and the other with acceptors such as NO_2 and SO_3K.



I

Interest in the nitrogen-free radicals with a sulphonic group in the molecule stems from their water-solubility. Since such radicals remain of high research interest because of their relevancy to the radiolysis of water [2] and biological reactions[3] — we extended our study to a new series of stable nitrogen free radicals.

In this paper we report the preparation and spectral properties of the stable dinitro-sulpho-phenyl-N-alkoxyaminyls II and III, obtained by oxidation of 2,6-dinitro-4-sulpho- and 2,4-dinitro-6-sulpho-phenyl-N-alkoxyamines IV and V. New stable free radicals were also obtained by treatment of IV and V with alkali, and details on them will be published later

RESULTS AND DISCUSSION

2,6-Dinitro-4-sulpho-N-alkoxyamines (IVa—IVd) and 2,4-dinitro-6-sulpho-N-alkoxyamines (Va—Vd) were prepared by aromatic nucleophilic substitution [4] of the activated halogen in 1-chloro-2,6-dinitro-4-sulpho-benzene [5] and respectively 1-chloro-2,4-dinitro-6-sulpho-benzene [6] through alkoxyamines (methoxy-,[7–9] ethoxy-,[10,11,9] propoxy-,[11] and butoxy-amine[11])

$$KO_3S(NO_2)_2C_6H_2Cl \xrightarrow[-HCl]{H_2NOR} KO_3S(NO_2)_2C_6H_2NHOR$$

Actually, the alkoxyamines hydrochlorides and not the free bases were used, in a ratio of two moles to a mole of chloro-dinitro-sulpho-ben-

zene, carrying out the reaction in boiling ethanol in the presence of sodium bicarbonate.

The resulting dinitro-sulpho-phenyl-N-alkoxyamines IV and V are stable crystallized compounds. It is worth saying that the dinitro-sulpho-phenyl-N-propoxy- and dinitro-sulpho-phenyl-N-butoxyamines (IVc, IVd, Vc and Vd) are as stable as their lower homologues (IVa, IVb, Va and Vb), whereas in the polynitrophenyl-N-alkoxyamines series [9] the higher homologues (2,4,6-trinitro-phenyl-, 2,6- and 2,4-dinitro-phenyl-propoxy- and butoxyamines) were unstable.

The dinitro-sulpho-phenyl-N-alkoxyamines IVa—IVd and Va—Vd were characterised by melting point, analysis (Table 1), infrared spectra (Table 2) and UV-visible absorption spectra (Table 3).

Infrared absorption spectra. The structure of 2,6-dinitro-4-sulpho- and 2,4-dinitro-6-sulpho-phenyl-N-alkoxyamines was confirmed by the infrared absorption spectra determined in potassium bromide pellets. The ν NH values presented in Table 2 are in good agreement with the literature data [12] concerning the NH stretching band, usually placed at frequencies between 3300—3400 cm^{-1}. The correct assignment of the bands corresponding to the sulphonic group was also made by comparison with the literature data (1180—1200 and 1040 — 1070 cm^{-1}).[13]

Table 2

Infrared NH and KSO_3 bands ($cm-^1$) of dinitro-sulpho-phenyl-N-alkoxyamines (IV and V) in potassium bromide pellets

Amine	*R* (Alkyl)	NH	SO_3K[13]		
			1180—1220	1040—1070	
IVa	CH_3	3295	1195	1045	1055
IVb	C_2H_5	3305	1195	1054	1055
IVc	C_3H_7	3300	1195	1045	1055
IVd	C_4H_9	3300	1195	1045	1055
Va	CH_3	3295	1180	1050	1070
Vb	C_2H_5	3295	1185	1050	
Vc	C_3H_7	3295	1185	1040	1070
Vd	C_4H_9	3310	1180	1050	

Other significant IR absorption band in the spectra of the secondary amines IV and V were the asymmetric and symmetric nitro group vibration frequencies [14] at 1540 and 1340—1360 cm^{-1}, the NH deformation vibration at 1430—1435 cm^{-1} and the strong benzene ring vibrations at 1620 cm^{-1}.

Ultraviolet and visible absorption spectra. Electronic absorption maxima of dinitro-sulpho-phenyl-N-alkoxyamines in ethanol are presented in Table 3. The electronic absorption bands are denoted by letters (A, B, C) in the order of decreasing wavelengths. Band C, present in all the eight compounds, appears in the compounds V as shoulders rising toward low wavelengths. The exact localization of these shoulders was difficult and the corresponding ε-values have not been calculated. Band B is present in compounds V. Band A is present in compounds IV and has a low extinction coefficient (except the compound IVd). The absence of the band A in compounds V and of the band B in compounds IV is in agreement with our previous discussions of electronic absorption spectra of polynitrophenyl derivatives.[4,9,15]

Electron spin resonance spectra. The oxidation of the secondary amines IV and V to the corresponding aminyl free radicals II and III was made by lead tetraacetate. The insolubility of the secondary amines IV and V in solvents currently used in the ESR techniques raised difficulties in the measurements. Capillaries or flat cells were used, but only high concentration of free radicals has been detected when solvents with high dielectric constant were utilized. Though sparingly soluble in dioxane we managed to oxidize in it the dinitro-sulpho-phenyl-N-alkoxyamines (IV and V) to paramagnetic species. Oxidation with lead tetraacetate in deaerated vials in the presence of helium gas, of the 2,6-dinitro-4-sulpho- and 2,4-dinitro-6-sulpho-phenyl-N-alkoxyamines (IVa — IVd and Va — Vd) afforded paramagnetic solutions whose ESR spectra were assigned to the corresponding dinitro-sulpho-phenyl-N-alkoxyaminyl free radicals (IIa — IId, IIIa — IIId). Since the 2,4-dinitro-6-sulpho-phenyl-N-alkoxyamines (V) are less soluble in dioxane than their 2,6-dinitro-4-sulpho-analogues, only weak and poorly resolved ESR signals were obtained. The ESR spectra of 2,6-dinitro-4-sulpho-phenyl-N-alkoxyaminyls (IIa — IId), obtained by oxidation of IVa — IVd with $Pb(OAc)_4$ in dioxane, in sealed vials under helium atmosphere are presented in figs 1, 2, 3 and 4.

---

[15] A. T. Balaban, P. T. Frangopol and E. Keplinger, *Spectrochim. Acta*, **19**, 367 (1963).

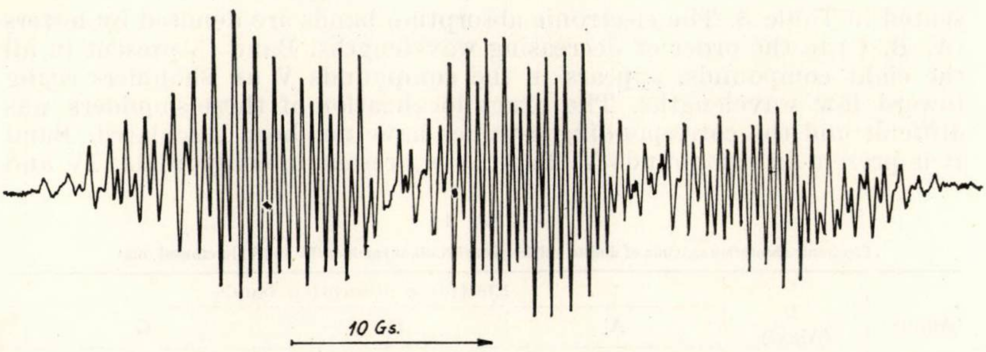

Fig. 1. — ESR spectrum of 2,6-dinitro-4-sulpho-phenyl-N-methoxyaminyl (IIa) in dioxane.

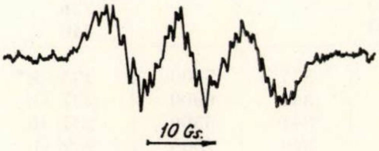

Fig. 2. — ESR spectrum of 2,6-dinitro-4-sulpho-phenyl-N-ethoxyaminyl (IIb) in dioxane.

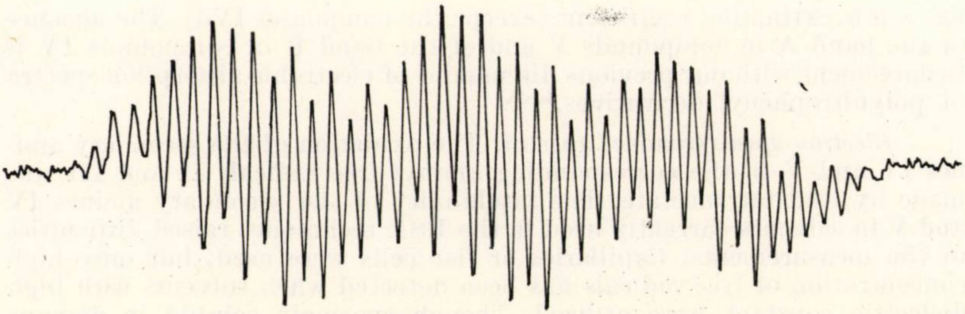

Fig. 3. — ESR spectrum of 2,6-dinitro-4-sulpho-phenyl-N-propoxyaminyl (IIc) in dioxane.

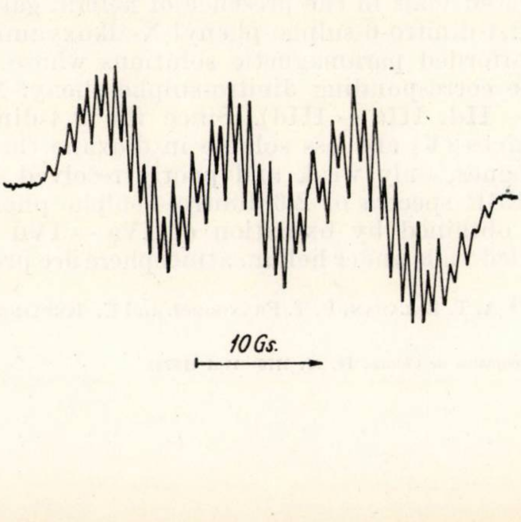

Fig. 4. — ESR spectrum of 2,6-dinitro-4-sulpho-phenyl-N-butoxyaminyl (IId) in dioxane.

The ESR spectra of the dinitro-sulpho-phenyl-N-alkoxyaminyls (II and III) have a total span of ~ 35 gauss and consist in a major triplet due to the interaction of the odd electron with the central nitrogen atom; the main triplet is split further into many lines revealing the interaction with other nitrogen or hydrogen atoms.

The *g*-values and the a_N coupling constants presented in Table 4 were determined by comparison with potassium peroxylamine disulphonate (Fremy salt, characterized by $g = 2.0055 \pm 0.00005$ and $a_N = 13.091$ gauss).[16] The isotropic *g*-values ranging from 2.0041 to 2.0047 are in agreement with the aminyl structure. It seems that the oxidation of the dinitro-sulpho-phenyl-N-alkoxyamines with lead tetraacetate did not lead to the corresponding nitroxides whose g-factor should have been higher than 2.0055.[17,18] The half-life of the dinitro-sulpho-phenyl-N-alkoxyaminyls is about two hours at room temperature in deaerated solutions in sealed vials.

Table 4

ESR spectral data for 2,6-dinitro-4-sulpho-phenyl-N-alkoxyaminyls

Radical	*R* (Alkyl)	*g*-value	a_N (gauss)	Total span (gauss)
IIa	CH_3	2.0046	11.7	36.9
IIb	C_2H_5	2.0041	10.0	36.1
IIc	C_3H_7	2.0043	10.1	32.3
IId	C_4H_9	2.0047	10.05	38.6

By analogy with the hydrazyls[19-21] and with the previously reported sulphonic diaryl-amino radicals [1] we assumed that the stability of sulpho-dinitro-phenyl-N-alkoxy-aminyls is due to the steric shielding exerted by the *ortho*-substituents and to the push-pull electronic effect introduced by the presence of both, the donor (alkoxy group) and the acceptor (nitro and sulpho substituents of the phenyl ring).

Treatment of dinitro-sulpho-phenyl-N-alkoxyamines [22] with alkaline solutions under N_2 atmosphere gave coloured paramagnetic solutions whose ESR signals paralleled the intensity of the colour.

[22] P. T. Frangopol and M. Frangopol, unpublished results.

The 2,6,dinitro-4-sulpho-phenyl-N-alkoxyamines (IV) generated in N NaOH under N_2 atmosphere blue solutions, while the 2,4,-dinitro-6-sulpho-analogues (V) gave red solutions. After evaporation of the blue and red solutions in an inert atmosphere, green and respectively red-brownish par amagnetic solide resulted, whose ESR spectra (simple line with g-value 2.0040 ± 0.0004) are exemplified by fig. 5.

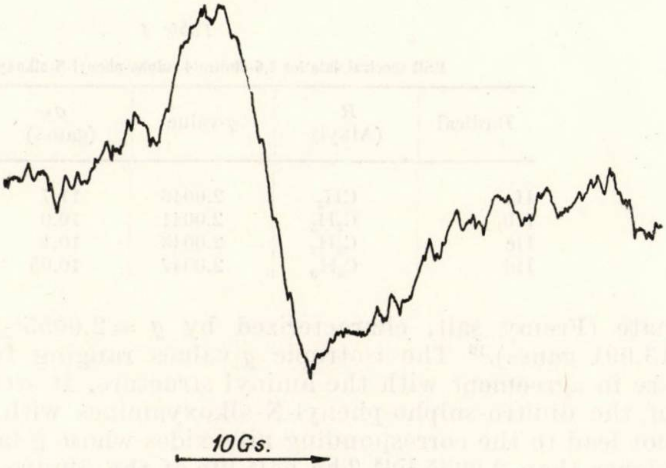

Fig. 5. — ESR spectrum of the solid free radical resulted from 2,6-dinitro-4-sulpho-phenyl-N-ethoxyamine (IVb) with N NaOH.

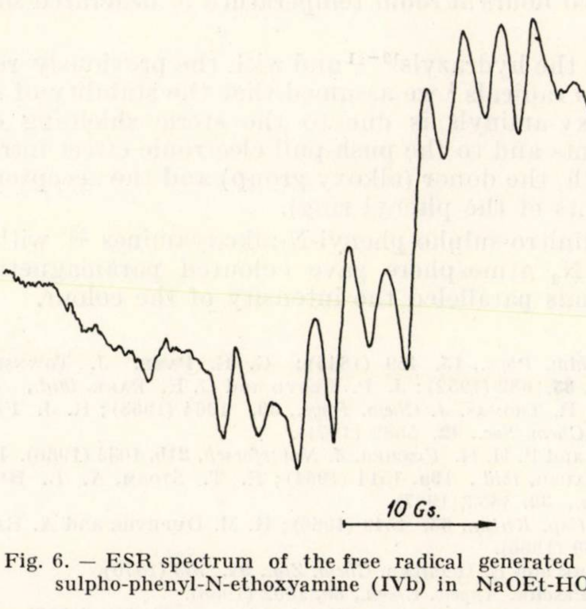

Fig. 6. — ESR spectrum of the free radical generated by 2,6-dinitro-4-sulpho-phenyl-N-ethoxyamine (IVb) in NaOEt-HOET-pyridine.

Attempts to transform into free radicals the dinitro-sulphophenyl-N-alkoxyamines were also carried out by treatment with a mixture of molar sodium ethoxide solution in ethanol — pyridine (1 — 1) under N_2 atmosphere. The paramagnetic species generated by the dinitro-sulpho-phenyl-

N-alkoxyamines in NaOEt-HOET-pyridine were violet for the 2,6-dinitro-4-sulpho- and purple for the 2,4-dinitro-6-sulpho-derivatives and displayed ESRspectra with *g*-values of 2.0033. The ESR spectrum of the free radical generated by the 2,6-dinitro-4-sulpha-phenyl-N-ethoxyamine (IVb) in NaOEt-HOEt-pyridine is represented in fig. 6.

EXPERIMENTAL

Apparatus. Infrared spectra were recorded on the Jena UR-10 double beam instrument in KBr pellets.

Ultraviolet-visible absorption spectra were recorded on the CF-4 Optica Milano spectrophotometer.

Electron spin resonance spectra were recorded on an instrument operating in the *X* band with a frequency of 9060MHz[23] and a Varian-E 12 instrument.

COMPOUNDS

Methoxyamine hydrochloride,[7-9] m.p.150°, was obtained by methylation with dimethylsulphate of potassium nitrosulphonate and acid hydrolysis of the resulted $MeON(SO_3K)_2$.

Ethoxyamine hydrochloride,[10] m.p.128°, was synthesized by ethylating acetoxime with 1-bromoethane and hydrolyzing the resulted O-ethyl-acetoxime, ($EtO-N=CMe_2$).

Propoxy-[10] and *butoxy-amine*[11] *hydrochlorides* were prepared by a procedure similar to that utilized for ethoxyamine hydrochloride, using 1-bromo-propane and 1-bromo-butane, respectively. After recrystallization from ethanol-ether, the melting point of propoxyamine hydrochloride was 155–157°, and the butoxyamine hydrochloride melted at 158° (as compared to 152–153° reported in the literature [24]).

Dinitro-sulpho-phenyl-N-alkoxyamines (IVa — IVd and Va — Vd). The reaction between two moles of alkoxyamine hydrochlorides and one mole of 1-chloro-2,6-dinitro-4-sulphobenzene [5] or 1-chloro-2,4-dinitro-6-sulphobenzene[6] in the presence of two moles of sodium bicarbonate was carried out in boiling ethanol by refluxing the mixture for 36 hours. The resulted secondary amines were purified by recrystallization from 95% ethanol.

The authors express their sincere thanks to Drs. I. Pascaru and R. Baican for the ESR spectra, to Mrs. M. Roman and C. Popescu for elementary analyses, to Mrs. E. Romaş and M. Paraschiv for IR and UV spectra and to Mr. D. Papae fof experimental assistance.

Two aminophenylbenzimidazoles were prepared by reacting 3,4,3′,4′-tetraaminodiphenylmethane and *m*- or *p*-aminobenzoic acids. Polyamic acid prepolymers were obtained by condensing benzimidazole containing diamines with pyromellitic anhydride. The prepolymers were cast onto glass plate and the films were obtained by heating at 80–100°. After a thermal treatment at 300° for 1 hr., the prepolymer films were converted to polybenzimidazole-imide films, with high thermal stability.

INTRODUCTION

Aromatic heterocyclic compounds have been used to prepare a wide variety of heat-resistant polymers. Among the more stable ring systems that have been used to prepare high polymers[1–5] are benzimidazoles and imides. These polymers are of considerable interest in preparing thermostable films, [6–8] fibers, [9,10], adhesives [11,12] and coatings. [13–15] An increasing interest in preparing and studying ordered copolymers [16–22] is apparent.

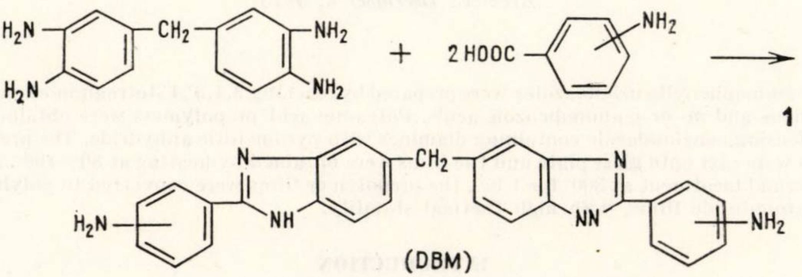
This paper deals with the synthesis and the properties of two new polybenzimidazole-imides.

RESULTS AND DISCUSSION

Two new benzimidazole containing diamines were prepared by reaction of 3,4,3′,4′-tetraaminodiphenylmethane and *m*- or *p*-aminobenzoic acids, as follows :



H₂N
CH₂
NH₂
H₂N
NH₂

MONOMERS AND MODELS

Diamines were synthesized by condensing 3,4,3′,4′- tetraaminodiphenylmethane with *p*- or *m*-aminobenzoic acids, using polyphosphoric acid as solvent and condensing agent, by heating at 150°, under nitrogen flow for 10 hrs. Diamines were purified by methanol extraction, charcoal treatment, and water precipitation.

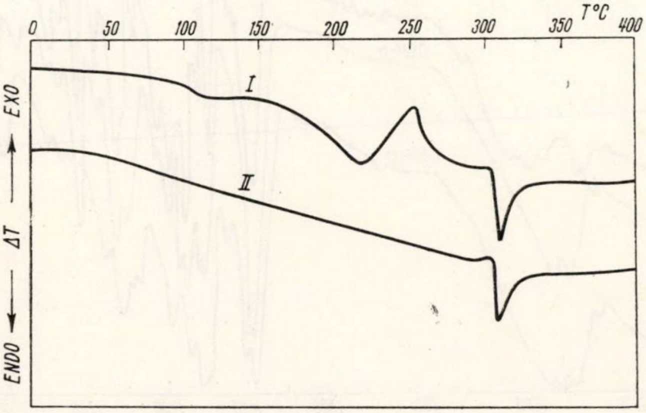

Fig. 1. — I. DTA thermogram of undried DBM-*p*, showing desolvation and melting point near 320°; II. DTA thermogram of dried DBM-*p*, showing only melting point.(Sample size : 20mg., heating rate: 12°/1 min., atmosphere : air).

The differential thermal analysis of undried DBM-*p* (fig. 1) shows diamine solvent complexing with loss of solvent near 230°.

Elemental analysis of undried and dried diamines are summarized in table 1.

Table 1

Elemental analysis of monomers

Compound	Condition	Carbon, %		Hydrogen, %		Nitrogen, %	
		Calcd.	*Found*	*Calcd.*	*Found*	*Calcd.*	*Found*
DBM-*p*	Undried	75.33	70.89	5.15	5.33	19.52	18.56
	Dried	75.33	75.31	5.15	5.17	19.52	19.83
DBM-*m*	Undried	75.33	70.80	5.15	5.78	19.52	18.45
	Dried	75.33	74.96	5.15	5.26	19.52	19.23

These results are in agreement with the proposed structure.

As model compounds for the study of infrared spectral changes we prepared 2-(*p*-aminophenyl) benzimidazole (M_1), phthalomonoanilide (M_2), N-phenylphtalimide (M_3), 2,2′ — di-(*p*-phthalaminodiphenyl)-5,5′-dibenzimidazolyl-methane (M_4) and 2,2′-diphthaliminophenyl)-5,5′ dibenzimidazolyl-methane (M_5).

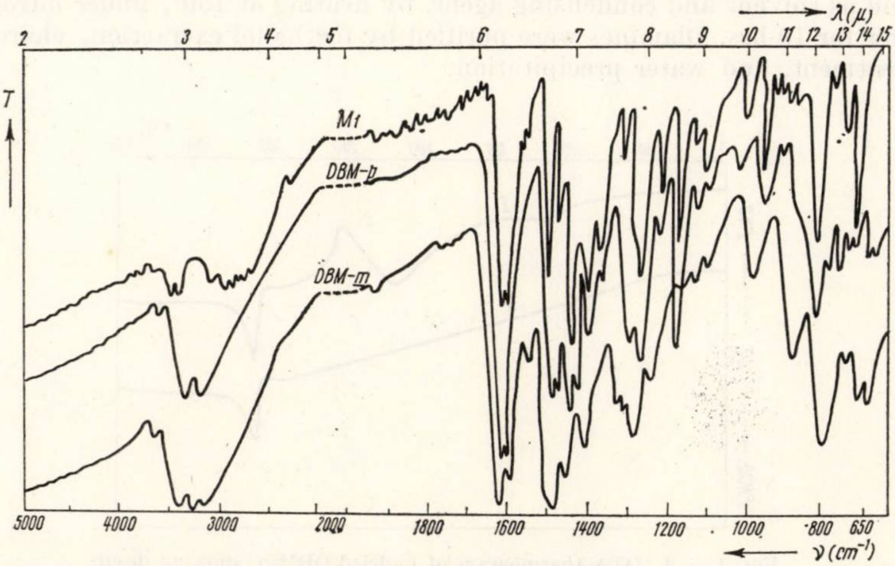

Fig. 2. — Infrared spectra of di-aminophenylbenzimidazoles (DBM) and the respective model compound M_1 (KBr pellet).

The infrared spectra of model compounds, monomers and polymers, shown in figs. 2—4, were recorded on a SP—200 Infrared Spectrometer.

POLYMERS

Polybenzimidazole-imides were prepared by the condensing reaction of benzimidazole containing diamines and pyromellitic anhydride by using dimethylsulfoxide as solvent. Other solvents as N-methylpyrrolidone, N-dimethylacetamide provide lower molecular weight polyamic acid prepolymers.

It was observed that the order of adding the reagents plays a proeminent part in obtaining high molecular weight polymers. High molecular weight polymers were obtained by adding theoretical amounts of solid dianhydride into a solution of diamine.

The condensation reaction takes place at 0° for 1 hr and for 8 hrs at room temperature. When the reaction takes place at room temperature only, a rapid growth of viscosity is observed, and the apparent "gel" yielded could be broken down by heating at 70° and vigorous stirring.

Absorption peaks of carboxyl groups were clearly observed in the infrared spectrum of model phthalomonoanilide (M_2) at 2450—2650, 1730 and 1240cm^{-1}. These absorption peaks of carboxyl groups in the polyamic acid and model compound (M_4) which contain benzimidazole rings, appear attenuated or replaced by absorption due to carboxylate ion near 1560 cm^{-1} (figs. 3 and 4).

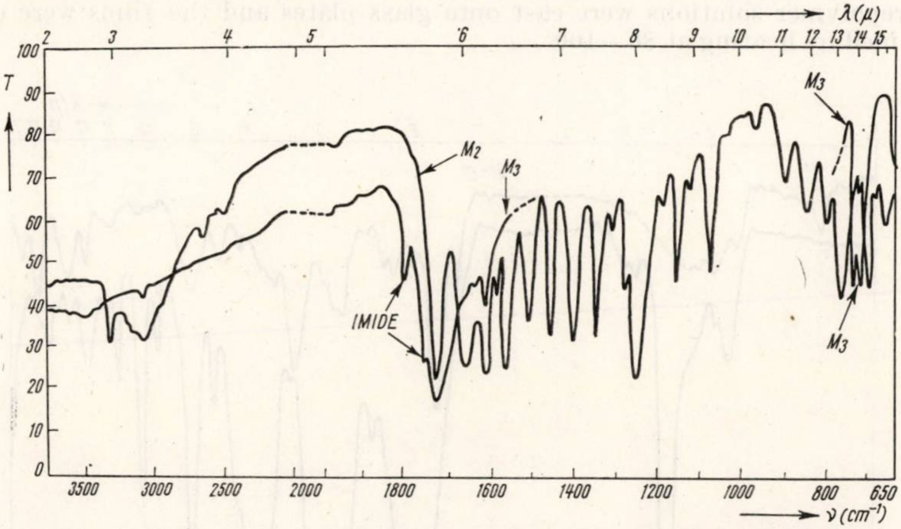

Fig. 3. — Infrared spectra of phthalomonoanilide (M_2) and N-phenylphthalimide (M_3) (KBr pellet).

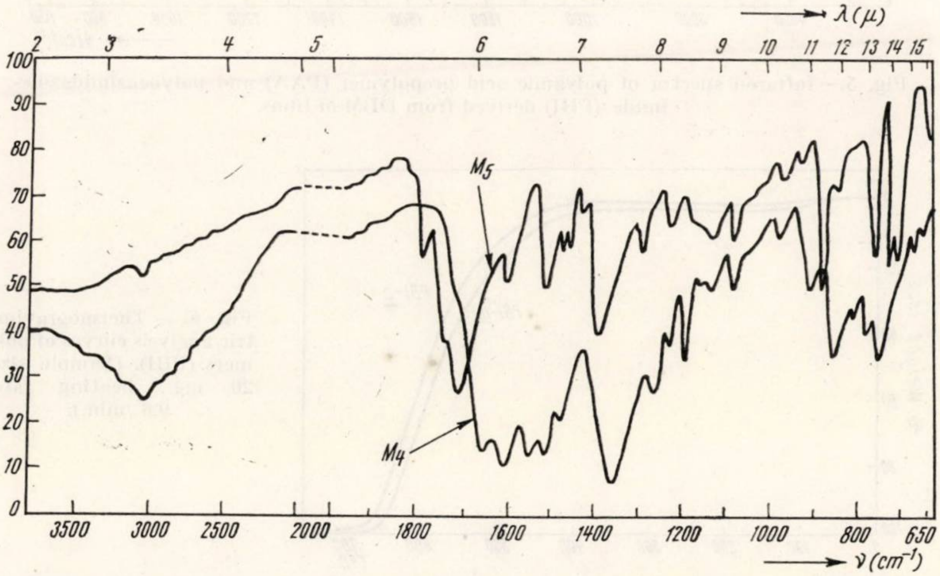

Fig. 4. — Infrared spectra of 2,2′-bis-(*p*-phthalamidophenyl)-5,5′-dibenzimidazolyl-methane (M_4) and 2,2′-bis-(*p*-phthaliminophenyl)-5,5′-dibenzimidazolyl-methane (M_5). (KBr pellet).

The broadening of the absorption peaks in the region of 1620 — —1720 cm^{-1} in the case of polyamic acid prepolymers, could be explained by the combined effects of carboxylate ions, nonionized acid and the amide groups, as supposed by Kurosaki and co-workers.[23] (fig. 5).

From polyamic acid prepolymer solutions good films could be cast. Prepolymer solutions were cast onto glass plates and the films were obtained by heating at 80–100°.

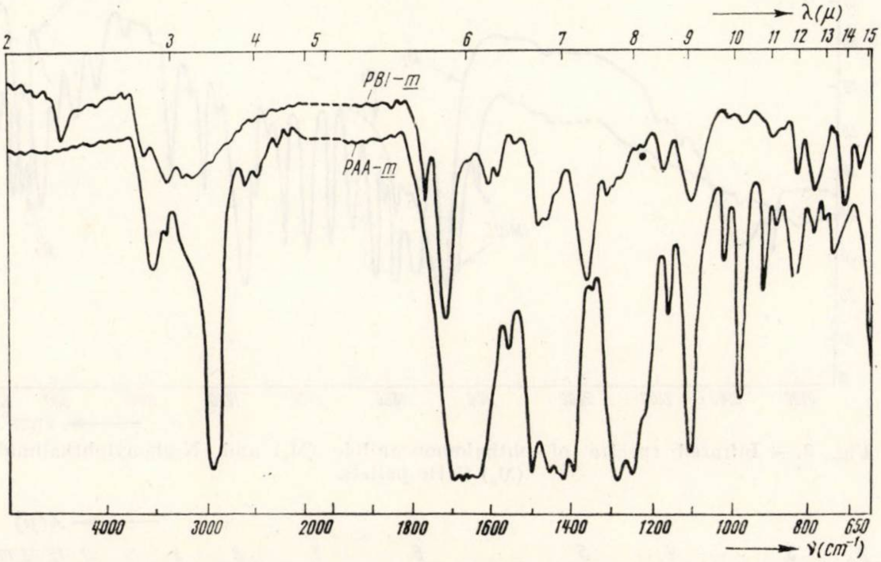

Fig. 5.—Infrared spectra of polyamic acid prepolymer (PAA) and polybenzimidazole-imide (PBI) derived from DBM-*m* films.

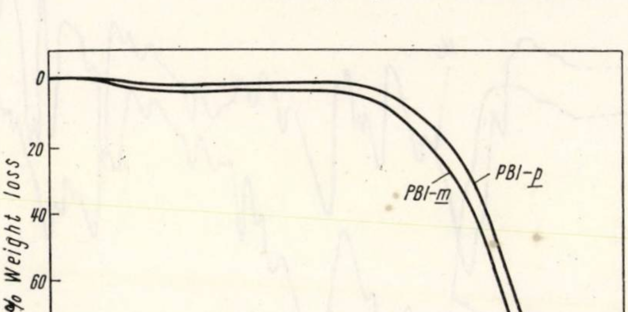

Fig. 6. — Thermogravimetric analysis curves of polymers (PBI). (Sample size: 20 mg., heating rate: 9.8°/min.).

Polyamic acid films were cured by 15′ heating at 150°, 180°, 230°, 260° and for 1 hr heating at 300° and converted in this way into transparent, flexible polybenzimidazole-imide films with great thermal stability. Disappearance of infrared absorption peaks of carboxyl and amide groups after thermal treatment at 300°, indicates that imidization took place (fig. 5).

---

[23] T. Kurosaki and P. R. Joung, *J. Polymer Sci., C*, **23**, 57 (1968).

Imide-absorption peaks appeared in the infrared spectra of polymers (PBI) around 720, 1710 and 1790 cm^{-1} (Fig. 5).

The inherent viscosities of polyamic acid prepolymers and the thermal stability of polymers (PBI) are summarized in table 2.

Table 2

Viscosity of polyamic acid prepolymers and thermal degradation of polymers (PBI)

Polymers	η inh[1]	Thermal degradation of polymers[2] (PBI) %				
		400°C	450°C	500°C	550°	600°C
PBI-*p*	1.68	0	3	9	21	53
PBI-*m*	0.74	0	6	14	35	62

[1] Inherent viscosity (η inh.) measurements were determined on a solution of 0.5 g. polymer dissolved in 100 ml dimethylsulfoxide.

[2] Samples were heated in air, temperature being increased at a rate of 9.8° C/min.

Thermal stabilities of polymers as depicted by TGA curves (fig. 6.) Initial weight losses occurred in the range 420–450°, in air.

EXPERIMENTAL

3,4,3′,4′-tetraaminodiphenylmethane was obtained, according to Meyer's method, [24–26] by the condensation of *o*-nitroaniline with formaldehide and reduction with tin and hydrochloric acid. It was recrystallized from benzene. m.p. 137–138° Lit. [26] m.p. 137–138°).

Aminobenzoic acids were purchased from Serva, Heidelberg. The commercial products were recrystallized from water, to yield colourless crystals, with m. p. 187–188° for *p*-aminobenzoic acid and m.p. 173–174°, for *m*-aminobenzoic acid.

Diaminophenylbenzimidazoles were prepared by Iwakura's method [27] of condensation of aminobenzoic acids and 3,4,3′,4′-tetraaminodiphenylmethane in polyphosphoric acid at 150° for 10 hrs. After purification and thermal treatment in vacuum, m.p. 322–323° was obtained (by DTA thermogram) for DBM-*p* and 206–209° for DBM-*m* (by the capillary method).

2-(p -aminophenylbenzimidazole (M_1) was prepared by the reaction of *o*-phenylenediamine and *p*-aminobenzoic acid. A 3.24 g (0.03 mole) amount of *o*-phenylenediamine was added with stirring to 80 ml of polyphosphoric acid (116 % P_2O_5) under a nitrogen atmosphere at 120°. *p*-Aminobenzoic acid (4.11g 0.03 mole) was added in small portions and heating was maintained at 150°, with stirring for 10 hrs, under nitrogen. The reaction mixture was precipitated with water. After filtration, the product was neutralized with aqueous ammonium hydroxide solution, filtered and dried. The product was purified by dissolution in methanol, treatment with charcoal, filtration and reprecipitation with water. Product yield was 48 %, m.p. 250–252° Lit. [23] m.p. 252°).

Phthalomonoanilide (M_2) was prepared by the reaction of phthalic anhydride (5.0 g., 0.0338 mole) and aniline (3.0 g, 0.0323 mole) in 30 ml. of benzene with stirring at 50°. The reaction product was recrystallized from ethanol. The yield of colourless crystals, m.p. 183—184°, was 85 %.

N-Phenylphthalimide (M_3)[23], was prepared from phthalomonoanilide by heating at 240° in a nitrogen atmosphere for 3 hrs. The product was recrystallized from tetrahydrofuran. m.p. 208—210°.

2,2′-bis-(p-Phthalamidophenyl)-5,5′-dibenzimidazolylmethane (M_4). 0.6 g of phthalic anhydride was added to a mixture of 0.86 g, 2,2′-di-(*p*-aminophenyl)-5,5′-dibenzimidazolyl-methane in 15 ml. of dimethylacetamide with stirring for 0.5 hr. The solid obtained was collected by filtration and washed with ethanol to give a yellow, infusible powder.

Anal. *Calcd.* for $C_{43}H_{30}N_6O_6$: C, 71.04 ; H, 4.02 ; N, 11.57 ;
Found : C, 69.48 ; H, 4.56 ; N, 11.88. (The product was complexed with solvent).

2,2′-bis-(p-Phtaliminophenyl)-5,5′-dibenzimidazolyl-methane (M_5). A 0.5 g amount of 2,2′-bis-(*p*-phthalamidophenyl)-5,5′-dibenzimidazolyl-methane was heated at 300° in a nitrogen atmosphere for 3 hrs. A yellow , infusible product was obtained.

Anal. *Calcd.* for $C_{43}H_{26}N_6O_4$: C, 74.76 ; H, 3.79 ; N, 12.17 ;
Found : C, 74.29 ; H, 3.86 ; N, 11.85.

Pyromellitic dianhydride. The dianhydride was purchased from Fluka AG, Buchs SG. The product was recrystallized from acetic anhydride and then sublimed at 260° at 1 mm, before use. m.p. 284—286°.

Polymerization. 2.15 g. of DBM-*p* or DBM-*m* was introduced into 29.2 ml dimethylsulfoxide with stirring, under nitrogen atmosphere, the solution being cooled to 0°. Solid dianhydride powder (1.10 g) was added slowly with stirring. The mixture was stirred at 0° for 1 hr and then at room temperature for 8 hrs. Sometimes, a "gel" was obtained. By heating at 70° or adding of solvent and rapid stirring the apparent "gel" was converted to a polymer solution.

The viscous polymer solution (from DBM-*p*) was cast by spreading polyamic acid solution onto glass plates, the solvent being evaporated at 80—100°, for 2—3 hrs. Polyamic acid films were cured by heating for 15′ in an oven at 150°, 180°, 230°, 260° and for 1 hr. at 300° in a nitrogen atmosphere. The films were brown, transparent, with great thermal stability.

HEAT TRANSFER WITH CHEMICAL REACTION MODELLING OF THERMAL DECOMPOSITION REACTIONS

RADU Z. TUDOSE
Polytechnic Institute of Jassy, Str. 23 August, 11, Jassy, Romania

Received September 17, 1973

The modelling of thermal decomposition reaction is derived for which heat transfer and chemical reaction may be limiting elementary processes. The unreacted-core shrinking model theory is extensively developed. Temperature distribution within the ash layer, as well as temperature at the grain surface and in the reaction zone are calculated. Conversion and conversion time are also estimated.

The study of heterogeneous catalytic reactions has attained a stage of development in which the theoretical basis of reactor design and operation have been laid. Engineering of the heterogeneous non-catalytic reaction is now in the stage of modelling and developing process mechanisms. Numerous attempts have been noticed in recent years for elucidating and systematizing the principal phenomenological aspects of these problems. Although these non-catalytic heterogeneous reactions are very complex, current knowledge of moment, heat and mass transfer processes on the one hand, and of kinetic data, on the other hand enable a comprehensive approach to these reactions.

Non-catalytic solid-gas reactions may often be influenced by a series of physical processes. In many practical cases mass and heat transfer are rate-controlling steps, influencing the chemical reaction to a greater extent.

A heterogeneous chemical reaction may develop by diffusing the gaseous reagent within the grain, where it reacts with the solid reagent, the heat effect being more or less important. However, in other cases, the gaseous phase does not contain the reagent, it acting only as heat carrier and as medium for gaseous reaction products. Consequently, the non-catalytic solid-gas reaction may be influenced, not only by the internal or external diffusion of reagents or reaction products, but also by the internal or external heat transfer, or by both.

According to the general model, developed in a previous paper, [1] the process takes place in three stages, the reaction developing within a reaction zone of δ_r thickness. By particularizing this model [2] one obtains the two models known in the literature as the "unreacted-core shrinking model"[3] and the "homogeneous model".[4,5] Mixed models[6] were also proposed which take into account the change of the process mechanism during reaction, as a consequence of the elementary process rate ratio variations. Wen and co-workers have extended the concept of "effectiveness factor,"[5] introduced for the catalytic reactions and developed the theory of non-catalytic heterogeneous reactions with thermal effects.[7]

---

[1] R. Z. Tudose, *Bul. Inst. Politeh. Iași,* **16**, 241, (1970).

The study of decomposition reactions, for which heat transfer is one of the determining elementary processes, is now at the stage of mathematical modelling trials, but all reported trials were devoted to particular cases.[8-10]

In the present paper an attempt is made to model these thermal decomposition reactions, for which either the external or internal heat transfer, or chemical reaction may be rate-controlling steps, some models being proposed whereby such a process can take place.

MODELLING OF THERMAL DECOMPOSITION REACTIONS

Decomposition reactions of carbonates and bicarbonates are endothermal. The gaseous phase is the heat carrier serving, at the same time, for entraining the reaction products. The overall process is based on the following elementary processes: heat transfer through the external limiting film, ash layer and reaction zone, chemical reaction and reaction products diffusion through the reaction zone, ash layer and external limiting film.

We shall discuss the case for which only the internal and external heat transfer as well as the reaction rate may be rate-controlling steps. This is the case of reactions developed at temperatures much higher than those corresponding to the equilibrium with reaction products.

Let us consider a reaction of the type given below:

$$B_{(s)} \rightarrow S_{(s)} + P_{(g)} + \Delta H \qquad (1)$$

where B is the solid reagent, S and P are the solid and gaseous reaction products, respectively and ΔH is the thermal effect of the reaction. Under certain reaction conditions the chemical reaction rate may be considered to be of zero order:

$$r_B = -k_s \qquad (2)$$

where k_s denotes the reaction rate constant related to the surface. The physical model, accounting for the mechanism of such a reaction, depends on the ratio between the external, internal heat transfer resistance and chemical reaction resistance.

When the intensity of the thermal flux required for the reaction to develop is of the same order of magnitude as the intensity of the heat flux transferred by thermal conductivity within the grain, the reaction takes place within a zone of δ_r thickness. Its value will satisfy the condition $0 < \delta_r < R$. In this case the reaction develops in three stages, according to the general model with reaction zone, as shown in fig.1.

In the first stage, that of the formation of the reaction zone, two zones are to be found inside the grain : the reaction zone and the unreacted-core zone, fig. 1a.

At the very moment when the solid reagent is completely exhausted on the outer surface of the grain, the second stage, that of the shifting of the reaction zone, begins. One can distinguish now the outer ash layer, the reaction zone and the inner unreacted-core (fig. 1b). The third stage, the disappearance of the reaction zone, begins when the reaction zone reaches the centre of the grain, the unreacted-core disappearing completely. Thus, only the ash layer and the reaction zone remain inside the grain.

For cases in which resistance to chemical reaction is much greater than resistance to internal transfer, the reaction is considered to take place according to the two-stage homogeneous model, fig. 2., the thickness of the reaction zone being equal to the granule radius (($\delta_r = R$). In the first stage — forming of the reaction zone — only one zone exists inside the grain (fig. 2 a). The second stage — disappearence of the reaction zone — begins when the solid reagent concentration is equal to zero at the outer surface of the grain. Therefore only the reaction zone and the ash layer will coexist in the grain. fig. 2 b.

Thermal decomposition heterogeneous non-catalytic reactions in which resistance to chemical reaction is much smaller than resistance to internal heat transfer, take place according to the "one-stage unreacted-core shrinking model" of shifting of the reaction zone, fig. 3. Reaction zone thickness is zero, the reaction develops on a surface, and in the grain an ash layer and an unreacted-core zone separated by reaction interface is detected. The models presented in this paper lead to the conclusion that the mechanism of a thermal decomposition reaction depends significantly upon elementary process rate ratios. Depending on this ratio, for a R radius grain, a reaction zone is formed with a thickness comprised between zero and R, $0 \leqslant \delta_r \leqslant R$.

It is obvious that a perfect analogy exists between the models established for non-catalytic solid-gas reactions and for thermal decomposition reactions ; in both cases the reaction mechanism depends upon the ratio of elementary process rates. From the previously reported experimental studies on the decomposition of calcium carbonate[8] and sodium bicarbonate [9,10] one may conclude that the reaction takes place according to the "unreacted-core shrinking model". But the conclusions drawn on theoretical and practical grounds, by investigators of heterogeneous thermal descomposition reactions are sometimes rather contradictory.

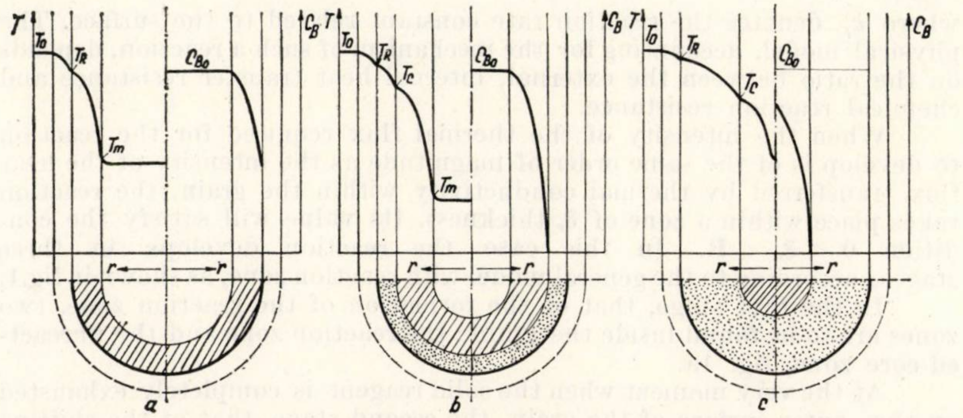

Fig. 1. — General model.

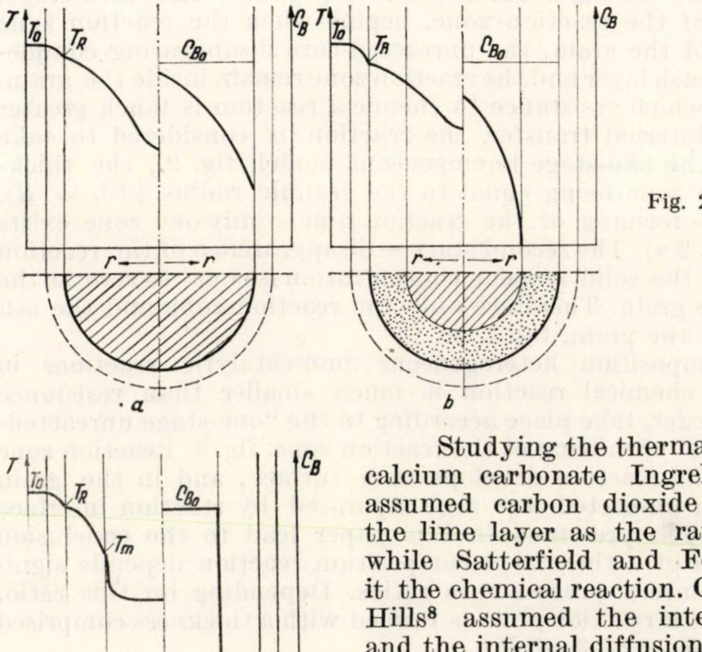

Fig. 2. — Homogeneous model.

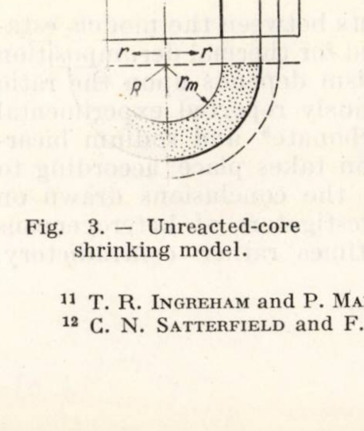

Fig. 3. — Unreacted-core shrinking model.

Studying the thermal decomposition of calcium carbonate Ingreham and Marier[11] assumed carbon dioxide diffusion through the lime layer as the rate-controlling step, while Satterfield and Feakes[12] considered it the chemical reaction. On the other hand, Hills[8] assumed the internal heat transfer and the internal diffusion of carbon dioxide as rate-controlling steps.

For the case of thermal decomposition of carbonates and bicarbonates the equilibrium relationship between the partial pressure of carbon dioxide and temperature has the shape shown in fig. 4 (curve 1).

If the process develops at atmospheric pressure and the temperature corresponds to equilibrium T_e, the reaction is influenced by the partial pressure of carbon dioxide in the entraining gas; the reaction order may be above zero. When $P_{CO_2}=1$, the reaction stops. Under the same pressure conditions there is a limiting temperature T_1, above which the reaction is not influenced by the carbon dioxide concentration in the entraining gas.

---

[11] T. R. Ingreham and P. Marier, *Canad. J. Chem. Eng.*, **41**, 170, (1963).

[12] C. N. Satterfield and F. Feakes, *Amer. Inst. Chem. Engineers J.*, **5**, 115 (1959).

At temperatures higher than the limiting temperature T_1, the reaction is of zero order. Thus, curve II separates a region (hatched) where the reaction is not influenced by the partial pressure of carbon dioxide in the entraining gas, its order being zero. Under these temperature conditions one may consider the reaction controlled either by external or internal heat transfer, or by heat consumption required for the chemical reaction to develop or only by one of these elementary processes.

The thermal effect of most thermal decomposition reactions is substantial and the reaction zone is an important heat consumer. As the thermal resistance of the ash layer is great, due to small thermal conductivity, it is obvious that most thermal decomposition reactions take place according to the unreacted-core shrinking model.

In the present paper the decomposition reactions of zero order taking place within the high temperature region (hatched region, fig. 4.) are modelled.

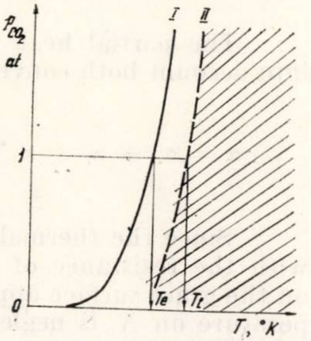

Fig. 4.—The equilibrium curve for the thermal decomposition of carbonates and bicarbonates.

THEORETICAL PART

Let us consider a spherical grain of homogeneous composition. At high temperatures a decomposition reaction takes place within the grain according to eq. 1. The grain diameter remains unchanged during the process. Based on the heat balance, for an unsteady-state regime, and taking the thermal effect into account one may write the following differential equation:

$$\frac{\partial T}{\partial t}=\frac{a}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial T}{\partial r}\right)-\frac{q'}{c_p\rho}$$

By differentiating the above equation and assuming a quasi-stationary regime one obtains:

$$\frac{\mathrm{d}^2 T}{\mathrm{d}r^2}+\frac{2}{r}\frac{\mathrm{d}T}{\mathrm{d}r}-\frac{q'}{\Lambda}=0 \tag{3}$$

where q' denotes the amount of heat expended per unit volume of the reaction zone and unit time. When the reaction takes place according to the unreacted-core shrinking model, hence on a surface, there is no heat-consuming within the ash layer and equation (3) is reduced to :

$$\frac{\mathrm{d}^2T}{\mathrm{d}r^2}+\frac{2}{r}\frac{\mathrm{d}T}{\mathrm{d}r}=0 \tag{4}$$

The boundary conditions at the two faces of the ash layer, according to fig. 3 will be :

$$\Lambda_c\frac{\mathrm{d}T}{\mathrm{d}r}=\alpha\,(T_0-T)\quad \text{at } r=R \tag{5}$$

$$T=T_m\qquad \text{at } r=r_m$$

The partial heat transfer coefficient, in the first condition, takes into account both convection and radiation heat transfer.

$$\alpha=\alpha_c+\alpha_r=\alpha_c+\alpha_r'\frac{T_0^4-T^4}{T_0-T}=\alpha_c+\alpha_r'\,(T_0+T)\,(T_0^2+T^2)$$

Since the thermal resistance of the gas film is small in comparison with the resistance of the other elementary processes, the temperature on the grain surface approaches T_0 and $\alpha_r\approx 4\alpha_r'\,T_0^3$. The effect of temperature on Λ_c is neglected.

By solving the equation (4) for the boundary conditions (5), the temperature distribution within the ash layer is obtained :

$$\frac{T-T_m}{T_0-T_m}=\frac{1-\dfrac{\lambda_m}{\lambda}}{1-\lambda_m+\dfrac{\lambda_m}{K_{\mathrm{Nu}}}} \tag{6}$$

The temperature at different points of the ash layer depends both on the reaction zone position and the value of Nusselt comparison number. This relationship is clearly depicted by the plots shown in fig. 5.

The reaction zone temperature may be determined by equating the heat amount transferred by thermal conductivity through the ash layer in the vicinity of the reaction zone, to the heat consumed during the chemical process.

The heat required for the grain to reach the reaction temperature is either neglected or included in the thermal effect of the reaction, under the assumption that heating of the solid to reaction temperature takes place as the reaction develops.

The heat transferred by thermal conductivity will be given by the Fourier laws :

$$q=-\Lambda_c\frac{\mathrm{d}T}{\mathrm{d}r}$$

The heat consumed during an endothermal reaction, of zero order, will be:

$$q = k_0 \, \Delta H \, \exp\left(- \frac{E}{R_g T_m} \right)$$

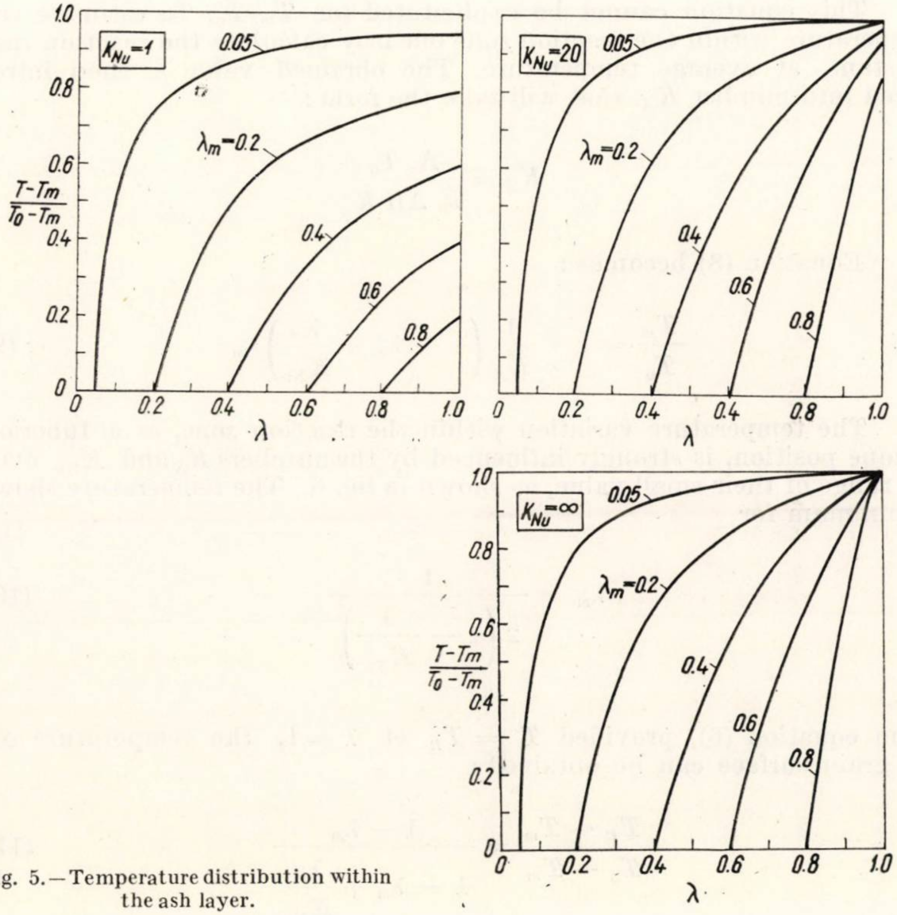

Fig. 5. — Temperature distribution within the ash layer.

For the case of quasi steady-state regime the two above heats may be equated, resulting the following equation:

$$\Lambda_c \frac{\mathrm{d}T}{\mathrm{d}r} = k_0 \, \Delta H \, \exp\left(- \frac{E}{R_g T_m} \right) \tag{7}$$

From eq. (7) and eq. (6) derivative, for $r = r_m$, the temperature of the reaction zone is obtained :

$$\frac{T_m}{T_0} = 1 - \frac{1}{K_A}\left(1 - \lambda_m + \frac{\lambda_m}{K_{\mathrm{Nu}}}\right)\lambda_m \exp\left(-\frac{K_{\mathrm{Ah}}}{T_m/T_0}\right) \tag{8}$$

This equation cannot be explicitated for T_m/T_0. To estimate the temperature within the reaction zone one may calculate the reaction rate constant, at average temperature. The obtained value is then introduced into number K_A, that will take the form :

$$\bar{K}_A = \frac{\Lambda_c\, T_0}{\bar{k}_s\, \Delta H\, R}$$

Equation (8) becomes :

$$\frac{T_m}{T_0} = 1 - \frac{1}{\bar{K}_A}\left(1 - \lambda_m + \frac{\lambda_m}{K_{\mathrm{Nu}}}\right)\lambda_m \tag{9}$$

The temperature variation within the reaction zone, as a function of zone position, is strongly influenced by the numbers K_{A} and K_{Nu} over the range of their small value, as shown in fig. 6. The temperature shows a minimum for

$$\lambda_m = \frac{1}{2\left(1 - \dfrac{1}{K_{\mathrm{Nu}}}\right)} \tag{10}$$

From equation (6), provided $T = T_R$ et $\lambda = 1$, the temperature on the grain surface can be obtained :

$$\frac{T_R - T_m}{T_0 - T_m} = \frac{1 - \lambda_m}{1 - \lambda_m + \dfrac{\lambda_m}{K_{\mathrm{Nu}}}} \tag{11}$$

Elimination of temperature T_m from eqs. (9) and (10) gives :

$$\frac{T_R}{T_0} = 1 - \frac{\lambda_m^2}{\bar{K}_B} \tag{12}$$

where number $\bar{K}_A = \bar{K}_A\, K_{\mathrm{Nu}} = \dfrac{\alpha\, T_0}{\bar{k}_s \Delta H}$

The temperature at the grain surface depends on the comparison numbers K_{Nu} or $\overline{K}_B$, as shown in fig. 7. At the onset of the conversion, for values $\overline{K}_R > 100$, the temperature at the grain surface is less than 1 % smaller compared to heat carrier temperature. This difference decreases as the conversion progresses.

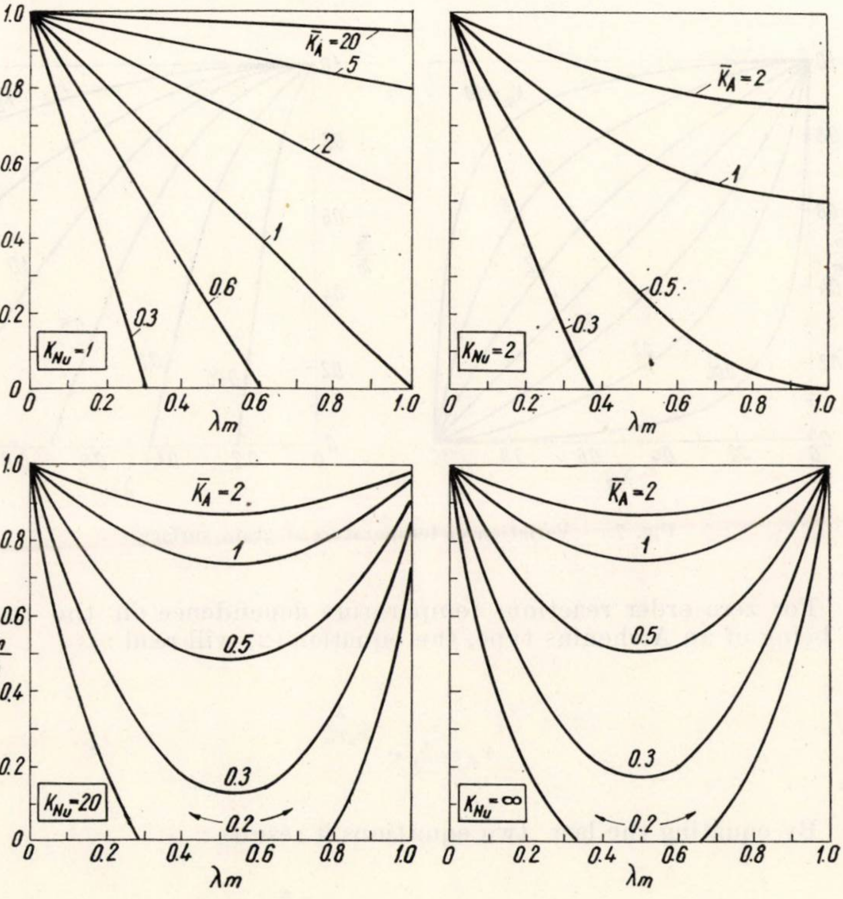

Fig. 6. — Variation of the reaction zone temperature, calculated by means of eq. (9)

The thermal decomposition reaction developing according to the "unreacted-core shrinking model" involves only one stage. The unreacted core of a homogeneous spherical grain keeps its size invariant, and the conversion is given by :

$$x = 1 - \left(\frac{r_m}{R}\right)^3 = 1 - \lambda_m^3 \tag{13}$$

During reaction the radius of the unreacted core is varying from R to zero. The reaction rate will have the form :

$$r_B = -\frac{1}{S}\frac{\mathrm{d}N_B}{\mathrm{d}t} = -\frac{1}{4\pi r_m^2} = \frac{\mathrm{d}\,(4/3\ \pi r_m^2\ C_{B_0})}{\mathrm{d}t} = -C_{B_0}\frac{\mathrm{d}\,r_m}{\mathrm{d}\,t} \qquad (14)$$

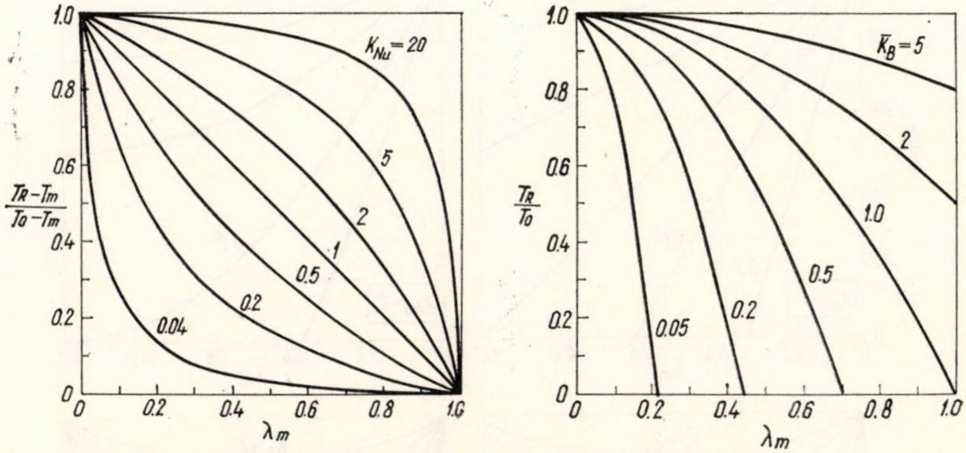

Fig. 7. — Variation of temperature at grain surface.

For zero order reactions temperature dependence on the reaction rate being of an Arrhenius type, the equation (2) will read :

$$r_B = k_0\,\mathrm{e}^{-\frac{E}{R_g T_m}} \qquad (15)$$

By equating the last two equations it results :

$$-\ C_{B_0}\frac{\mathrm{d}\,r_m}{\mathrm{d}\,t} = k_0\ \ \mathrm{e}^{-\frac{E}{R_g T_m}} \qquad (16)$$

After substituting the temperature of the reaction zone from equation (9) to equation (16) and separating the variables, the conversion time is obtained :

$$t_{1r} = -\frac{C_{B_0}}{k_0}\int_R^{r_m} \exp\left[\frac{E}{R_g\,T_0}\,\frac{1}{\frac{1}{\overline{K}_A R^2}\left(1 - \frac{1}{K_{\mathrm{Nu}}}\right) r_m^2 - \frac{1}{\overline{K}_A\,R}\ r_m + 1}\right]\mathrm{d}r_m \qquad (17)$$

The denominator has to fulfil the following condition :

$$\frac{1}{\overline{K}_A R^2}\left(1-\frac{1}{K_{\mathrm{Nu}}}\right) r_m^2-\frac{1}{\overline{K}_A R}\, r_m+1 \neq 0$$

The integral in equation (17) is of a transcedental type and may be solved only by expending it in series. If the first two terms of the series are considered it results :

$$t_{1r}=-\frac{C_{B_0}}{k_0}\left[\int_R^{r_m} \mathrm{d} r_m+K_{\mathrm{Ah}} \int_R^{r_m} \frac{\mathrm{d} r_m}{\frac{1}{\overline{K}_A R^2}\left(1-\frac{1}{K_{\mathrm{Nu}}}\right) r_m^2-\frac{1}{\overline{K}_A R}\, r_m+1}\right] \tag{18}$$

The second integral may admit three solutions, depending on the following conditions :

$$\begin{gathered}
\frac{1}{4 \overline{K}_A}+\frac{1}{K_{\mathrm{Nu}}}<1 \\
\frac{1}{4 \overline{K}_A}+\frac{1}{K_{\mathrm{Nu}}}=1 \\
\frac{1}{4 \overline{K}_A}+\frac{1}{K_{\mathrm{Nu}}}>1
\end{gathered} \tag{19}$$

By analysing the order of magnitude of the $\overline{K}_A$ and K_{Nu} comparators, one may conclude that only the solution corresponding to the first condition is of interest. After solving the two integrals and rearranging the terms the conversion time is obtained :

$$\begin{aligned}
t_{1r}=\frac{C_{B_0} R}{k_0}&\left\{1-\lambda_m+K_{\mathrm{Ah}} \frac{2 \overline{K}_A}{\sqrt{4 \overline{K}_A\left(1-\frac{1}{K_{\mathrm{Nu}}}\right)-1}}\,\cdot\right. \\
&\left.\cdot \tan^{-1}\left[\frac{(1-\lambda_m) \sqrt{4 \overline{K}_A\left(1-\frac{1}{K_{\mathrm{Nu}}}\right)-1}}{\left[2\left(1-\frac{2}{K_{\mathrm{Nu}}}\right)-1\right] \lambda_m+2 \overline{K}_A-1}\right]\right\}
\end{aligned} \tag{20}$$

For $\lambda_m=0$ the overall conversion time is given by :

$$\begin{aligned}
t_1=\frac{C_{B_0} R}{k_0}&\left\{1+K_{\mathrm{Ah}} \frac{2 \overline{K}_A}{\sqrt{4 \overline{K}_A\left(1-\frac{1}{K_{\mathrm{Nu}}}\right)-1}}\,\cdot\right. \\
&\left.\cdot \tan^{-1}\left[\frac{\sqrt{4 \overline{K}_A\left(1-\frac{1}{K_{\mathrm{Nu}}}\right)-1}}{2 \overline{K}_A-1}\right]\right\}
\end{aligned} \tag{21}$$

When the heat transfer through the external limiting film is not determining, $K_{\mathrm{Nu}} = \infty$ and the last two equations reduce to the form :

$$t_{1r} = \frac{C_{B_0}R}{k_0}\left\{1 - \lambda_m + K_{\mathrm{Ah}}\frac{2\overline{K}_A}{\sqrt{4\overline{K}_A - 1}}\tan^{-1}\left[\frac{(1-\lambda_m)\sqrt{4\overline{K}_{\mathrm{A}} - 1}}{\lambda_m + 2\,\overline{K}_{\mathrm{A}} - 1}\right]\right\} \tag{22}$$

$$t_1 = \frac{C_{B_0}R}{k_0}\left\{1 + K_{\mathrm{Ah}}\frac{2\overline{K}_A}{\sqrt{4\overline{K}_A - 1}}\tan^{-1}\left[\frac{\sqrt{4\overline{K}_A - 1}}{2\overline{K}_A - 1}\right]\right\} \tag{23}$$

In the equation set (20—23) the term $(C_{B_0}R/k_0) = b_0$ has a time dimension, so that it is possible to write them in the form of a dimensionless time. For instance, the last two equations become :

$$\tau_{1r} = 1 - \lambda_m + K_{\mathrm{Ah}}\frac{2\overline{K}_A}{\sqrt{4\overline{K}_A - 1}}\tan^{-1}\left[\frac{(1-\lambda_m)\sqrt{4\overline{K}_A - 1}}{\lambda_m + 2\overline{K}_A - 1}\right] \tag{24}$$

$$\tau_1 = 1 + K_{\mathrm{Ah}}\frac{2\overline{K}_A}{\sqrt{4\overline{K}_A - 1}}\tan^{-1}\left[\frac{\sqrt{4\overline{K}_A - 1}}{2\overline{K}_A - 1}\right] \tag{25}$$

By means of equations (13), (24) and (25) the plots shown in fig. 8 were depicted.

It can be seen that the conversion time is influenced by comparators $\overline{K}_A$ and $\overline{K}_{\mathrm{Nu}}$, but the influence of Arrhenius comparator is more significant. For low values of $\overline{K}_A$ the conversion time increases notably during the last stage of the reaction.

By integrating equation (18) for the third condition given in (19) one obtains the following equations for the current and overall conversion time, respectively :

$$t_{1r} = \frac{C_{B_0}R}{k_0}\left\{1 - \lambda_m + K_{\mathrm{Ah}}\frac{\overline{K}_A}{\sqrt{1 - 4\overline{K}_A\left(1 - \frac{1}{K_{\mathrm{Nu}}}\right)}}\ln \times\right.$$

$$\left.\times\frac{\left[2\left(1-\frac{1}{K_{\mathrm{Nu}}}\right)\lambda_m + \sqrt{1-4\overline{K}_A\left(1-\frac{1}{K_{\mathrm{Nu}}}\right)} - 1\right]\left[2\left(1-\frac{1}{K_{\mathrm{Nu}}}\right) - \sqrt{1-4\overline{K}_A\left(1-\frac{1}{K_{\mathrm{Nu}}}\right)} - 1\right]}{\left[2\left(1-\frac{1}{K_{\mathrm{Nu}}}\right)\lambda_m - \sqrt{1-4\overline{K}_A\left(1-\frac{1}{K_{\mathrm{Nu}}}\right)} - 1\right]\left[2\left(1-\frac{1}{K_{\mathrm{Nu}}}\right) + \sqrt{1-4\overline{K}_A\left(1-\frac{1}{K_{\mathrm{Nu}}}\right)} - 1\right]}\right\} \tag{26}$$

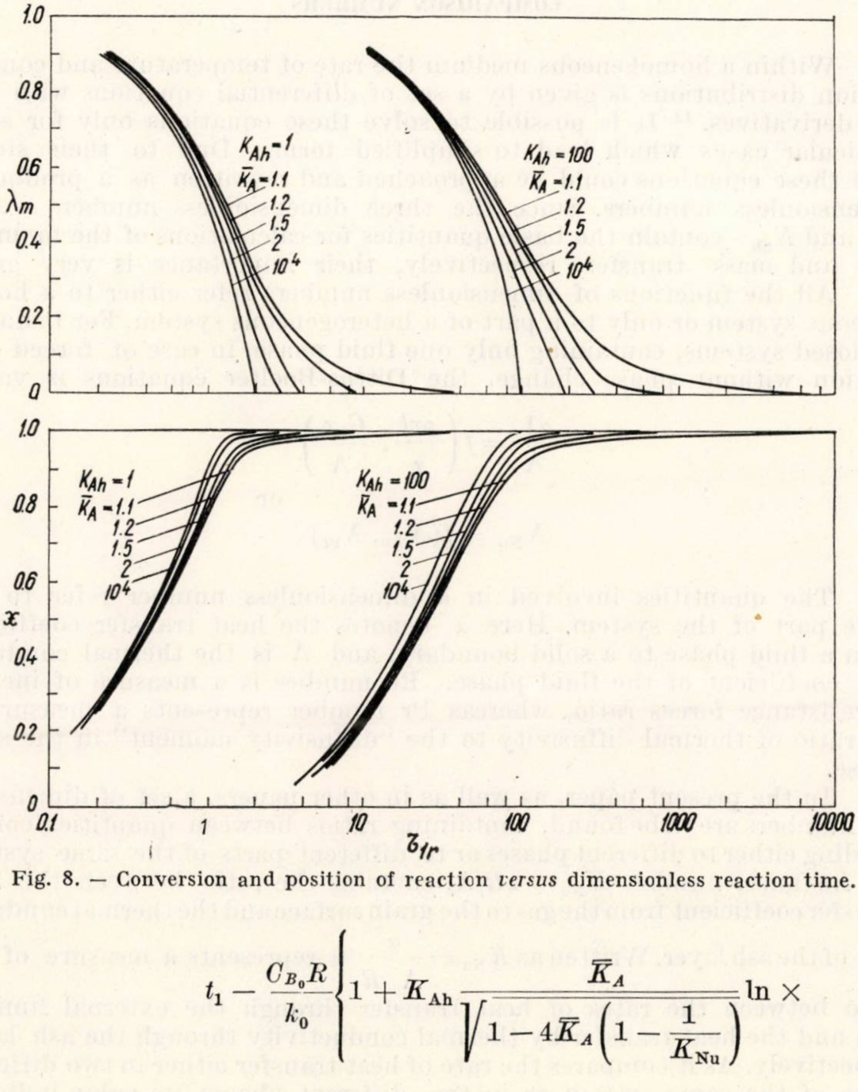

Fig. 8. — Conversion and position of reaction *versus* dimensionless reaction time.

$$t_1 = \frac{C_{B_0}R}{k_0}\left\{1 + K_{\mathrm{Ah}}\frac{\overline{K}_A}{\sqrt{1-4\overline{K}_A\left(1-\dfrac{1}{K_{\mathrm{Nu}}}\right)}}\ln \times\right.$$

$$\left.\times \frac{\left[1-\sqrt{1-4\overline{K}_A\left(1-\dfrac{1}{K_{\mathrm{Nu}}}\right)}\right]\left[2\left(1-\dfrac{1}{K_{\mathrm{Nu}}}\right)-\sqrt{1-4\overline{K}_A\left(1-\dfrac{1}{K_{\mathrm{Nu}}}\right)}-1\right]}{\left[1+\sqrt{1-4\overline{K}_A\left(1-\dfrac{1}{K_{\mathrm{Nu}}}\right)}\right]\left[2\left(1-\dfrac{1}{K_{\mathrm{Nu}}}\right)+\sqrt{1-4\overline{K}_A\left(1-\dfrac{1}{K_{\mathrm{Nu}}}\right)}-1\right]}\right\} \tag{27}$$

For $K_{\mathrm{Nu}} = \infty$ both equations get a simplified form. Nevertheless, their usefulness is rather limited.

COMPARISON NUMBERS

Within a homogeneous medium the rate of temperature and concentration distributions is given by a set of differential equations with partial derivatives.[13] It is possible to solve these equations only for some particular cases which lead to simplified forms. Due to their similitude these equations could be approached and rewritten as a product of dimensionless numbers. Since the three dimensionless numbers — N_{Eu}, N_{Nu} and N_{Sh} — contain the basic quantities for calculations of the moment, heat and mass transfer, respectively, their importance is very great.

All the functions of dimensionless numbers refer either to a homogeneous system or only to a part of a heterogeneous system. For instance, in closed systems, containing only one fluid phase, in case of forced convection without phase change, the Dittus-Boelter equations is valid:

$$\frac{\alpha 1}{\Lambda}=f\left(\frac{\rho v l}{\eta}, \frac{C_p \eta}{\Lambda}\right)$$

or

$$N_{\mathrm{Nu}}=f(N_{\mathrm{Re}}, N_{\mathrm{Pr}})$$

The quantities involved in a dimensionless number refer to the same part of the system. Here α denotes the heat transfer coefficient from a fluid phase to a solid boundary, and Λ is the thermal conductivity coefficient of the fluid phase. Re number is a measure of inertial to resistance forces ratio, whereas Pr number represents a measure of the ratio of thermal diffusivity to the "diffusivity moment" in the same phase.

In the present paper, as well as in other papers, a set of dimensionless numbers are to be found, containing ratios between quantities corresponding either to different phases or to different parts of the same system. For instance, number $K_{\mathrm{Nu}}=\alpha R/\Lambda_c$ contains the ratio between the heat transfer coefficient from the gas to the grain surface and the thermal conductivity of the ash layer. Written as $K_{\mathrm{Nu}}=\dfrac{\alpha}{\Lambda_c/R}$ it represents a measure of the ratio between the rates of heat transfer through the external limiting film and the heat transfer by thermal conductivity through the ash layer, respectively. As it compares the rate of heat transfer either in two different parts of the same system or in two different phases, its value indicates which of the processes is the determining one. Owing to their significance these numbers will be referred to as comparison numbers or comparators.

In equation (8) number K_A, given below, represents a measure of the ratio between the rate of heat transfer by thermal conductivity through the ash layer and the rate of heat consumption in the reaction zone.

The comparison number $K_{\mathrm{Ah}}=K_{\mathrm{Ah}}=E/\mathrm{R}gT$, known as exponent in the Arrhenius equation, has a similar meaning. The Arrhenius comparator is a measure of the reaction activation energy to the molecular kinetic energy ratio.

---

[13] R. B. Bird, W. E. Stewart and E. L. Lightfoot, "Transport Phenomena", John Wiley and Sons, New York, 1960, p. 71, 310, 554.

For the thermal decomposition reactions K_A and K_{Ah} comparators are particularly important, their value giving indications on the rate determined processes.

Temperature variation on the grain surface, given by equation (12), is a function of $\bar{K}_A$ and K_{Nu} comparators product. This product, written as $K_B = \alpha T_0/k_0 \; \Delta H$, is a measure of the ratio between the heat amount transferred through the external limiting film and that consumed in the reaction zone. Its value specifies which of the two processes above is the determining one.

In a previous paper[1,2] on the modelling of non-catalytic solid-gas reactions, the Sherwood comparators were introduced :

$$K_{Sh_r} = \frac{k_t R}{D_r} \qquad K_{Sh_c} = \frac{k_t R}{D_c}$$

Both numbers give a measure of the ratio of the mass transfer rate through the external limiting film to that through the reaction zone or ash layer, respectively. Two denominations are encountered in the reported papers : "fictitious Sherwood number"[1] and "modified Sherwood number"[7]. For the non-catalytic heterogeneous reactions the Thiele comparator, known in literature as the Thiele modulus, has a particular significance.

$$K_{Ti,r} = R \sqrt{\frac{a' k_v C_{B_0}}{D_r}} \qquad K_{Ti,c} = R \sqrt{\frac{a' k_v C_{B_0}}{D_c}}$$

The above Thiele moduli compare the rate of reactant consumption to that of reactant diffusion through the reaction zone or ash layer, respectively.

DISCUSSION

The models developed in this paper refer to those grains which do not change their size in the course of the process. To establish the mechanism (model), according to which a thermal decomposition reaction takes place, the dimensionless thickness of the reaction zone λ_r was taken as a principal criterion. In the case of endothermal reactions, with significant thermal effect, the thickness of the reaction zone is zero, the reaction taking place according to the unreacted-core shrinking model.

The mathematical analysis of endothermal heterogeneous non-catalytic chemical reactions, for which the internal and external heat transfer and the rate of heat consumption can be rate-determined processes, allows to calculate the temperature on the grain surface and in the reaction zone, as well as temperature distribution within the ash layer. The equations derived contain four dimensionless numbers which were termed comparison numbers or comparators. Each comparator gives a measure of a two elementary-processes rate ratio, its value providing information on the rate determined process. For thermal decomposition reactions comparators K_A and K_{Ah} are particularly important.

The temperature variation in the reaction zone, as a function of conversion, is given by eq. (8). However, its usefulness is rather limited because it cannot be explicited for estimating the T_m/T_0 ratio. By replacing the unexponential factor in the Arrhenius type equation of the reaction rate constant with the reaction rate constant itself, calculated at average temperature, equation (9) was obtained.

The reaction rate constant is significantly influenced by temperature. The admission of an average value $\bar{k}_s$ to simplify equation (8), seems to introduce great errors. However, calculating the temperature of the reaction zone relative to its position, based on eq. (8), by means of a computer, it was found that for numbers $K_A > 5$, the temperature in the reaction zone varies over a rather narrow range. The use of comparator K_A, calculated by means of the reaction rate constant average value, will introduce errors which do not affect significantly chemical engineering calculations.

As shown in figs. 6,9 the temperature passes through a minimum during conversion. The minimum, according to eq. (9) will correspond to the reaction zone position predicted by eq. (10). When the thermal resistance of the external limiting film is small enough to be completely neglected, the temperature on the grain surface is equal to T_0, and the minimum of the reaction zone temperature corresponds to $r_m = R/2$, when the external limiting film has a thermal resistance, $T_R < T_0$ and the minimum shifts to the grain centre.

The reaction zone temperature passes through a minimum, its position being strongly influenced by K_{Nu} comparator and, to a lesser extent, by K_{Ah}. This minimum may be assigned to the variation of the ratio

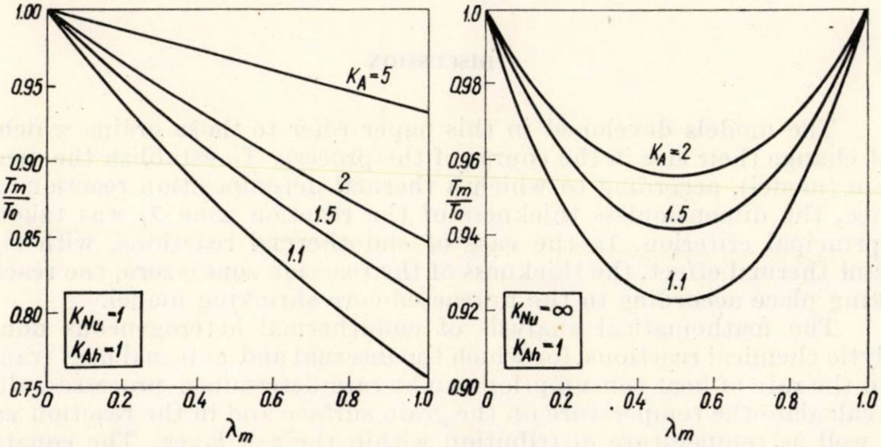

Fig. 9. — Variation of the reaction zone temperature estimated by means of eq. (8).

between the heat amount required for the reaction to develop and that transferred by thermal conductivity through the ash layer, during conversion course. The heat amount consumed during reaction is directly proportional to r_m^2, while the thermal resistance of the ash layer is directly proportional to the difference $(1/r_m) - (1/R)$.

These relationships account for the existence of a temperature minimum.

The time of conversion may be calculated by means of equations (20) and (21), as well as by means of the simplified equations (22, 23, 24 or 25). For numbers $K_A > 10$ variation of the reaction zone temperature is quite insignificant. Calculations may be made by using an average value $T_m = \overline{T}_m$ or, in cases in which the Nusselt comparator has great values, by letting $T_m = T_0$. Thus, equations (16) may be rewritten as follows :

$$- C_{B_0} \frac{\mathrm{d}r_m}{\mathrm{d}t} = \bar{k}_s \tag{28}$$

where $\bar{k}_s$ denotes the reaction rate constant, calculated by means of the average reaction zone temperature. Therefore, $\bar{k}_s$ is independent of r_m.

After separating the variables equation (28) becomes :

$$t_{1r} = - \frac{C_{B_0}}{k_0} \exp\left(\frac{E}{R_g \overline{T}_m}\right) \int_R^{r_m} \mathrm{d}r_m$$

and then:

$$t_{1r} = - \frac{C_{B_0}}{k_0} (1 - \lambda_m) \exp. \overline{K}_{\mathrm{Ah}} \tag{29}$$

For $\lambda_m = 0$, the overall conversion time is :

$$t_1 = \frac{C_{B_0} R}{k_0} \exp. \overline{K}_{\mathrm{Ah}} \tag{30}$$

Equations (29) and (30) may be rewritten under a dimensionless form, as given below :

$$\tau_{1r} = (1 - \lambda_m) \exp. \overline{K}_{\mathrm{Ah}} \tag{31}$$

$$\tau_1 = \exp. \overline{K}_{\mathrm{Ah}} \tag{32}$$

By comparing eq. (31) and (32) to eq. (24) and (25) it has been ascertained that they are approximately identical. For $K_{\mathrm{Ah}} > 10$ eq. (24) and (25) get the simplified forms :

$$\tau_{1r} = (1 - \lambda_m)(1 + K_{\mathrm{Ah}}) \tag{33}$$

$$\tau_1 = 1 + K_{\mathrm{Ah}} \tag{34}$$

where $1 + K_{\mathrm{Ah}}$ denotes the first two terms of the exponential series. The graphical representation of equation (31) in logarithmic coordinates results in a family of straight lines with slope equal to unity, as shown in fig. 10. The intersection of these lines with the line of abscissa of unity gives the overall conversion time.

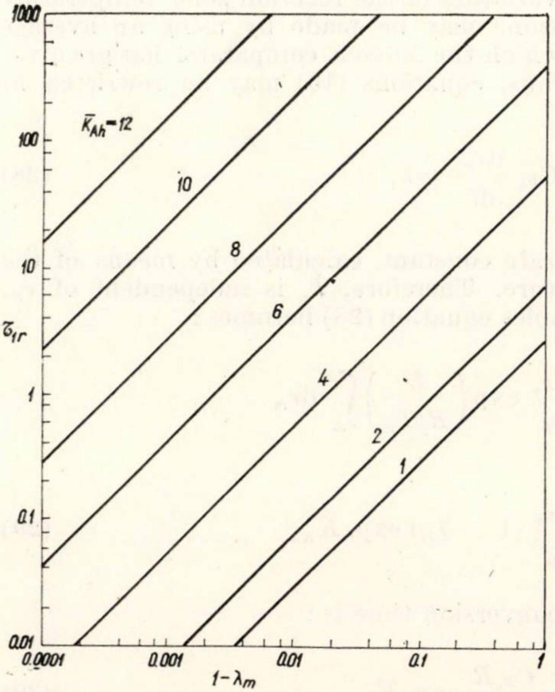

Fig. 10. — Conversion time *versus* position of the reaction zone for different values of K_{Ah} comparator.

Some studies concerning the kinetics of thermal decomposition reactions provide data for the activation energy and the rate constant of the reaction. These quantities depend upon the nature of the material i.e. on temperature, but also upon granulosity, which means that the apparent activation energy and the apparent reaction rate were determined, as the chemical process was masked by the physical one.

The modelling of these reactions points out the possibilities for determining the exact values of the two quantities. First, it is recomended to perform a kinetic study of the decomposition reactions on materials of different granulosities. Then, the relationship between the apparent reaction rate constant and the grain diameter is represented graphically. Extrapolation of the curve, for granulosity values of zero, will give the real reaction rate constant. The activation energy may be obtained in the same way, as well as by means of the real reaction rate constants determined at different temperatures.

The models developed in the present paper account for the mechanism whereby a thermal decomposition reaction takes place. Development of the unreacted-core shrinking model theory permits to calculate the temperature distribution in the ash layer, as well as the dependence of the reaction zone temperature and that of the grain surface upon the position of the reaction zone.

By means of the equations derived in the last part of the paper the conversion time may also be calculated.

NOMENCLATURE

a — thermal diffusivity coefficient, m^2/h

a' — stoichiometric coefficient, dimensionless

C_{B_0} — initial concentration of the solid reactant in the grain, mol/m^3

C_p — specific heat, $J/Kg°C$

D — effective diffusion coefficient, m^2/h

D_c — effective diffusion coefficient through the ash layer, m^2/h

D_r — effective diffusion coefficient through the reaction zone, m^2/h

E — activation energy of the reaction, J/mole

ΔH — thermal effect of the reaction, J/mole

k_s — reaction rate constant referred to area, $mole/m^2h$

$\bar{k}_s$ — ibid., calculated at the average temperature of the reaction zone, mol/m^2h

k_v — reaction rate constant referred to volume, $mole/\,/m^3h$

k_t — mass transfer coefficient through the external limiting film, m/h

$K_A = \dfrac{\Lambda_c T_0}{R k_0 \Delta H}$, comparison number A, dimensionless

$\bar{K}_A = \dfrac{\Lambda_c T_0}{R \bar{k}_s \Delta H}$, comparison number A, calculated by means of the average value of the reaction zone temperature, dimensionless

$K_{Ah} = \dfrac{E}{R_g T_0}$, Arrhenius comparison number, dimensionless

$K_B = \dfrac{\alpha T_0}{k_0 \Delta H}$, comparison number B, dimensionless

$\bar{K}_B = \dfrac{\alpha T_0}{\bar{k}_s \Delta H}$, comparison number B, calculated by means of the average value of the reaction rate constant, dimensionless

$K_{Nu} = \dfrac{\alpha_R}{\Lambda_c}$, Nusselt comparison number, dimensionless

$K_{Sh} = \dfrac{k_t R}{D}$, Sherwood comparison number, dimensionless

K_{Sh_c} — Sherwood comparison number referred to the ash layer, dimensionless
K_{Sh_r} — Sherwood comparison number referred to the reaction zone, dimensionless
$K_{\mathrm{Ti}} = R\sqrt{\frac{a' k_v C_{B_0}}{D}}$, Thiele comparison number, dimensionless
K_{Ti_c} — Thiele comparison number referred to the ash layer, dimensionless
K_{Ti_r} — Thiele comparison number referred to the reaction zone, dimensionless
l — current length, m
$N_{\mathrm{Eu}} = \Delta p/v^2\rho$, Euler number, dimensionless
$N_{\mathrm{Nu}} = \alpha l/\Lambda$, Nusselt number, dimensionless
$N_{\mathrm{Pr}} = C_p\eta/\Lambda$, Prandtl number, dimensionless
$N_{\mathrm{Re}} = \rho v l/\eta$, Reynolds number, dimensionless
p — partial pressure of a gaseous component, N/m^2
q — intensity of thermal flux, J/m^2h
q' — heat consumed during reaction, J/m^3h
r — distance from the grain centre m
r_B — chemical transformation rate of the solid reagent, B, mole/m²h
r_m — unreacted core radius, m
R — grain radius, m
R_g — gas constant, J/mole°C
S — area, m²
t — time, h
t_0 $= C_{B_0}R/k_0$, h
t_{1r} — current conversion time, h
t_1 — overall conversion time, h
T — temperature, K
T_0 — gaseous phase temperature, K
T_m — reaction zone temperature, K
T_R — temperature at the grain surface, K
v — velocity, m/s
x — conversion, dimensionless
α — partial heat transfer coefficient, w/m² °C
α_c — partial convective heat transfer coefficient, w/m² °C
α_r — partial radiation heat transfer coefficient, w/m² °C
α_r' — partial radiation heat transfer coefficient, w/m² $(\mathrm{C}^\circ)^4$
δ_r — reaction zone thickness, m
η — dynamic viscosity, N s/m²
λ $= r/R$, dimensionless
λ_m $= r_m/R$, dimensionless
Λ — thermal conductivity, w/m °C
Λ_c — thermal conductivity of the ash layer, w/m °C
ρ — density, kg/m³
τ — time, dimensionless
τ_{1r} $= t_{1r}/t_0$, conversion time, dimensionless
τ_1 $= t_1/t_0$, overall conversion time, dimensionless

SILVER-SILVER HALIDE ELECTRODES IN MOLTEN SODIUM NITRATE-BARIUM NITRATE EUTECTIC

SURENDER K. JAIN
Hindu College, University of Delhi, Delhi-110007, India.

Received January 17, 1974

Considering Ag/Ag^+ (1 mole kg^{-1}), as standard reference, the thermodynamic parameters for the electrode process have been evaluated from the temperature dependence of emf of the concentration cell (A). The reversibility of silver-silver halide electrodes in molten eutectic mixture of sodium nitrate-barium nitrate has been examined at 623 K.

INTRODUCTION

For the study of association equilibria in molten salts *emf* methods are among the most accurate and convenient, when suitable reversible electrodes are available. In molten nitrates, Ag/Ag^+ electrode has been the only suitable electrode of first kind and has been extensively used for the study of the association of silver ions with halide ion.[1–6] In similar studies for the metal cations e.g. Cd^{2+}, Pb^{2+} and TI^+, for which the electrode of first kind is not available, silver-silver halide electrodes, are successfully employed.[7] The only restricting factor is solubility of silver halides at working temperature in desired solvent. Solubilities of silver halides in this solvent, measured[8] over the range 620–695 K, are found reasonably low to facilitate the functioning of such electrode systems. As a preliminary step towards the studies for the association of Cd^{2+} and TI^+ with halide ions in this solvent it was necessary to establish the reversibility of the silver-silver halide electrode system in this solvent. The results obtained are presented in the paper.

EXPERIMENTAL

A concentration cell (A) was set up. Experimental details were similar to those reported earlier.[8]

$$\begin{array}{c|c||c|c} \begin{array}{c}\mathrm{Ag}\\(-)\end{array} & \begin{array}{c}\mathrm{AgNO_3}(m')\text{ in}\\\text{molten solvent}\end{array} & \begin{array}{c}\mathrm{AgNO_3}(m)\\ \overset{+}{\mathrm{Na_X}}\text{ in molten solvent}\end{array} & \begin{array}{c}(\mathrm{Ag})\\(+)\end{array} \end{array} \qquad (A)$$

Reference half-cell Indicator half-cell.

In the absence of NaX (X =Cl, Br, I) the cell emf. exhibited Nernst behaviour. For measurements of cell (A) containing about 10^{-2} mole $\mathrm{Kg^{-1}}$ $\mathrm{AgNO_3}$ an equivalent amount of NaX was added to the indicator half-cell to ensure saturation of the solution *w.r.t.* silver halides. Thereafter solid Nax was added in small quantities and the corresponding emf (at 623 K) of the cell was measured (reproducible to ±0.0002 volts), the temperature dependence of the emf. was investigated in the presence of excess of AgX in the melt.

RESULTS AND DISCUSSION

In the presence of excess of halide ions (in a solution saturated w.r.t. AgX), the electrode system of right hand half-cell could be regarded as a silver-silver halide (second-kind) electrode, and the standard electrode potential of it would be expressed as,

$$E^\circ_{\mathrm{Ag\,|\,AgX(s)\,|\,X^-}} = E^\circ_{\mathrm{Ag\,|\,Ag^+}} + \frac{RT}{F}\ln K^\circ_{\mathrm{sp}} \qquad (1)$$

Taking Ag/Ag$^+$ (1 mole kg^{-1}) electrode as reference, eq. (1) becomes:

$$E^\circ_{\mathrm{Ag\,|\,AgX\,|\,X^-}} = \frac{RT}{F}\ln K^\circ_{\mathrm{sp}} \qquad (2)$$

and as a result of this assumption regarding standard reference, all thermodynamic quantities for the silver-silver halide electrode reaction are equal to the corresponding quantities for the dissolution process. If the enthalpy and entropy change over the entire range of temperature are assumed to be constant, the free energy for the dissolution reactions can be expressed as:

$$\Delta G^\circ = \Delta G^\circ_{623} - \Delta S^\circ\,(T - 623) \qquad (3)$$

The parameters ΔG°_{623} and ΔS°_{623} have been determined for AgCl, AgBr and AgI, by the least-square method. A non-random systematic distribution of the residuals when plotted *vs* temperature reflect that the linear relation is unsatisfactory for expressing these data, hence ΔH°, and ΔS° may not be temperature independent (Cf. ref.[9]) (equivalent to assuming $\Delta C_p \neq 0$). Now, assuming that $\Delta C_p^\circ \neq 0$, but remains constant over the temperature range, the expression for the various thermodynamic parameters are :

---

[9] G. A. Sacchetto, G. A. Mazzocchin and G. G. Bombi, *J. Electronalyt. Chem.*, **20**, 435 (1969).

$$\Delta H^{\circ} = \Delta H^{\circ}_{623} + \Delta C^{\circ}_{p}(T-623) \qquad (4)$$

$$\Delta S^{\circ} = \Delta S^{\circ}_{623} + \Delta C^{\circ}_{p} \ln\ (T/623) \qquad (5)$$

$$\Delta G^{\circ} = \Delta G^{\circ}_{623} + \Delta C^{\circ}_{p}\,(T-623-T\ln\,(T/623)) - \Delta S^{\circ}_{623}\,(T-623) \qquad (6)$$

Parameters ΔG°_{623} ΔC°_{p} and ΔS°_{623}, computed by least square method, are tabulated in table 1. Although eq. (16) did not completely eliminate nonrandomness of residuals it significantly reduced the standard deviations of the fit [0.064 to 0.029 for AgCl (32 points); from 0.042 to 0.028 for AgBr (24 points); and from 0.215 to 0.100 for AgI (58 points)]. It may be pointed out that ΔC°_{p} values, however, show a regular increasing trend from chloride to iodide but their magnitude should be taken with some cautions since a small error in the temperature dependence of the measured function could introduce significant error in ΔC°_{p}. The temperature dependence of various parameters for the electrode process is given by the following equations:

Table 1

Standard Thermodynamic Quantities (at 623 K) for the electrode reaction

$AgX(s) + \bar{e} \rightleftarrows Ag(s) + X^{-}$

The reversibility of the silver-silver halide electrode systems (at 623 K) was investigated by measuring the *emf* of the cell (B):

$$\begin{array}{c|c|c|c} \text{Ag} & \text{X}^-\ (R')\ \text{in molten} & \text{X}^-\ (R)\ \text{in molten} & \text{Ag} \\ (-) & \text{solvent (sat. with} & \text{solvent (sat. with} & (+) \\ & \text{AgX)} & \text{AgX).} & \end{array} \quad \text{(B)}$$

Reference half-cell Indicator half-cell

as a function of halide ion concentration in indicator half-cell, the concentration of the reference half-cell being fixed. Plots of *emf vs*

$$\log\ (R_{X^-}/R'_{X^-})$$

where:

$$R_{X^-} = \frac{n_{X^-}}{n_{\text{NO}_3^-} + n_{X^-}}$$

over a considerable concentration range of halide ion are given in fig. 1. For Ag/AgCl and Ag/AgBr electrode system the Nernst slope in the plots ranged within ±1 mV to the theoretical value of 123.6 mV for one electron process at 623 K. The higher slope noted in the case of Ag/AgI system might be attributed to the partial oxidation of iodide to iodate in this solvent at higher temperatures.

ACKNOWLEDGEMENTS. The author wishes to express his sincere thanks to Prof. H.C. Gaur, University of Delhi, for providing research facilities.

Received January 31, 1974

Unlike methoxides, the Li, Na, and K ethoxides present interionic associations even in pure alcohol. The association constant varies appreciably with the variation of the dielectric constant of the solvent. The inadequacy of the significance assigned to the interionic parameter in the electrostatic theory of interionic association is pointed out. Conductance data are discussed comparatively with the results from the Raman spectra.

INTRODUCTION

The Alkoxides have both a theoretical and a practical interest; theoretically, they are interesting owing to their complex reaction mechanism in solutions, whereas practically, methoxides and ethoxides can be used as catalysts in many solution-phase reactions. The problems raised by such uses have revealed the insufficient knowledge of the properties of this class of compounds.

Conductometric and spectral (infrared and Raman) studies carried out upon solutions of alkoxides in pure alcohol or solvent mixtures containing alcohol have proved to be very useful for demonstrating the main interactions occurring among the particles of these systems: the ion-ion and ion-solvent interactions.

In this paper, some results are reported of conductometric and Raman-spectrometric studies carried out upon solutions of Li, Na, and K ethoxides in pure ethanol and in mixtures of ethanol with non-polar solvents (benzene) and with strongly polar solvents (dimethylformamide).

EXPERIMENTAL

Ethanol was anhidrised on iodine-activated magnesium, which had been refluxed in distillation flask for 10 – 15 hours and then fractionated in an inert atmosphere. The purity criterion was the specific conductance (in all determinations $\chi < 10^{-6} \Omega^{-1} cm^{-1}$). Traces of water were determined by the K. Fischer method, the higest admitted content being 0,01 %.

Benzene, kept on Na wire was freshly distilled before each utilization; benzene utilized in dielectric constant determinations was initially crystallized fractionary, retaining only the 5.50° fraction.

Dimethylformamide was dried on 4Å molecular sieves and then distilled at reduced pressure. ($\chi < 10^{-6}\Omega^{-1}\text{cm}^{-1}$).

Ethoxides were prepared by the direct reaction of the high purity metal with desaerated alcohol, in a vessel as in fig. 1. All manipulations were carried out under inert gas, in a chamber, to protect the reaction.

The determination of the ethoxide solution was made by conductometric titration with 0.1 N hydrochloric acid, as in the case of methoxides.[1]

Conductance determinations were carried out with an accuracy of 0.05% using a Wynne-Kerr bridge and a cell with a constant of $0.7790\ \text{cm}^{-1}$, estimated with KCl solutions in a range of $(1-6).10^3$N, according to the Fuoss-Zwolenik method.[2]

The experimental device used for the determination of conductance changes vs. concentration was described earlier.[3]

Determinations of the dielectric constant were performed with a DM01–WTW-type bridge with a dial extension of 4500 units; a self-made cell was used, that allowed to estimate the dielectric constant in a range of 1–35 DK units with an accuracy of 0.05%. (Fig. 2). The apparatus calibration was made with benzene, methanol, n-propanol and nitrobenzene, purified according to Bunger and Reddicks indications.[4]

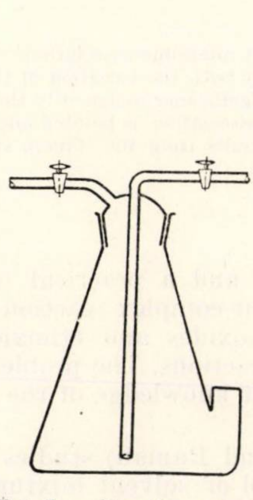

Fig. 1. — Reaction vessel.

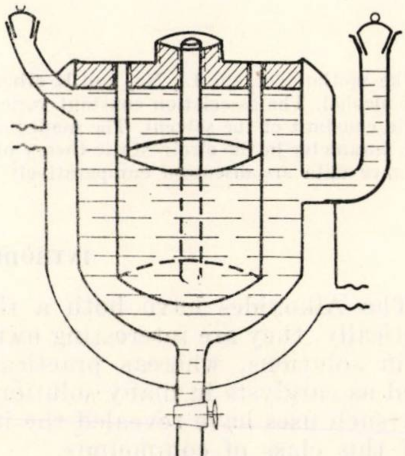

Fig. 2. — Cell for dielectric constant determination.

Viscosity determinations were made with a Höppler BH-2-type viscosimeter, the accuracy being 1%.

Densities were measured with a picnometer.

The Raman spectra were photoelectrically recorded with a Steinheil GH spectrograph, with a Toronto-type mercury lamp as excitation sourse. The accuracy in frequency measurement was ±1 cm^{-1} for narrow lines and $\pm 2-3\ \text{cm}^{-1}$ for broad lines.

RESULTS AND DISCUSSIONS

In table 1 the values of determined conductances in terms of ethoxide concentration in various solvents, at 25°, are given.

Processing of conductance data was made using the Fuoss-Onsager[5] equation for the associate electrolytes:

$$\Lambda = \Lambda_0 - Sc^{1/2} r^{1/2} + Ecr \log cr + Jcr - K_A \Lambda cr f_\pm^2 \qquad (1)$$

using an IBM computer and a Fortran IV program. The constants necessary for the estimation of the coefficients in equation (1) (densities, viscosities, dielectric constants) had been previously determined, the corresponding values being given in table 2.

In table 3 the values for the Λ_0, K_A and a parameters resulting from the optimisation of equation (1) are given, as well as the values of the limiting slopes, those calculated, $S_{calcd.}$, and those obtained from the experimental data, $S_{expl.}$, from the slope of the straight line $\Lambda(\sqrt{c})$. According to table 3, the difference between the experimental and the theoretical slope is positive for all ethoxides in pure alcohol, increasing with the decrease of the dielectric constant which accompanies the increase of the benzene content in solvent mixture. In DMF mixtures the difference decreases gradually, becoming insignificant at a molar fraction of 0.166 DMF.

The variation of the limiting slope is in agreement with the variation of the association constant, explaining satisfactorily the variation of the limiting equivalent conductance with the fraction of added solvent.

The study of the total Walden product, $\Lambda_0\eta_0/D_0$[6], determined in these mixtures, shows that this product is constant in the case of $C_2H_5OH-C_6H_6$ and presents small variations, within 0.1%, in the case of C_2H_5OH-

---

[6] J. Lind and R. M. Fuoss, *J. Phys. Chem.*, **65**, 1413 (1961).

DMF. However, we could hardly conclude that in passing from one mixture of solvents to another, any change would occur in ion solvation.

Determiation of the interionic parameter from the $J(a)$ coefficient of the conductance equation has resulted in values that vary appreciably with the composition of the solvent. An increase of the interionic parameter with the decrease of dielectric constant was noticed, in disagreement with the requirements of the electrostatic theory of the interionic association, reminding the dependence of the critical parameter of association (R) on the dielectric constant, $R = e^2/2DkT$.

Starting from this remark, the plotting $\log \cdot K_A = f(1/D)$ must be a curve like that of fig. 3 and not a straight line, as it follows from the electrostatic theory of association, where a is a specific parameter for the electrolyte and is independent of the nature of the solvent. The logarithms of the association constants determined for the Li, Na, and K ethoxides present a linear variation in terms of $1/D$ (Fig. 4). This fact is due to the relative restricted range, of 19—27 D.K. units, on which the determinations were made.

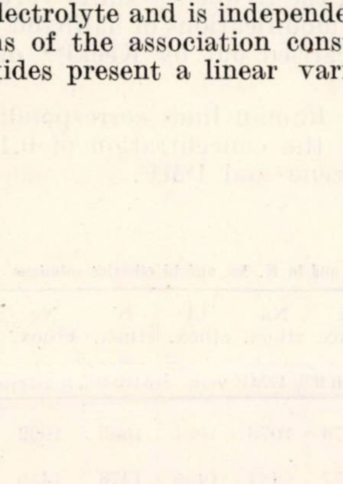

Fig. 3. — Variation of the association constant *vs.* reciprocical dielectric constant, provided that $a = f(1/D)$.

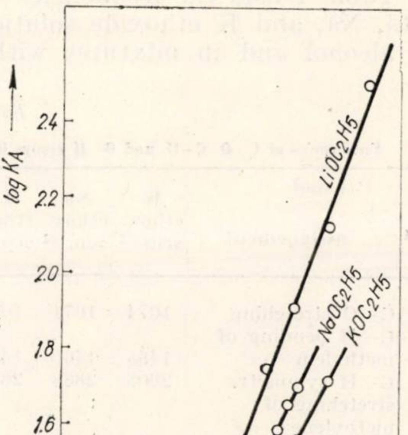

Fig. 4. — Variation of the association constant in the series of ethoxides *vs.* dielectric constant.

Other authors[7] effecting for association constants determinations on wider dielectric constant ranges have pointed out concavities like those in fig. 3. This fact was considered to result from systematic errors of determinations and not from discrepancies in the significance of the interionic parameter itself, as emphasized by our data.

At the same time we recorded the Raman spectra of ethoxides in pure ethanol and of ethoxides in ethanol with addition of benzene and DMF.

The modification of the frequencies corresponding to the vibration modes of the C—O, C—H, and O—H bonds was followed, as a consequence of the ion-ion or ion-solvent interactions that appear in the presence of the ethoxide. Also, together with the frequency shifts variations appear in the molar integral intensity and modifications of halfband width of the Raman lines. Such studies were carried out by Keçki[8,9] only in the case of methoxides.

Table 4 lists the frequencies of the Raman lines corresponding to the Li, Na, and K ethoxide solutions at the concentration of 0.1N, in pure alcohol and in mixtures with benzene and DMF.

Table 4

2960	C—H unsymmetrical stretching of methylene	2968	2958	2974	2962	2960	2960	2965	2945	2944
3001	—	3010	3000	3001 strong	3008	3001	3007 strong	3010	2989	2990 strong
3245	O—H	3244	3242	3248 strong	3264	3263	3256 strong	3243	3234	3230 strong

The presence of ethoxide in alcohol leads to a shift towards lower values of the frequency associated with C—O vibration and to the corresponding modifications of the frequencies associated with methyl and methylene C—H vibrations. It is observed that the frequency shift corresponding to the C—O vibration depends on the nature of the cation, being larger when the cation radius is smaller. This shift was assigned to an interaction with a positive charge on the bond direction, that is, to the formation of ion pairs. This fact is in agreement with the variation of the association constant obtained from the conductance data in the series of the studied ethoxides. The modification of the vibrations associated with the C—O bond leads to changes in the vibration modes of the other bonds e.g. of the C—H bond of methyl and methylene (table 4). At the same time the Raman spectra show modifications of the 3245 cm^{-1} band corresponding to the O—H bond in pure alcohol. In the case of ethoxides in pure alcohol this band does not present any great modifications in the frequency value, as an indication of the conservation and also of the intensification of interactions through hydrogen bonds in these systems. This band splits in the presence of benzene and DMF, showing a trend for O—H group frequency shift towards values corresponding to the O—H free vibration. Also, in the 3000 cm^{-1} region a strong line was observed, which is very weak in pure alcohol and increases with the increase of the ethoxide concentration. The assignment of this line to a vibration mode and the explanation of the problem will make the object of a future paper.

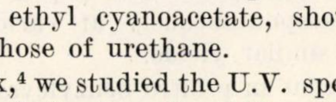
SYNTHESIS AND SPECTROPHOTOMETRIC STUDIES IN THE TRISUBSTITUTED CARBETOXYPHENYLHYDRAZONES SERIES

LUCIA BEU and JANA RUSSU
Institute of Chemical and Pharmaceutical Research
Str. Fabricii 126, Cluj, Romania

Received February, 26, 1974

Twelve trisubstituted arylhydrazones containing a nitrile group have been prepared. Their I.R. and U.V. spectra, dissociation and rate constants related to the substituent and its position in the molecule have been studied.

This report is a sequel to the studies concerning the relations between the structure and properties of the trisubstituted phenylhydrazones having the general formula :



$$\underset{\displaystyle CN}{R-C}=N-NH-C_6H_4-Z \qquad (I)$$

In the last few years it has been established that azo-, respectively hydrazo groups,[1-3] confer antineoplastic, bactericidal and antiviral properties to these derivatives and the tests performed with the substances prepared by coupling ethyl cyanoacetate, showed their antileukemic properties, similar to those of urethane.

In a previous work,[4] we studied the U.V. spectra of some compounds having the general formula I, where $R = C_6H_5$ and $Z = H$, *o*, *m*, $p-COCH_3$. We are continuing these studies in the series of derivatives having $R = C_6H_5$, $p-NO_2-C_6H_5$ or $COOC_2H_5$ and $Z = H$, *o*, *m*, $p-COOC_2H_5$.

The synthesis of these phenylhydrazones has been performed either through direct coupling of diazonium salt with a compound possessing an active methylene group (equation 1 *a*) or an active methine

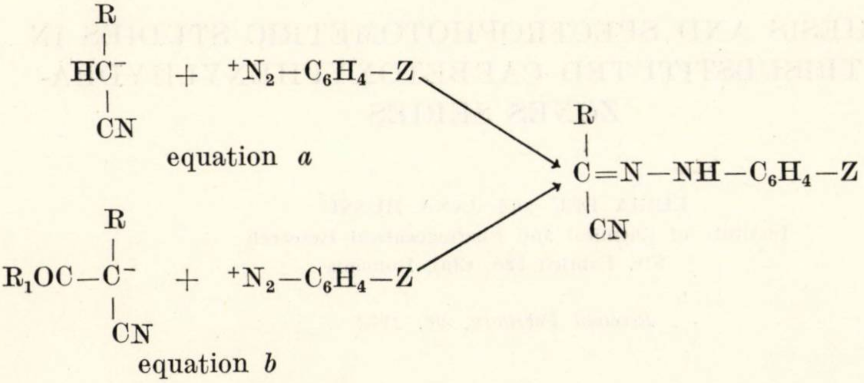
group (equation 1 *b*) :



(1)

where $R_1 = H, CH_3, C_6H_5, OC_2H_5$

R	Z	R	Z	
C_6H_5	H (I)	$C_6H_4-NO_2(p)$	$m-COOC_2H_5$	(VII)
C_6H_5	$o-COOC_2H_5$(II	$C_6H_4-NO_2(p)$	$p-COOC_2H_5$	(VIII)
C_6H_5	$m-COOC_2H_5$(III)	$COOC_2H_5$	H	(IX)
C_6H_5	$p-COOC_2H_5$(IV)	$COOC_2H_5$	$o-COOC_2H_5$	(X)
$C_6H_4-NO_2(p)$	H (V)	$COOC_2H_5$	$m-COOC_2H_5$	(XI)
$C_6H_4-NO_2(p)$	$o-COOC_2H_5$(VI)	$COOC_2H_5$	$p-COOC_2H_5$	(XII)

The results of the coupling reaction are listed in table 1.

As the reactivity of methylene in benzylcyanide is much reduced, the product cannot react directly with diazonium salts, so we have synthesized the phenylhydrazones of benzoylcyanide (I–IV) by coupling α-acyl-benzylcyanide with diazonium salts (eq. 1 *b*). Acyl splitting, i.e. decarboxylation took place spontaneously at various temperatures and pH values, giving quite similar yields.

The nitro group present in p-nitro-benzylcyanide, enhances methylene reactivity and permits a direct reaction with the diazonium salts (eq. 1 *a*) (V–VIII). The phenylhydrazones IX–XII resulted from coupling ethylcyanoacetate with diazonium salts (vide 1*a*). The need for the presence of sodium or potassium acetate, or for other basic reagents such as : pyridine, triethylamine, dicyclohexylamine, N-methyl- and N-benzyldicyclohexylamine, in these reactions, should be emphasized.

The infrared spectra of these phenylhydrazones show the following stretching vibration ν_{NH}, $\nu_{C\equiv N}$, $\nu_{C=O}$, $\nu_{C=C/arom}$ and ν_{NO_2} in the case of substances having a NO_2 substituent (table 2).

The spectra show a strong band at 3200–3280 cm^{-1}, characteristic of the NH group, confirming the hydrazo structure of these derivatives

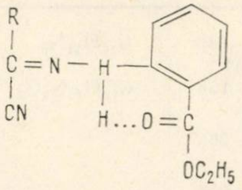
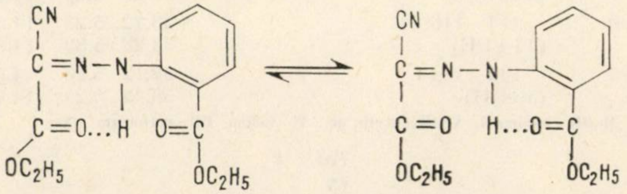
in solid state.[11-15] The shift of this band to 3140 cm^{-1} in the case of two *ortho* derivatives, II and VI, and its disappearance in the case of substance X is being explained by the marked tendency of the *ortho* derivative to give hydrogen bonds of the following type:



This fact is illustrated by the comparative I.R. spectra of *ortho*-respectively *para*-carbethoxyphenylhydrazones of benzylcyanide, shown in table 2.

The *ortho* derivative II ($Z = o-COOC_2H_5$) has, at 3140 cm^{-1}, a ν_{NH} vibration with lower intensity and wavelength and the *para* derivative IV ($Z = p - COOC_2H_5$) has a high maximum at 3200 cm^{-1}. In the case of carbethoxy derivatives II—IV and VI—VIII, R and $C \equiv N$ groups do not form hydrogen bondings. *Ortho*-derivatives having $R = COOC_2H_5$ may possibly form two kinds of internal hydrogen bondings (equation 2):



(eq. 2)

In the I.R. spectra of the *ortho* derivative X, the stretching vibration ν_{NH} is absent. The shift of the C=O band is obvious due to the presence of the hydrogen bonding, in the case when $Z = o-COOC_2H_5$, from 1720 to 1680 cm^{-1}.

The exact assignment of the C=N vibration, close to the C=O and C=C/arom., was made by synthesizing the I and V derivatives in which the C=O group is absent. These derivatives show a fairly strong stretching vibration due to the conjugated double bond of the aromatic nucleus at 1590—1600 cm^{-1}. We may, thus, consider the mean intensity band at 1615 cm^{-1} as due to the C=N stretching vibration.

This was also confirmed by studying spectra of tetrasubstituted phenylhydrazones.[16]

The ultraviolet spectra serve to confirm the hydrazone structure of these substances. The literature[8,13,14,18] attributes the band of about 350 nm to a $>C=N-NH-$ structure and that of about 450 nm to a $>CH-N=N-$ structure.

In our case the spectra in hexane, methanol and carbon-tetrachloride show two maxima at 240 nm and 360 nm which may be attributed to a $>C=N-NH-$ structure.

Table 3

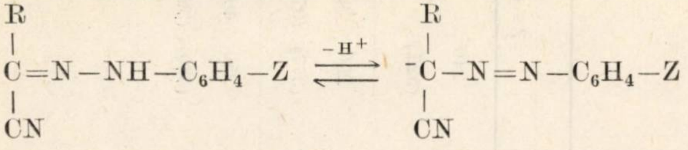
The U.V. spectra of the phenylhydrazones $R-\overset{\displaystyle CN}{\overset{|}{C}}=N-NH-C_6H_4-Z$ in methanolic solution

R	$\lambda_{max}/(E_1^1)$			
	$Z=H$	$Z=o-COOC_2H_5$	$Z=m-COOC_2H_5$	$Z=p-COOC_2H_5$
$COOC_2H_5$	240 360 (424) (1035)	250 360 (332) (862)	245 350 (384) (822)	240 350 (300) (1080)
C_6H_5	240 370 (910) (1150)	220 380 (698) (950)	230 370 (832) (790)	240 380 (587) (1300)
$C_6H_4-NO_2(p)$	245 400 (490) (1175)	230 400 (431) (838)	— 400 (960)	265 410 (492) (1160)

In these spectra the R substitution influences the 360 nm maximum. The Z substitution is being evidenced on the 240 nm maximum especially in the case of the *ortho* derivatives. The bathochromic shift in the case of the substances where $R=C_6H_5$, $Z=o-COOC_2H_5$ confirms the existence of intramolecular hydrogen bonding (eq. 2).

In the case of $Z=o-COOC_2H_5$ the derivatives having $R=C_6H_5$, or $p-NO_2-C_6H_4$, show a strong steric effect which produces a shift of the maximum from 240 nm to shorter wavelengths (220 resp. 230 nm).

The spectra in hexane, carbontetrachloride, aqueous methanol (1 :1), HCl 1 N in aqueous methanol and $HClO_4$ 1N in methanol do not show differences if compared to spectra in pure methanol. In sodium methoxide solution or in KOH in methanol-water (1 : 1) the 350–400 nm band has a bathochromic shift up to 420–520 nm corresponding to the following equilibrium :



$$\begin{array}{c} R \\ | \\ C=N-NH-C_6H_4-Z \\ | \\ CN \end{array} \underset{}{\overset{-H^+}{\rightleftharpoons}} \begin{array}{c} R \\ | \\ {}^-C-N=N-C_6H_4-Z \\ | \\ CN \end{array} \qquad \text{(eq.3)}$$

The equilibrium established very quickly and could not be studied spectrophotometrically.

Table 4

The U.V. spectra of phenylhydrazones in alkaline (KOH 1 N) methanol-water solution (1;1)

R	λ_{max} nm$(E^{1\%}_{1cm})$											
	Z=H			$Z=o-COOC_2H_5$			$Z=m-COOC_2H_5$			$Z=p-COOC_2H_5$		
$COOC_2H_5$	240		380	240		380	240		385	240		400
	(527)		(1160)	(445)		(795)	(406)		(885)	(402)		(1150)
C_6H_5	250	320	440	250		380	255	320	440	260	330	460
	(377)	(376)	(1265)	(486)		(852)	(440)	(274)	(997)	(420)	(281)	(1755)
$p-NO_2-C_6H_4$	250	400	530	250	400	530	240	400	530	260	400	530
	(380)	(380)	(1325)	(266)	(284)	(907)	(440)	(309)	(1130)	(301)	(354)	(1190)

The $C_6H_5-\overset{\overset{\textstyle CN}{|}}{C}=N-NH-C_6H_4-NO_2(p)$ derivative has been synthesized to prove the azo structure in alkaline media. Its spectrum in alkaline medium was compared with that of the $R=p-NO_2-C_6H_4$, $Z=H$ derivative (fig. 1). It may be seen that the intensity of the 540 nm band shows higher increases when $Z=p-NO_2$ than when $R=p-NO_2-$ $-C_6H_4$, thus confirming the $\rangle CH-N=N-$ structure in this case.

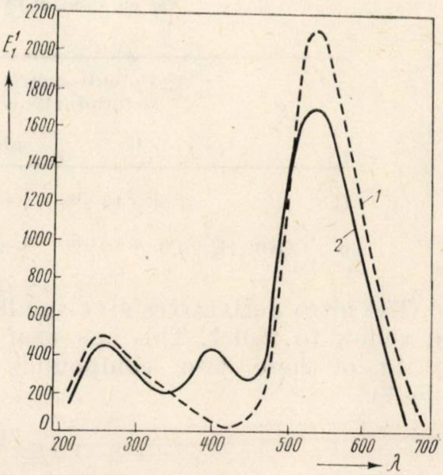

Fig. 1. — The U.V. spectra of phenylhydrazones in aqueous methanolic solution (1 :1) 1 N.

1 $C_6H_5-\overset{\overset{\textstyle CN}{|}}{C^-}-N=N-C_6H_4-NO_2(p)$;

2 $(p)NO_2-C_6H_4-\underset{\underset{\textstyle CN}{|}}{C^-}-N=N-C_6H_5$

The dissociation constants of the studied derivatives depend upon the **R** substitution (table 5). The acidity of these substances descreases in the order $R=COOC_2H_5$, $p-NO_2-C_6H_4$, C_6H_5.

Table 5

pK values of the phenylhydrazones $\overset{\overset{\textstyle R}{|}}{\underset{\underset{\textstyle CN}{|}}{C}}=N-NH-C_6H_4\,Z$ spectrophotometric determinations

R	*Z=H*		$Z=o-COOC_2H_5$		$Z=m-COOC_2H_5$		$Z=p-COOC_2H_5$	
	K	pH	K	pK	K	pK	K	pK
$-COOC_2H_5$	$1.94.10^{-10}$	9.71	$5.44.10^{-11}$	10.26	$8.95.10^{-10}$	9.04	$5.08.10^{-10}$	9.25
$C_6H_4NO_2$ (p)	$2.00.10^{-11}$	10.70	$1.34.10^{-12}$	11.87	$3.40.10^{-11}$	10.47	$3.55.10^{-11}$	10.26
$-C_6H_5$	$1.50.10^{-13}$	12.72	$5.90.10^{-14}$	13.23	$4.65.10^{-13}$	12.34	$3.10.10^{-12}$	11.51

As regards the substitution, the *ortho* derivatives are the weakest acids in each series, the unsubstituted and *p*-substituted derivatives having very similar acidities in each series. The values of the dissociation constants, vary in the same order for the *Z* = *ortho*, *metha*, and *para* substitution, irrespective of the *R* substitution.

The spectrophotometrically obtained dissociation constants were verified in the case of the two derivatives which have $R=COOC_2H_5$. The data obtained by means of a potentiometric titration are very similar to spectroscopic ones.

Table 6

The pK values of

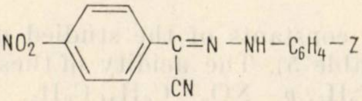
$$\begin{array}{c}CN-C=N-NH-C_6H_4-Z\\ | \\ COOC_2H_5\end{array}$$

Z	Potentiometric determinations		Spectrophotometric determinations	
	K	pK	K	pK
H	1.58×10^{-10}	9.80	1.94×10^{-10}	9.71
$p-COOC_2H_5$	4.36×10^{-10}	9.36	5.08×10^{-10}	9.29

The nitro derivatives give in alkaline solution a sharp colour change from yellow to violet. This has enabled us to determine the dissociation constant of these two compounds by spectrophotometric titration (table 7).

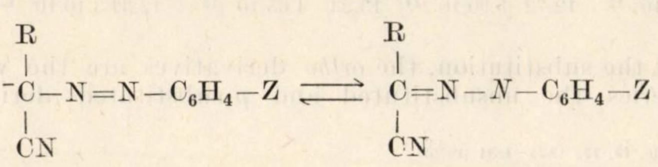
Table 7

The pK values of



Z	Colorimetric determinations		Spectrophotometric determinations	
H	K	pK	K	pK
H	1.5×10^{-11}	10.59	2.00×10^{-11}	10.70
$COOC_2H_5$	3.46×10^{-11}	10.46	3.40×10^{-11}	10.47

The phenylhydrazones studied show, as in the previously studied cases, a decrease of the 400–530 nm maximum in alkaline media. The reaction is independent of the KOH concentration and takes place also in the absence of oxygen. Simultaneously, an increase of the 350–400 nm maximum has been observed (eq. 4), suggesting a monomolecular transition of the chromophore :

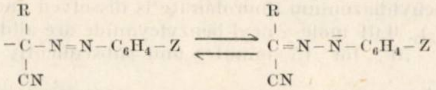


$$\begin{array}{l}R\\ |\\ {}^{-}C-N=N-C_6H_4-Z\\ |\\ CN\end{array} \rightleftarrows \begin{array}{l}R\\ |\\ C=N-\mathit{N}-C_6H_4-Z\\ |\\ CN\end{array} \qquad \text{(eq. 4)}$$

The rate constants are given in table 8. The transition is reversible, acid treating of the solution restores the initial spectra in acid solution.

Table 8

Variation of phenylhydrazones rate constants relative to R and Z substitution



$$-\overset{R}{\underset{CN}{C}}-N=N-C_6H_4-Z \rightleftarrows \overset{R}{\underset{CN}{C}}=N-\bar{N}-C_6H_4-Z$$

R	Z=H	Z=o−COOC$_2$H$_5$	Z=m−COOC$_2$H$_5$	Z=p−COOC$_2$H$_5$
	k sec.$^{-1}$			
COOC$_2$H$_5$	7.20×10^{-7}	4.86×10^{-6}	6.96×10^{-7}	2.06×10^{-6}
C$_6$H$_5$	3.63×10^{-5}	5.25×10^{-5}	7.94×10^{-5}	4.57×10^{-6}
C$_6$H$_4$ NO$_2$(p)	1.37×10^{-6}	2.00×10^{-4}	6.80×10^{-6}	1.88×10^{-6}

In conclusion, the new phenylhydrazones prepared by us have a hydrazonic structure in solid form and in organic solvents or aqueous-organic solvents, as confirmed by I.R. and U.V. spectra. The anionic form which exists in alkaline solution undergoes reversible isomerization. These reactions largely depend upon R substitution as against Z substitution.

EXPERIMENTAL

Melting points are uncorrected.

Infrared spectra were recorded in KBr pellets with a Carl Zeiss UR−10 spectrophotometer. The U.V. spectra were determined with a Carl Zeiss VSU−1 spectrophotometer, with 1 cm quartz cells. The concentration of phenylhydrazones was $0.5-2\times10^{-1}$ M/1. The solutions were prepared in methanol, hexane, carbontetrachloride, methanol-H$_2$O 1 :1, 0.1 N sodium-methoxide, 0.1 N methanolic HClO$_4$ and methanolic aqueous solution (1 :1) of KOH or HCl 0.05 1 N. The dissociation constants were determined at 25° and the rate constants at 20°. The extinctions were determined at every 2 nm. The ionic strength reached 0.1 with KCl. The values of the dissociation constants were corrected to 0 time, when necessary.

The potentiometric pK values were determined with a MV 11 type pH-meter, with a glass electrode and a SKE, titrated with a methanolic water solution (1 :1) of KOH 0.1 N. The end point was sufficiently clear to permit pK determination. The temperature was maintained at 25±1°.

Colorimetric pK determinations were made by first establishing the end point approximately; subsequently more accurate determinations were made at constant ionic strength and temperature.

SYNTHESIS OF PHENYLHYDRAZONES

Method A. 0.01 mole of derivative possessing an active methine or methylene group are suspended in 10 ml AcOH and 5 ml B (OCH$_3$)$_3$ are added. The solution is cooled to 0° and 0.01 mole of Z-phenyldiazonium fluoroborate is added under stirring. After 10 minutes 5 g AcONa dissolved in 10 ml AcOH are added. The reaction mixture is kept under stirring for 3 hours, then poured over 300 ml water. The precipitate formed is filtered off, washed with water and dried at room temperature.

Method B. 0.01 mole of Z-phenyldiazonium fluoroborate is suspended in the cold in 20 ml methanol and 3 ml $B(OCH_3)_3$. To this mixture, 0.01 mole derivative possessing an active methine is added under stirring. After 2 hours the reaction mixture is diluted with 200 ml water, and subsequently the precipitate formed is filtered off.

Method C. 0.01 mole Z-phenyldiazonium fluoroborate is dissolved under gentle heating in 20ml AcOH and 10 ml $N(OCH_3)_3$. 0.01 mole α-acyl-benzylcyanide are added, and the reaction mixture is maintained at 60–70°, for 15 minutes and subsequently the precipitate formed is filtered off.

Method D. 0.01 mole Z-phenyldiazonium fluoroborate and 0.01 mole of derivative possessing an active methine group, are dissolved in 20 ml AcOH at 50–60°. A spontaneous precipitation occurs. An hour later the mixture is diluted with 500 ml water and filtered off.

Method E. 0.01 mole Z-phenylamine are dissolved in 25 ml AcOH and 2.5 ml HCl and are diazoted at 0° with 1.2 ml butylnitrite. This solution is poured into a solution containing 0.01 mole derivative possessing an active methine or methylene group dissolved in 20 ml AcOH and 5 ml $B(OCH_3)_3$. 3 g AcOK dissolved in 15 ml AcOH are added under continuous stirring. After an interval of 24 hours the mixture is diluted with 400 ml water and the precipitate filtered off.

Method F. 0.01 mole Z-phenylamine are dissolved in a mixture of 25 ml AcOH and 2.5 ml HCl and diazotized at 0° with 2 ml solution containing 0.9 g $NaNO_2$. After 20 minutes the mixture is treated with 5 ml $B(OCH_3)_3$. 0.01 mole derivative possessing an active methine or methylene group and 2.5 g AcONa are dissolved in 10 ml AcOH. After 3 hours the mixture is poured into water and the precipitate formed is filtered off.

Method G. 0.01 mole Z-phenylamine. HCl is dissolved in 20 ml AcOH and 2 ml $HClO_4$ 70% and diazotized in the cold with 1.2 ml butylnitrite. To this solution, 0.01 moles p-nitrobenzylcyanide is being added under stirring. After 30 minutes 2.5 g AcONa dissolved in 10 ml of water are added. Two hours later the reaction mixture is diluted with 300 ml water and the precipitate formed is filtered off after another 3 hours.

Method H. To 2 ml phenylcyanoacetate 7.6 ml ethanolic KOH 8% are added. The mixture is cooled at 0° and 0.01 mole Z-phenyldiazoniumfluoroborate are added. After 2 hours the mixture is poured into 400 ml water and the precipitate formed is filtered off.

The products are recrystallized from the solvents indicated in table 1.

Revue Roumaine de Chimie, 19, *11*, 1835–1836

COMPTE RENDU

C. LITEANU and S. GOCAN, "Gradient Liquid Chromatography" Ellis Horwood Ltd., Chichester, 1974, 338 p.

This book was issued in the analytical chemistry series published by Dr. R. A. Chalmers and is intended for the chemists who work in research laboratories and in industry and also for the students in the upper classes. It has many fields of application, as it refers not only to chemistry, but also to biology, metallurgy, agriculture, mining, pharmacy, food industry, environmental control, sanitary control etc.

Its contents are divided into two main parts: the fundamental problems of chromatography (Part I) and the use of gradients (Part II).

Chapter 1, under the title: "Kinetics of Eluent Migration", has a theoretical character and includes open-column kinetics (ascending, descending and horizontal chromatography) and closed-column kinetics. It also discusses the non-uniform distribution of single-component and multicomponent eluents.

The kinetics of zone migration are described in Chapter 2. The problems debated are: migration rate in open chromatographic columns (isothermal chromatography and temperature-gradient chromatography) as well as relative migration rate of the zone.

The factors which influence the reproducibility of R_f values are discussed in Chapter 3. Thus, the factors determined by the composition of the stationary phase, by the composition of the mobile phase and by the medium are taken into consideration. Thence ensue the working conditions for achieving a reproducibility of R_f values both with paper and thin-layer chromatography.

The highly important problem of the estimation of separation efficiency is described in Chapter 4. Both the closed and the open chromatographic columns were taken into account in this case, too. A clear definition of the basic parameters (HEPT — the height equivalent to a theoretical plate, N — the number of theoretical plates of a chromatographic column etc.) is followed by a description of the possibilities of determining experimentally the separation efficiency.

This chapter also includes a discussion on chromatographic selectivity. After defining the fundamentel constants, the selectivity coefficient and the separation factor, they are correlated to the R_f values and examined from the viewpoint of practical results.

Resolution and the parameters of resolution both closed-column and open-column ones, are then defined.

In Chapter 5 the authors discuss the optimization of the chromatographic process, taking into account all the factors which influence separation. The chapter is divided in terms of the nature of the process. Thus, in the case of adsorption and partition chromatography in closed columns the following factors are taken into consideration: the dimensions of the column, the nature of the adsorption agent, the flow rate and viscosity of the eluent, the structure of the bed, as well as temperature, pressure and time. The next to be discussed are the ion-exchange chromatography and the partition and adsorption chromatography in open columns (choice of the mobile and stationary phase, pH, humidity, temperature).

Part II refers to the use of gradients and opens with an introduction (Chapter 6) offering a short history of gradient chromatography, the classification of gradients and their nomenclature.

Chapter 7 deals with the mobile-phase gradients. The appliances for obtaining such gradients are described first. Thus, as far as the closed columns are concerned, the information offered involves the discontinuous elution gradients, the concave and convex exponential gradients, the linear gradient, the concave and convex parabolic gradients, the composite gradients. A description of the methods for obtaining gradients with paper and thin-layer chromatography is also included.

The next section of this chapter (7.2) is of particular importance as it goes deeply into the theory of mobile-phase gradient chromatography. Following the same sequence, the closed columns are discussed first, as regards the calculation of the position of the peak and resolution and open columns next.

The last part of Chapter 7 refers to the use of mobile-phase gradients in the separation of substances (organic acids, carbohydrates, aromatic hydrocarbons, amino acids, proteins, lipids, nucleic acids, steroids, antibiotics, inorganic ions).

The stationary-phase gradients are comprised in Chapter 8, which offers a description of appliances (for discontinuous and continuous gradient), resolution and the applications of composition, impregnation, activity and pH gradients.

The environmental gradients (temperature, vapour, section and flow velocity) are discussed in Chapter 9, which describes the appliances for various cases (parallel, antiparallel and orthogonal gradient), the variation in R_f, resolution and a comparison between the parallel temperature gradient technique and other chromatographic techniques.

The last chapter (10) includes a description of combined gradients : mobile-phase and temperature, combined mobile-phase.

Three annexes are appended.

Each chapter is provided with figures and auxiliary graphs, which illustrate with the utmost clarity both the practical and the theoretical part. Moreover, each chapter comprises exhaustive references, judiciously selected according to the theoretical and practical value of the works.

The clear, concise and consistent style is to a great extent a help in assimilating the content and in rendering it profitable. The excellent graphic conditions deserve special mention.

This book, written by two remarkable researchers in the field of gradient chromatography is of the highest topical interest. It distinguishes itself by its high theoretical level and by its practical utility. The readers have the possibility of going thorougly into the theory, modelling and use of the calculations for the forectasting and optimization of separations. At the same time, they are offered an efficient means for assimilating and completing various gradient chromatography techniques. By its investigating and selecting a great number of works published up to the present, this book is, at the same time, a complete monograph of the field.

NOTE POUR LES AUTEURS

La *Revue Roumaine de Chimie* publie des articles en anglais, français, russe, allemand ou espagnol. Les auteurs sont priés d'envoyer des articles, notes, communications et comptes rendus inédits.

Les manuscrits seront dactylographiés à deux intervalles. Les tableaux seront dactylographiés sur feuilles séparées, de même que la légende des figures. Les diagrammes seront tracés à l'encre de Chine sur papier calque. Les tableaux et les figures seront numérotés par des chiffres arabes, en nombre strictement nécessaire. Prière de ne pas inscrire les mêmes données dans les tableaux et les figures. Les formules chimiques seront incluses dans le texte ; en outre, elles seront transcrites sur des feuilles séparées. Les auteurs sont priés d'indiquer les caractères italiques (en soulignant les lettres au crayon), ainsi que tout autre caractère spécial. L'ordre des références bibliographiques sera celui de leur mention dans le texte ; le nom de l'auteur sera précédé de l'initiale du prénom ; les publications périodiques seront présentées suivant les prescriptions internationales. Les références seront ajoutées à la fin de l'article ; elles paraîtront comme des notes, au bas de la page. Le texte sera précédé d'un résumé comprenant 15 lignes au maximum.

L'entière responsabilité du contenu des articles appartient aux auteurs. On publie des articles dus aux collaborateurs roumains ou étrangers.

Raluca Ripan

Academician professor dr. doc. Raluca Ripan, a prominent personality of Romanian science, celebrates 55 years of highly reputed activity developed in the field of scientific research, of education and of social-cultural life.

On this occasion, the journal Revue Roumaine de Chimie pays tribute to the personality of the eminent scientist, of the dedicated teacher and of the active militant for progress.

Acad. Raluca Ripan was born in Iaşi on June 27, 1894.

She graduated from the Faculty of chemistry in the year 1919 and was appointed assistant professor at the chair of physical chemistry of the Iassy University.

In 1920 she was transferred to the University of Cluj, the chair of inorganic chemistry headed by professor Gh. Spacu. While carrying out a dedicated and untiring activity, she passed through all the hierarchical levels of higher education, holding the position of professor of inorganic chemistry in 1941.

Her rich and many-sided activity has assumed a new meaning after the country's liberation from the fascist yoke when comrade Academician Raluca Ripan became a member of the Romanian Communist Party.

The scientific activity of Acad. Raluca Ripan is comprised in a number of approximately 300 works published in Romanian and foreign journals in her field of interest. Most studies are concerned with the elucidation, the constitution and the application of complex compounds to analytical chemistry and their use in industry.

Special mention should be made of studies on iso- and heteropolycompounds. Acad. Raluca Ripan and her coworkers have made valuable contributions to this field by applying some modern techniques such as chromatography, electrochromatography, radiochromatography, spectrography, polarography and the use of radioactive isotopes.

One of Acad. Raluca Ripan's basic concerns was to link research to production, to the needs of our national economy. An example in this sense, are the studies concerning the development of some technological methods for using to great advantage some indigenous raw materials (kaolin from Arghireş, colloidal gold, etc).

For the valuable results obtained in the sphere of research she was elected member of the Academy of the Socialist Republic of Romania.

Part of the results of scientific research were presented at international chemistry congresses in Budapest, Moscow, Lisbon, Geneva, Paris, Detroit, Munich, London, Wroclaw, etc and aroused a great interest, being unanimously appreciated by participants.

An expression for the wide international recognition given to her scientific activity was the title of doctor honoris causa awarded to her by the Copernicus University from Poland.

In her capacity of professor and head of the chair of inorganic chemistry she developed an untiring activity devoted to training and guiding the young members of the staff.

By published textbooks, by well-equipped laboratories and particularly by her personal example she has trained a number of highly-qualified researchers who carry out a notable activity in the universities and laboratories of our country.

In parallel with the didactic and scientific activity, Acad. Raluca Ripan has also developed a rich managing and political-public activity.

As a Dean of the Faculty of Chemistry, Rector of the University, Director of the Institute of Chemistry and then President of the Cluj Branch of the Academy of the Socialist Republic of Romania, her main concern was to assure to students, teaching staff and researchers the best possible conditions for study and for work.

As a deputy in the People's Council of the Cluj-Napoca town, chairman of the Committee for Culture and Art of the Cluj district, deputy in the Great National Assembly, member of the Presidium of the Great National Assembly, she has fully manifested all her potentialities as a real revolutionary scientific worker in the political life of our country, making an active contribution to the building of socialism in our country.

Acad. Raluca Ripan's remarkable scientific and political-public activity was honoured by orders, titles and medals. She is a State Prize laureate and has been awarded the following titles: hero of socialist work and emeritus scientist; she has also been granted the orders Star of the Socialist Republic of Romania, Ist class, and 23 August, Ist class. In 1959, the World Peace Council conferred on her a diploma of honour.

The whole activity developed by Acad. Raluca Ripan is an example of commitment to the noble mission of a teacher and of a scientist who has devoted all her efforts to the advancement of education and of science in our country.

RALUCA RIPAN
on the occasion of her 80th anniversary

PYROLYSIS AND OXIDATIVE PYROLYSIS OF ISOBUTENE. I

I. G. MURGULESCU and I. BICĂ
Institute of Physical Chemistry
Str. Galaţi, 31 – Bucharest, Romania

Received October 10, 1974

A comparative kinetic study of the pyrolysis and the oxidative pyrolysis of isobutene has been performed at an atmospheric pressure and over a 500–600° temperature range. The primary products have been determined as well as the influence of the reaction time and of the isobutene/oxygen ratio on the distribution of products. The addition of small oxygen amounts to the pyrolysis reaction does not modify the isobutene order yet it causes a marked decrease of the activation energy.

INTRODUCTION

Pyrolysis of isobutene has formed the subject of a number of studies, [1-3] which have focused on the mechanism of this reaction.

By introducing various substances in the reactant medium it was possible to draw valuable conclusions concerning the role of additives and of various radicals in the pyrolysis reaction.[4,5]

Letort [6] has shown that a part of the oxygen at 100,000 doubles the initial decomposition rate of acetaldehyde at 477°.

Neiman *et al* [7] have found that the decomposition of n-butene is sensitized by addition of small amounts of oxygen. Subsequently, other researchers have also confirmed that oxygen traces accelerate the initial pyrolysis rate of n-butane and of other hydrocarbons.[8-12]

[12] G. SCACCHI, Thèse de doctorat in sciences physique, Nancy, 1969.

However, little attention was paid to the role played by O_2 in the pyrolysis of olefines. Mention must be made of the work of Bradley *et al.*[13] which has been concerned with the pyrolysis of propene in the presence of O_2 in a strongly argon-diluted medium.

The present paper is an attempt to find out whether oxygen traces manifest a similar action in the case of olefines as well. To do this, we made a comparative study of the pyrolysis and of the oxidative pyrolysis of isobutene.

EXPERIMENTAL

INSTALLATION

The installation used is schematically illustrated in Fig. 1. The cylindrical-shaped reactor (Fig. 2) with an inner diameter of 1 cm and a volume of 5.1 cm^3 was made up of quartz.

The reduction of the exit pressure of feeding gases and the adjustment and measuring of their flows were made by means of pressure reducers, gas taps and flowmeters (Fig. 1).

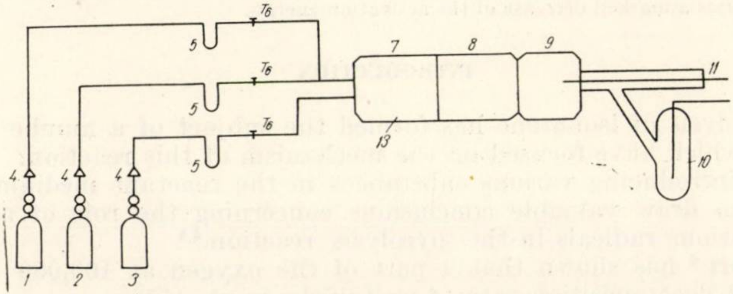

Fig. 1. — Schematic representation of the installation.

1, isobutene ; *2*, oxygen ; *3*, argon ; *4*, control valves for gas discharge ; *5*, flowmeter ; *6*, *3*-way tap ; *7*, preheater ; *8*, reactor ; *9*, refrigerator ; *10*, trapping vessel for liquid products ; *11*, Cr-Al thermocouple.

The temperature of the furnace was kept constant by using a voltage stabilizer, a transformer and a thermoregulator connected to the furnace by means of a Pt-Rh-Pt thermocouple. It was thus possible to maintain the desired temperature in the reactor.

SUBSTANCES

Oxygen and isobutene of 99.9% and 99.7% purity, respectively, were used without further processing. The impurities in isobutene were methane (0.03%) propene (0.02%) 1-butene (0.2%) and 2-butene (0.09%).

The purification of argon used in the simple pyrolysis reaction was achieved by removing the oxygen content on a column with B.T.S. catalyst.

The moisture from isobutene was removed by passing the gas through a tube containing anhydrous calcium sulphate while a column of indicator silicagel was used in the case of the other gases.

Impurities from the argon used as a carrier gas in the chromatographic analysis were retained on a molecular sieve column which was periodically regenerated.

---

[13] J. N. Bradley and D. A. Durden, *Combustion and Flame*, **19**, 452 (1972).

EXPERIMENTAL PROCEDURE

Reactant gases were preheated in separate tubes and their rapid mixing in the reactor was accomplished by the axial introduction of oxygen in the isobutene current through small orifices situated on the surface of a tube whose plane was perpendicular to the axis of the reactor (Fig. 2).

To avoid subsequent reactions, when leaving the reaction zone, the mixture of products and nontransformed gases was suddenly cooled in a refrigerator fixed at the end of the reactor. This helped to eliminate complications usually resulting when large volumes of inert cooling diluent are introduced. From the refrigerator, the gases were passed into a vessel cooled to 0° for the condensation of products with higher boiling points and were then led to the chromatograph.

Two Pye chromatographs, series 104, were used for the analysis; one was equipped with a thermal conductivity cell and the other was fitted with a flame ionization detector.

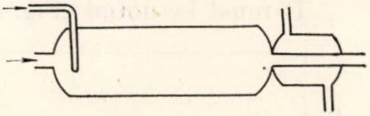

Fig. 2. — Schematic representation of the reactor.

The following columns were used :

— one formed of polyethylene glycol for the determination of carbon dioxide and of the unreacted isobutene;

— another with 5A molecular sieves for the determination of permanent gases.

A Squalan column was used for the other gases.

Tests were also made on a silicagel column and also on a dimethylsulpholan column.

The qualitative identification was made by comparing the retention times of the products under analysis with the retention times of pure compounds supposed to be present. The quantitative determination was made by using calibration curves corrected for each component in terms of certain variations recorded on the chromatograph, using iC_4H_8 as a standard.

The reaction was studied in a dynamic regime at atmospheric pressure and at temperatures ranging between 500 and 600° and the reaction time varied between 0.3 and 1.8 sec, small conversions being thus obtained.

RESULTS AND DISCUSSIONS

The main reaction products both in the case of simple pyrolysis and of oxidative pyrolysis were : methane, propene, ethylene and alene.

Apart from these products, the oxidative pyrolysis provided carbon dioxide in a proportion similar to propene and also significant amounts of water and liquid products.[14] The water was also found in the pyrolysis of butane in the presence of small amounts of oxygen.[9-11]

Carbon oxide could not be identified at the conversion obtained and with the sensitivity of the catarometer used, regardless of the working conditions. Although Bradley[13] and Blakemore[15] support the existence of carbon oxide in the pyrolysis in the presence of O_2 of propylene and of n-butane, respectively, they have failed to determine it.

On the other hand, Dechaux[16] and Knox[17] observe an increase in the CO_2 content to the detriment of CO with the increase in the hydrocarbon/oxygen ratio during the combustion of butane and of propylene, respectively.

Similarly, neither propane nor ethane were found among the products in accordance to Leftin's results.[1]

Molera and Stubbs[18] also note the absence of propane in the pyrolysis of isobutene and Rice[19, 20] obtains alene over a large domain of conversions.

By extrapolating the concentration of products to zero conversions of isobutene we find which are the primary products in the pure pyrolysis (Fig. 3) and in the oxidative pyrolysis (Fig. 4).

It must be noted (Fig. 3) that whereas methane presents a constant growth, propylene has a sensible initial growth and it becomes almost constant thereafter. It is clear that while methane is both a primary and a secondary product, propene is certainly a primary product.

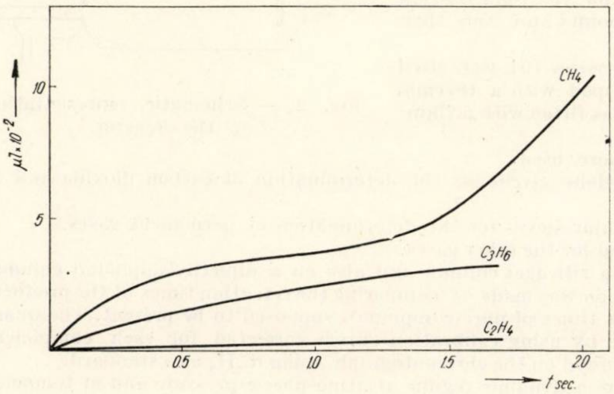

Fig. 3. — Variation of products with time in isobutene pyrolysis. $T = 500°$.

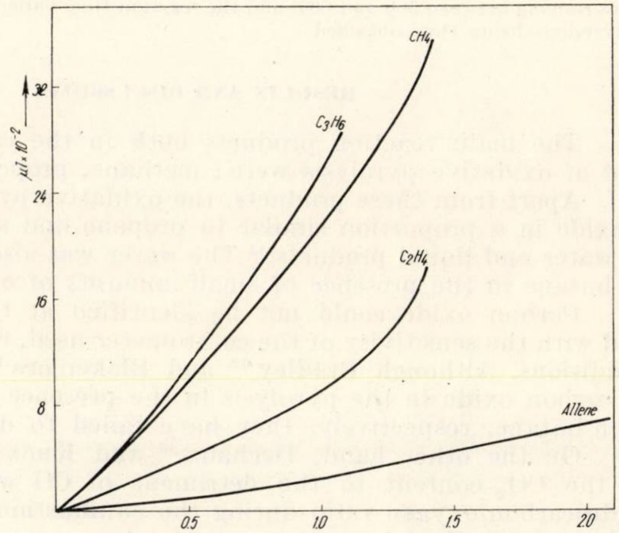

Fig. 4. — Variation of products with time in the oxidative pyrolysis of isobutene. $T = 500°$; $iC_4H_8/O_2 = 20$.

[19] F. O. Rice and W. S. Haynes, *J. Amer. Chem. Soc.*, **70**, 964 (1948).

[20] F. O. Rice and L. A. Wall, *J. Amer. Chem. Soc.*, **72**, 3967 (1950).

At the same time, although the shape of the curves in Fig. 4 is less evident, it permits however to conclude that propene and alene are only primary products whereas methane and ethylene are also secondary products.

INFLUENCE OF THE iC_4H_8/O_2 RATIO

The concentration of oxygen in the initial mixture varied between 5 and 10%. At all isobutene/oxygen ratios used during the working procedure, oxygen consumed at 500° represents merely a small part of the total oxygen present in the reactant mixture.

We observe from Figs. 5 and 6 that the distribution of cracking products in the presence or the absence of oxygen is approximately similar. For a given concentration of isobutene, the increase in the O_2 amount in the reactant mixture resulted in the increase of the amount of products (points 1′, 2′, 3′). A comparison between these data and those obtained in the simple pyrolysis, shows that oxygen has a marked increasing effect on the reaction products. At 550° the formation of methane and of ethylene

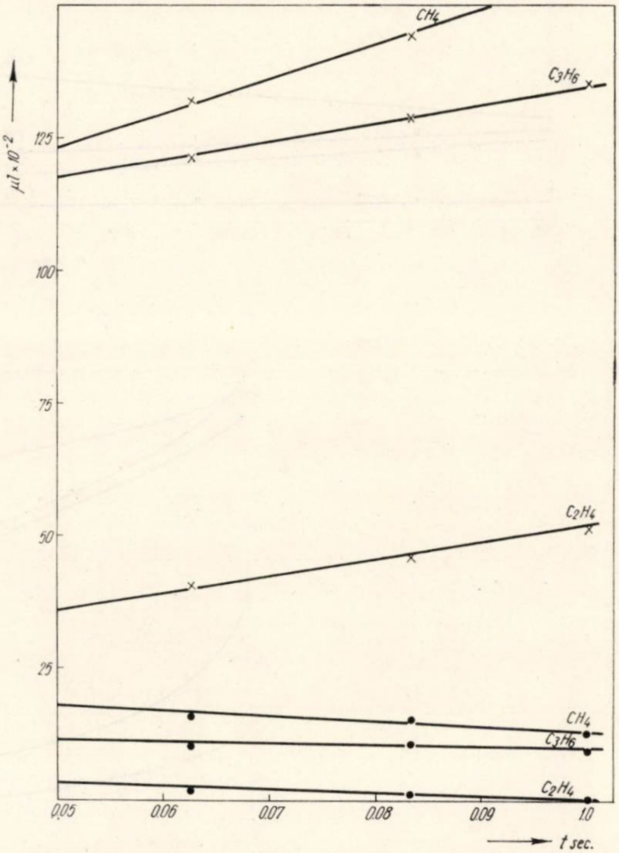

Fig. 5. — Influence of the oxygen/isobutene (X) and Ar/isobutene (.) ratio on the products. $T = 550$; $t = 1.4$ sec.

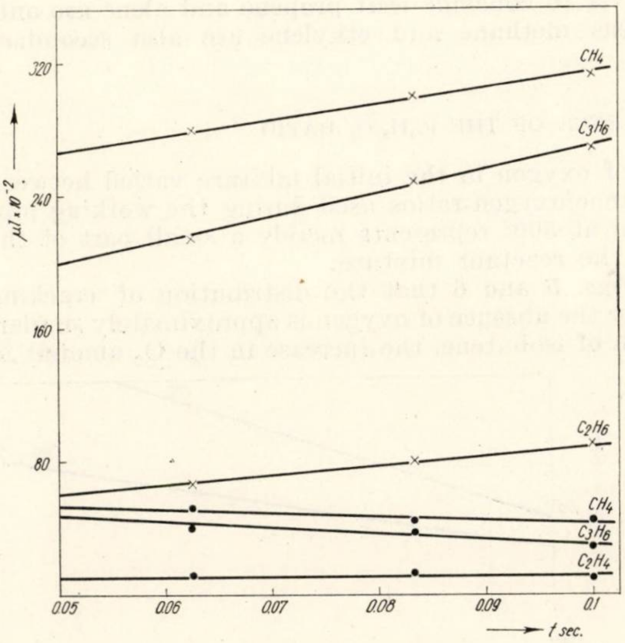

Fig. 6. — Influence of the oxygen/isobutene (x) and Ar/isobutene (.) ratio on the products. $T = 600°$; $t = 1.0$ sec.

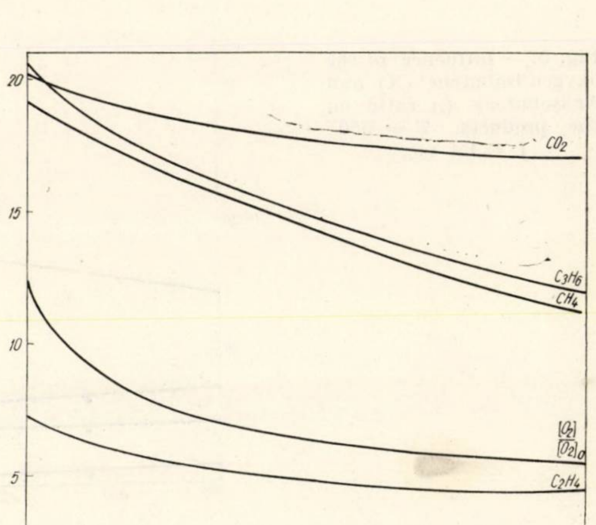

Fig. 7. — Variation of oxygen conversion and of the selectivity of the main products with the oxygen/isobutene ratio. $T = 500°$; $t_r = 0.3$ sec.

is the most strongly influenced whereas at 600° propylene is the product with the most marked increase. The substitution of O_2 by equivalent argon amounts, the other conditions remaining unchanged, leads to a slight decrease in the amount of products (points 1, 2, 3, Figs. 5 and 6).

It must be observed that the largest oxygen fraction is consumed at lower concentrations of the latter (Fig. 7). At all iC_4H_8/O_2 ratios, the propene selectivity was maintained higher than that of methane and the low O_2 concentrations favour the formation of C_3H_6 more than that of CO_2.

By increasing the oxygen concentration one observes a sensible decrease in the selectivity of all products, the strongest variation being found with C_3H_6 and CH_4. This proves that since oxygen participates in the reaction with various radicals, it largely hinders those leading to the formation of methane and of propylene. The carbon dioxide presents a more pronounced decrease at low oxygen concentrations, tending to become independent of it thereafter.

INFLUENCE OF TEMPERATURE AND OF THE REACTIONN TIME

Fig. 8 illustrates the variation with temperature of the main products resulting from the simple pyrolysis (1, 2, 3, 4) and from the oxidative pyrolysis (1, 2, 3, 4). One observes a strong effect of the temperature increase on the products and in particular on those resulting from the oxidative pyrolysis. It can be noted that the reaction products are more sensitive to temperature variations than to the change in the hydrocarbon/oxygen ratio, at the used oxygen concentrations. The ethylene behaviour is worth noticing, as it presents in both cases less sensible growths.

Nevertheless we think that the influence of the reaction time on the amount of the main reaction products is edifying (Figs. 9—11). In the oxidative pyrolysis, methane, propene and ethylene (dotted curves) have a pronounced growth tendency with the increase in the reaction time. Yet in the case of pure pyrolysis, while methane and propylene present monotonous growths with the increase of the reaction time, ethylene tends rather to decrease.

A plot of the variation in the selectivity of products with the reaction time (Fig. 12) in the oxidative pyrolysis shows that short reaction times are more favourable to the formation of such products.

KINETICS OF THE PROCESS

Two sets of experiments were carried out for the determination of reaction orders. The procedure applied in the first set involved various iC_4H_8/O_2 ratios and the initial rates were measured from plots of oxygen concentration at various reaction times (Fig. 13). The total order was determined from plots of the slopes of lines log V versus log O_2 (Fig. 14).

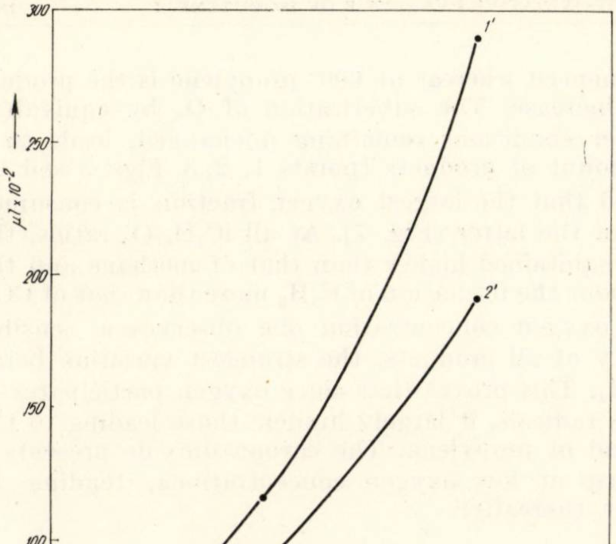

Fig. 8. — Distribution of products as a function of temperature. *1—1'*, CH_4 ; *2—2'*, C_3H_6 ; *3—3'*, C_2H_4 ; $iC_4H_8/O_2 = 20$; $t_r = 1.0$ sec.

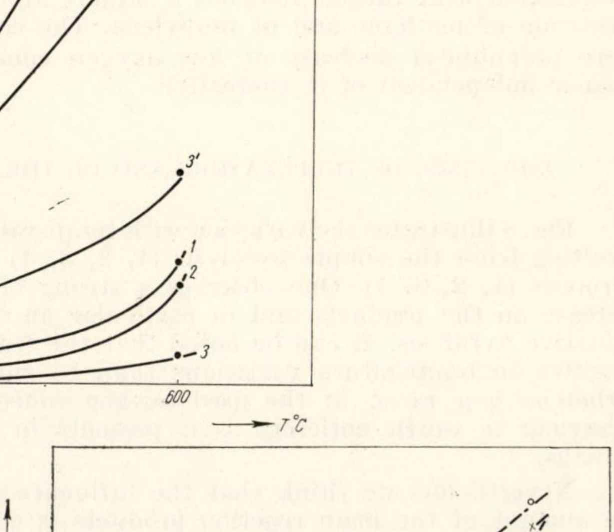

Fig. 9. — Methane distribution as a function of time. $T = 550°$; $iC_4H_8/O_2 = 20$ ($\times = 16$; ○ $= 12$) ; iC_4H_8/Ar (● $= 20$; $\times = 16$; ○ $= 12$).

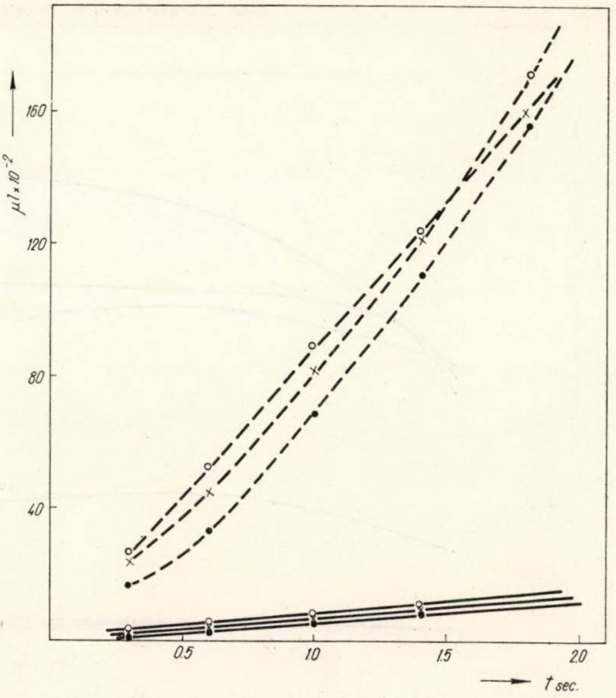

Fig. 10. — Propylene distribution as a function of time. $T = 550°$; iC_4H_8/O_2 (◉ =20 ; × =16 ; ○=12) ; iC_4H_3/Ar (● = 20 ; × =16 ; ○ = 12).

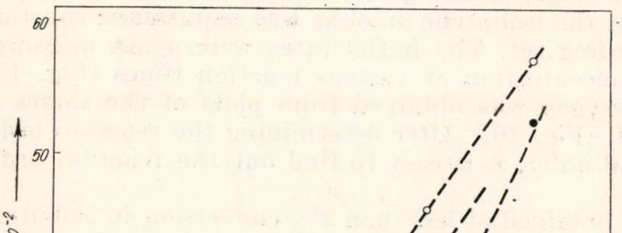

Fig. 11. — Ethylene distribution as a function of time. $T = 550°$; iC_4H_8/O_2 (● =20 ; × =16 ; ○=12) ; iC_4H_8/Ar (● =20 ; × = 16 ; ○ = 12).

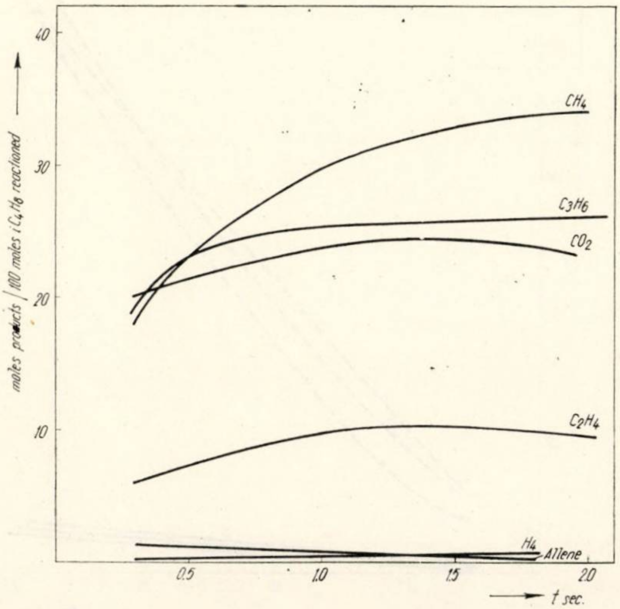

Fig. 12. — Variation of products selectivity with time in the oxidative pyrolysis. $T = 500°$; $iC_4H_4/O_2 = 20$.

The second set of experiments also involved various $i\text{-}C_4H_2/O_2$ ratios in which, however, the isobutene amount was maintained constant in contrast to the preceding set. The initial rates were again measured from plots of oxygen concentration at various reaction times (Fig. 15). The reaction order in oxygen was obtained from plots of the slopes of lines log V versus log O_2 (Fig. 16). After determining the reaction order of O_2 as well as the total order, it is easy to find out the reaction order in isobutene.

All the values were obtained at less than 2% conversion in isobutene and were therefore real measurements of reaction rates.

Experimental data indicate the value 1 of the reaction order both for oxygen and for isobutene and the rate differential equation assumes the form

$$\frac{d\,[O_2]}{dt} = K\,[iC_4H_8]\,[O_2].$$

A number of researchers [1, 2, 19] have also obtained a reaction order 1 in isobutene in the case of a simple pyrolysis of this hydrocarbon.

On the other hand, as in the case of the reaction studied by us, Appleby [9] and Scacchi [12] have found that the reaction order in butane and ethane remains the same regardless whether the pyrolysis of the respective hydrocarbons takes place in the presence or in the absence of oxygen.

The integrated form of equation (1) in our case, i.e. for an isobutene concentration much higher than that of oxygen [21] is the following :

$$\ln \frac{1}{\alpha} = K\,[iC_4H_8]_0\,(t - t_0)$$

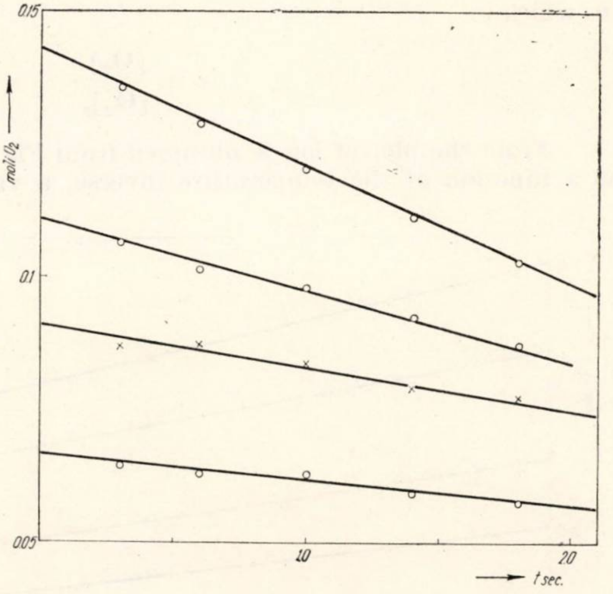
Fig. 13. – Variation of oxygen concentration with time. $T = 500°C$.



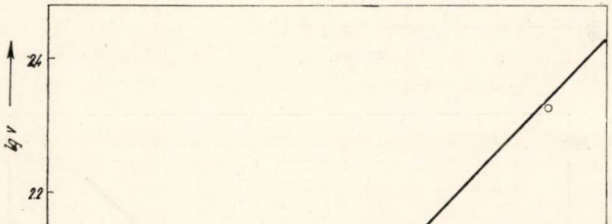


Fig. 14. – Plot of log V versus log $[O_2]_0$.

in which

$$\alpha = \frac{[O_2]}{[O_2]_0}.$$

From the plot of log K obtained from Fig. 16 and from formula (2) as a function of the temperature inverse, a value of 24.9 kcal/mol was determined for the activation energy (Fig. 17) of the oxidative pyrolysis reaction. This value is much smaller compared to the value of the activation energy for the simple pyrolysis reaction, [2,18] of 48 kcal/mol in

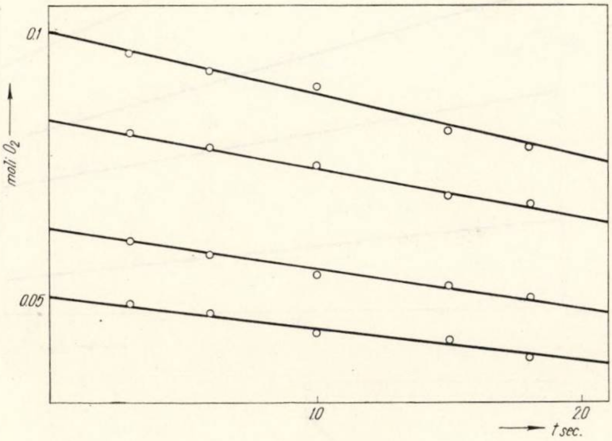

Fig. 15. — Variation of oxygen concentration with time.

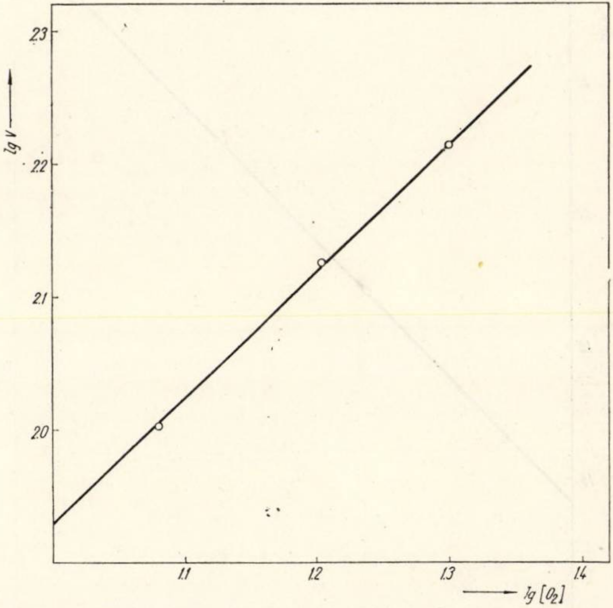

Fig. 16. -- Plot of log V versus log $[O_2]_0$.

the range 542—600° and 53.3 in the range 580° and is in agreement with the existence of an initiation stage in addition to that produced by pyrolysis in the absence of oxygen, with a lower activation energy.

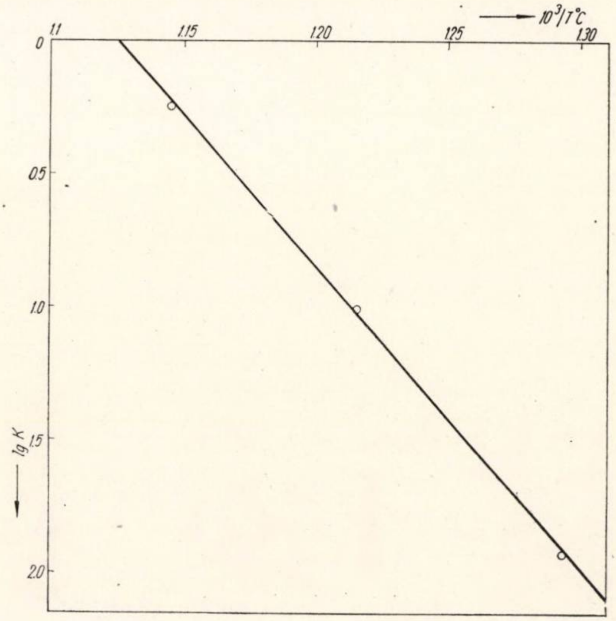

Fig. 17. — Arrhenius plot

It results that oxygen addition causes a lowering of the activation energy of the pyrolysis reaction, a fact also observed by Hausmann [22] in the pyrolysis of ethylbenzene in the presence of oxygen, where he obtains a value of 70 kcal/mol for the activation energy of the simple pyrolysis and 48.5 kcal/mol for that of pyrolysis in the presence of oxygen.

Similarly, in the pyrolysis of n-butane in the presence of oxygen, Appleby [9] obtains a very low value of the activation energy (21 kcal/mol) compared to the values necessary for the activation of the simple pyrolysis reaction of this hydrocarbon, values that vary between 61.4 and 73.9 kcal/mol.

UN NOUVEAU RÉACTIF DU TYPE EDTA

CONST. GH. MACAROVICI et EUGEN CHIŞ
Faculté de Chimie, Université « Babeş-Bolyai », Cluj,
Faculté de Physique et Chimie, Université de Braşov

Reçu le 16 mars 1974

On a synthétisé l'acide 4,4'-diaminodiphénylméthane-N,N'-diacétique et son sel de sodium. On en a établi la composition et la structure par analyse chimique, titrage potentiométrique, conductométrique, analyse thermogravimétrique et le spectre en infrarouge (formule II). Le sel de sodium respectif se comporte tout comme un ligand tétradenté à possibilités d'utilisation en chimie analytique.

Depuis l'apparition du réactif complexométrique EDTA proposé par Schwarzenbach et Ackermann [1] on a manifesté un intérêt particulier pour obtenir des substances aminopolycarboxyliques comme réactifs plus sensibles, plus sélectifs ou plus spécifiques pour différents ions métalliques. Actuellement on connaît tout une série de ce type de substances ayant à la base différentes amines aliphatiques ou aromatiques.

Dans le présent ouvrage nous nous sommes proposé d'obtenir un réactif similaire à partir du 4,4'-diaminodiphénylméthane, d'en étudier la structure, les propriétés et les éventuelles applications en chimie analytique.

PARTIE EXPÉRIMENTALE

On a synthétisé la substance de base, c'est-à-dire le 4,4'-diaminodiphénylméthane à partir des données de la littérature[2], au point de fusion 92–93°.

Pour la synthèse de l'acide 4,4'-diaminodiphénylméthane-N, N'-diacétique, non signalé encore dans la littérature de spécialité, plusieurs variantes ont été essayées.

Selon l'une des variantes (a), une solution formée de 48 g (0,5 moles) d'acide monochloracétique en 200 ml eau distillée se neutralise le plus exactement possible, à froid (au-dessous de 10°) par NaOH *n* en présence de phénolphtaléine. Cette solution est ajoutée progressivement et sous agitation continue à une suspension en 200 ml eau distillée de 49 g (0,25 moles) de 4,4' diaminodiphénylméthane ; on réchauffe progressivement de 30 à 70° au bain-marie. Par la suite de cette réaction qui a lieu au niveau des groupes $-NH_2$ et de l'abaissement du pH, grâce aux ions H^+ libérés, à commencer aux environs du pH = 5, l'acide libre, 4,4'-diaminodiphénylméthane-N,N'-diacétique se sépare. Au bout d'environ une heure on ajoute encore, sous agitation continue, un excès (environ 20%) de solution chaude (30—40°) d'acide monochloracétique neutralisé. On continue de réchauffer tout le mélange, sous agitation continue, à 70—80°, pendant encore 1—2 heures, après quoi on le laisse refroidir. On filtre et on lave à l'eau distillée (30—40°) jusqu'à l'élimination de l'ion Cl—. On continue le lavage à l'eau et alcool éthylique (de préférence) mélangés en proportions égales, afin d'éliminer les petites quantités de base qui éventuellement n'ont pas entièrement réagi.

---

[1] G. Schwarzenbach et A. Ackermann, *Helv. Chim. Acta*, **30**, 1798 (1948).

[2] H. Rivier et A. Marne, *Helv. Chim. Acta*, **12**, 865 (1947).

Selon une autre variante (b) les réactants pris dans les proportions mentionnées ci-dessus sont réchauffés progressivement et sous agitation continue à une température modérée de 55—60° jusqu'à ce que l'acide libre commence à se séparer. On refroidit jusqu'à 30° et on ajoute goutte à goutte et sous agitation continue NaOH *n* jusqu'à la dissolution de l'acide, respectivement jusqu'à la réalisation du pH 8—9. On continue de réchauffer à 45—50° en ajoutant goutte à goutte du NaOH, lorsqu'on remarque l'abaissement du pH au-dessous de 8. La réaction est considérée finie approximativement après l'addition d'une quantité de NaOH équivalente à celle de l'acide chlorhydrique mis en liberté par la réaction, respectivement alors que pendant 1—2 heures on ne remarque plus de baisse du pH au-dessous de 8. La solution contient le sel de sodium de l'acide 4,4'-diaminodiphénylméthane-N,N'-diacétique. Après filtrage, pour écarter les impuretés résineuses habituellement formées en petite quantité, la solution du sel de sodium est diluée d'une volume approximativement double d'eau distillée et on y ajoute goutte à goutte, sous agitation lente du HCl *n*. A mesure que le pH de la solution baisse, à environ 4,5—5 commence la séparation de l'acide libre, de couleur blanc-jaune. Lorsqu'on parvient au pH 3—3,5 on laisse le tout en repos pendant quelques heures. On filtre et on procède par la suite tout comme au cas de la variante (a) ci-dessus. Des données analytiques (tableau 1) on déduit la formule brute $C_{17}H_{18}O_4N_2$ à masse moléculaire 314,35, confirmée par la méthode Rast (en camphre).

Tableau 1

Données de l'analyse élémentaire

Substance		C %	H %	N %	Na %
$C_{17}H_{18}O_4N_2$	calculé :	64,95	5,73	8,91	—
$C_{17}H_{18}O_4N_2$ variante a	trouvé :	65,00	5,96	9,19	—
$C_{17}H_{18}O_4N_2$ variante b	trouvé :	64,61	5,88	8,50	—
$C_{17}H_{16}O_4N_2Na_2$	calculé :	56,98	4,50	7,82	12,83
$C_{17}H_{16}O_4N_2Na_2$	trouvé :	57,15	5,06	8,09	12,62

La synthèse de l'acide 4,4'-diaminodiphénylméthane-N,N'-diacétique peut également être réalisée en utilisant à la place de l'acide monochloracétique, l'acide monobromacétique ou monoiodacétique. Avec ces réactifs la vitesse de réaction est visiblement plus grande même à 45—50°. Les réactions qui ont lieu peuvent être représentées schématiquement de la manière suivante :

$$\underset{\text{I}}{H_2N-C_6H_4-CH_2-C_6H_4-NH_2} + 2ClCH_2-COOH \longrightarrow$$

$$\longrightarrow \underset{\text{II}}{HOOC-CH_2-NH-C_6H_4-CH_2-C_6H_4-NH-CH_2-COOH} + 2HCl$$

Le point de fusion de l'acide libre est compris entre 180—185°. Il est pratiquement insoluble dans l'eau froide, éther éthylique, benzène, toluène, tétrachlorure de carbone, chloréthane, sulfure de carbone, acétone, dioxanne. Il est peu soluble dans l'eau bouillante (2% à 80°) dont on peut facilement le recristalliser. Il est moins soluble dans le méthanol (0,5%) et l'éthanol (0,2%) ; facilement soluble dans l'acide acétique glacial et les acides minéraux.

Le sel de sodium ($C_{17}H_{16}O_4N_2Na_2$, M = 358,31) s'obtient par évaporation à sec, à vide, de la solution d'acide 4,4'-diamino-diphénylméthane-N,N'-diacétique neutralisée par NaOH,

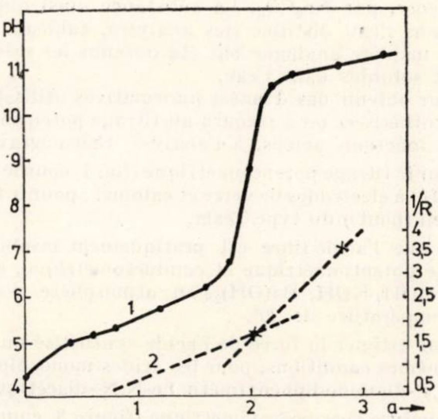

Fig. 1. — Courbe de titrage potentiométrique de l'acide 4,4'-diaminodiphénylméthane-N,N'-diacétique n/100 avec NaOH n/10.

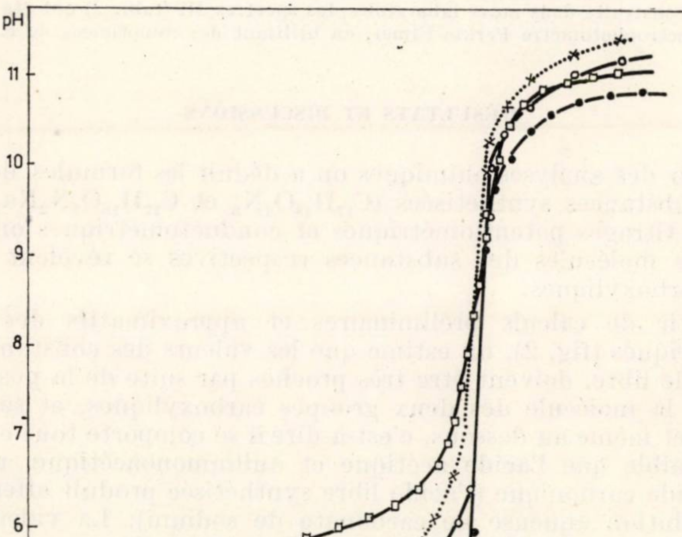

Fig. 2. — Courbes de titrage potentiométriques des : *1*, L'acide monochloracétique n/100 avec NaOH n/10 ; *2*, L'acide acétique n/100 avec NaOH n/10 ; *3*, L'acide anilinmonoacétique n/100 avec NaOH n/10 ; *4*, L'acide 4,4'-diaminodiphénylméthane-N,N'-diacétique n/100 avec NaOH n/10.

mieux encore, par Na_2CO_3. La substance ainsi obtenue est de couleur jaune et facilement soluble dans l'eau distillée (les analyses, tableau 1).

De manière analogue ont été obtenus les sels de lithium, potassium, calcium, baryum, également solubles dans l'eau.

Pour obtenir des données informatives utilisables en vue d'établir la structure des substances synthétisées on a recouru au titrage potentiométrique et conductométrique pour déterminer les fonctions acides, à l'analyse thermogravimétrique et les spectres en infrarouge.

Pour le titrage potentiométrique (fig. 1, courbe *1*) on a utilisé le pH-mètre du type Radelkis OP 401/2 à électrodes de verre et calomel ; pour le titrage conductométrique (fig. 1, courbe *2*), un appareil (pont) du type Tesla.

Vu que l'acide libre est pratiquement insoluble dans l'eau (à froid on a eu recours à son titrage potentiométrique et conductométrique, en suspension aqueuse, avec des solutions n/10 de NaOH, KOH, $Ba(OH)_2$, en atmosphère d'azote, à la puissance ionique de 0,1 mole KCl et température de 20°.

Pour estimer la force de l'acide synthétisé on a effectué des titrages potentiométriques dans les mêmes conditions, pour les acides monochloracétique, acétique, anilinmonoacétique et l'acide 4,4'-diaminodiphénylméthane-N,N'-diacétique (fig. 2).

L'analyse thermogravimétrique (figure 3, courbes *1*, et *2*) a été réalisée au moyen d'une thermobalance construite dans notre laboratoire, les spectres IR (tabl. 2) ont été obtenus au moyen d'un spectrophotomètre Perkin-Elmer, en utilisant des comprimées de KBr.

RÉSULTATS ET DISCUSSIONS

À partir des analyses chimiques on a déduit les formules de composition des substances synthétisées ($C_{17}H_{18}O_4N_2$ et $C_{17}H_{16}O_4N_2Na_2$), tandis que par des titrages potentiométriques et conductométriques on a établi que dans les molécules des substances respectives se révèlent les deux fonctions carboxyliques.

À partir de calculs préliminaires et approximatifs des données potentiométriques (fig. 2), on estime que les valeurs des constantes d'acidité de l'acide libre, doivent être très proches par suite de la position distancée dans la molécule des deux groupes carboxyliques, et seraient de l'ordre 10^{-7} et même au-dessous, c'est-à-dire il se comporte tout comme un acide plus faible que l'acide acétique et anilinmonoacétique, mais plus fort que l'acide carbonique (l'acide libre synthétisée produit effervescence avec une solution aqueuse de carbonate de sodium). La valeur exacte des constantes sera vérifiée aussi par d'autres moyens.

L'analyse thermogravimétrique révèle que l'acide libre (fig. 3, courbe *1*) commence à se décomposer à environ 100° et après quelques points d'inflexion à 250, 350 et 450° il se décompose complètement à 700°.

De la courbe thermogravimétrique du sel de sodium (fig. 3, courbe *2*) il s'ensuit que la décomposition de celui-ci commence à environ 200° et après une baisse brusque jusqu'à 430°, correspondant à une perte de poids de 42,75%, la succession des transformations, marquées par les points d'inflexion à 700 et 800° se finalise par un palier très peu incliné depuis environ 800° jusqu'à 1000°. Il est à remarquer le fait qu'à 750° le résidu est de 29,56% par rapport à la masse de l'échantillon mis en œuvre, une valeur pratiquement égale à celle calculée (29,58) correspondant à Na_2CO_3 qui devrait se former par la décomposition du sel de sodium de l'acide synthétisé. Nous estimons que cette concordance peut servir en tant que preuve de la composition du sel de sodium synthétisé. En continuant le chauffage, à 1000° environ, la masse de résidu arrive à 23,6% de la masse de l'échantillon analysé et correspond à un mélange de Na_2CO_3 et Na_2O. Le début de la décomposition du Na_2CO_3 à 750°, donc à une température de 100° inférieure à celle de décomposition qui lui correspond (850°) et la formation de Na_2O, s'expliquent par la réaction qui a lieu, à haute température, entre Na_2CO_3 et les restes de carbone qui proviennent par la combustion incomplète de la substance organique.

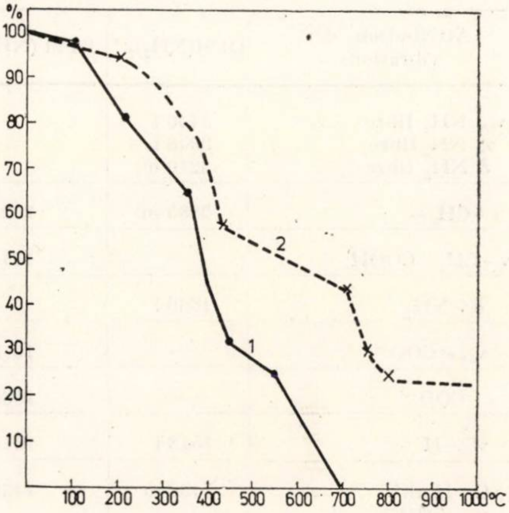

Fig. 3. —Courbes thermogravimétriques des : *1*, l'acide 4,4'-diaminodiphénylméthane-N,N'-diacétique ; *2*, le sel de sodium de l'acide 4,4'-diaminodiphénylméthane-N,N'-diacétique.

L'analyse des spectres en IR. Si l'on compare le spectre de la base (4,4'-diaminodiphénylméthane) au spectre de l'acide libre et à celui du sel de sodium respectif, on constate que dans les spectres de ces derniers les vibrations correspondant au groupement $-NH_2$ libre n'apparaissent plus ; cependant dans le spectre de l'acide libre apparaissent les vibrations caractéristiques au groupement acétique ($-CH_2-COOH$) à 1715, 1320, 1232 cm^{-1}, valeurs qui sont en bonne concordance avec celles signalées dans la littérature [3-6] ; ces vibrations n'apparaissent plus dans le spectre du sel de sodium. En plus, apparaissent aussi les vibrations du groupement $-COO^-$, tant au cas de l'acide libre (1580, 1430 cm^{-1}) qu'au cas du sel de sodium (1590 , 1425 cm^{-1}) [7].

Puisque dans le spectre IR de l'acide et du sel de sodium on ne remarque plus les vibrations qui correspondent aux groupements $-NH_2$ libres, on peut déduire que les groupements acétiques sont greffés symétriquement sur les deux fonctions amino des extrémités de la molécule.

[7] E. Uhling et D. Hermann, *Z. anorg. Chem.*, **359**, 135 (1968).

Cette supposition est également confirmée par l'aspect de la courbe de titrage potentiométrique de l'acide libre synthétisé.

Par conséquent, compte tenu des résultats de l'analyse chimique, des titrages potentiométriques et conductométriques, thermogravimétriques et de spectres en IR, on peut estimer que la formule de constitution de l'acide libre synthétisé est celle qu'on s'est proposée de réaliser (formule II).

PALLADIUM (II) AND PLATINUM (II) SQUARE-PLANAR COMPLEXES WITH TRIS (*p*-METHOXYPHENYL) ARSINE AND HALIDE IONS

P. SPACU, FLORICA POPEA, C. I. LEPĂDATU, A. C. BANCIU, EUGENIA IVAN,
SILVIA PLOŞTINARU, ZAMFIRA TOMA and CRISTINA RUSU
Centre of Physical Chemistry, Str. Dumbrava Roşie 23, Bucharest

Received March 11, 1974

In the present paper, 5 new *tris* (*p*-methoxyphenyl) arsine compounds of the general formula ML_2X_2 are reported ($M = Pd(II)$, $Pt(II)$; $L = As(p\text{-}CH_3OC_6H_4)_3$; $X = Cl^-$, Br^- or I^- for $M = Pd$ (II), and $X = Br^-$ or I^- for $M = Pt$ (II)). Chemical analyses and physical determinations (X-ray diffraction data, i.r. vibration spectra, electronic spectra, melting points) as well as a quantitative quantum study of the metal-ligand bonds in these square-planar complexes were performed. Some hints concerning the catalytic activity of these compounds are also given.

INTRODUCTION

In recent years, extensive studies concerning the coordination chemistry of the transition metals, are devoted to their applications to homogeneous catalysed processes.

Previous work reports [1-3] that among the coordination compounds of the transition metals, the d^8 square-planar of the VIIIth group (Pd > Pt) displays a remarkable catalytic activity enhanced by the presence of a halide ion in the coordination sphere, in the sequence $Cl < Br < I$.

Based on these considerations, the goal of the present work was to obtain some new complexes in view of their possible applications to homogeneous catalysed hydrogenation reactions. For this purpose Pd (II) and Pt(II) complexes formed by tris-(*p*-methoxy-phenylarsine) and halogen ions were synthetized. The last mentioned were Cl^-, Br^- and I^- for the Pd(II) complexes and Br^- and I^- for the Pt(II) complexes.

Indeed, the methoxy substituent in the para position on the benzene ring, displays besides the inductive effect a strong conjugation effect. This later effect enhances significantly the electronic density on the As atom bound to the aryl group and on the metal atom bound with As in the arsine complexes. These facts produce an increase in the cova-

lency degree of the metal-organic ligand bond and subsequently some increase in the stability of the complexes (compared with that of the triphenylarsine, the unsubstituted ligand).

In the last twenty years, the theoretical treatments concerning the transition metal complexes were confined mostly to the octahedral and tetrahedral ones.[4] Those regarding the square-planar compounds were only qualitative and sometimes conflicting.[5-11] One of the reasons is the more complicated effect of the ligands on the atomic orbitals of the central metal atom.

These facts substantiated the opportunity of a quantitative quantum treatment of the metal-ligand bonds in these compounds, possibly useful as homogeneous catalysts.

QUANTUM MOLECULAR STATES IN THE SQUARE-PLANAR COMPLEXES

For the reasons discussed above we shall present, in the following pages, the quantum treatment of the molecular states in the complex *trans*- [Pd (II) Ars_2Cl_2], where Ars = tris (*p*-methoxyphenyl) arsine, to which a *trans* coordination geometry which minimizes the repulsions between ligands has been ascribed (Fig. 1).

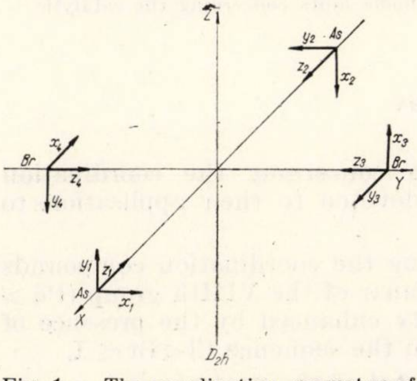

Fig. 1. — The coordination geometry of trans- [Pd (II)Ars_2Br_2] complex (D_{2h}).

For this purpose, the following minimal set of orbitals has been used :

Palladium (9 orbitals) : $4d_{xy}$, $4d_{xz}$, $4d_{yz}$, $4d_{z^2}$, $4d_{x^2-y^2}$; 5s ; $5p_x$, $5p_y$, $5p_z$

Chlorine (3 orbitals) : $h = 0.900 |3p_z> + 0.435 | 3s >$ (see the Appendix) $3p_x$,$3p_y$

Arsenic (1 orbital) : sp^3 (tetrahedral hybridization)

All the orbitals used are Slater type orbitals (STO), the effective principal quantum numbers and exponents being chosen according to Slater's rules[12], as follows

$$Pd^{2+} : \alpha_{4d} = 2.69 ; \quad n^* = 3.7$$

$$\alpha_{5s5p} = 1.525 ; n^* = 4$$

$$Cl^- : \ \alpha_{3s,3p} = 1.858 ; \ n^* = 3$$

$$As : \ \alpha_{4s\ 4p} = 1.78 ; \ n^* = 3.7$$

STO's instead of other analytical Hartree-Fock orbitals available in the related literature [13-14] have been preferred, since a preliminary analysis of the overlap integrals obtained with the last type of AO's, has led to numerical values incompatible with the radial extent assumed for the 4d-metal orbitals.

To solve the secular equation and to facilitate the interpretation of the results (especially the selection rules for transitions), the minimal orbital set of the interacting atoms has been classified according to the symmetry classes of the D_{2h} group to which the complex, as represented in Fig. 1, belongs. The group-theoretical analysis made according to the well known methods [15-16], leads to the results given in Table 1.

Table 1

The interacting orbitals set classified upon the symmetry classes of D_{2h} group

D_{2h}	Central metal AO's	Symmetry adapted ligand orbitals
A_g	$4d_{z^2}, 4d_{x^2-y^2}, 5s$	$\frac{1}{\sqrt{2}}(sp_1^3 + sp_2^3) ; \frac{1}{\sqrt{2}}(h_3 + h_4)$
B_{1g}	$4d_{xy}$	$\frac{1}{\sqrt{2}}(x_4 + y_3)$
B_{2g}	$4d_{xz}$	
B_{3g}	$4d_{yz}$	$\frac{1}{\sqrt{2}}(x_3 + y_4)$
B_{1u}	$5p_z$	$\frac{1}{\sqrt{2}}(x_3 - y_4)$
B_{2u}	$5p_y$	$\frac{1}{\sqrt{2}}(h_3 - h_4)$
B_{3u}	$5p_x$	$\frac{1}{\sqrt{2}}(sp_1^3 - sp_2^3) ; \frac{1}{\sqrt{2}}(x_4 - y_3)$

Since the symmetry classes have orthogonal representations, the total secular equation splits into A_g (5×5) ; B_{1g} (2×2) $B_{2g}(1)$; B_{3g} (2×2) ; B_{1u} (2×2) ; B_{2u} (2×2) ; B_{3u} (3×3), each factorized secular equation being of the form

$$C_{ij}\,[H_{ij} - G_{ij}E] = 0$$

[15] F. A. Cotton, "Chemical Applications of Group Theory", Interscience, New York, 1963.

[16] J. A. McMillan, "Introduction to Group Theory and Applications to Physics and Chemistry of Atoms and Molecules", 1973 (Book preprint).

where C_{ij} are the mixing coefficients of the molecular wavefunctions (Eigenfunctions),

G_{ij} — the group overlap integrals, i.e. the overlap integrals between the central metal orbitals and the symmetry adapted orbitals of the ligands,

H_{ij} — the energy matrix elements, and

E — the molecular energies (Eigenvalues).

The group overlap integrals have been expressed in terms of diatomic integrals, which have been estimated for the interatomic distances [17–18] $R_{Pd-Cl} = 2.37$ Å and $R_{Pd-As} = 2.38$Å.

The diagonal energy matrix elements have been approximated, in the usual way, to valence state ionization potentials, and the off-diagonal elements according to Cusach's approximation [19]

$$\underset{i>j}{H_{ij}} = G_{ij}(2 - |G_{ij}|)\frac{H_{ii} + H_{jj}}{2}$$

The ionization potentials used in the MO calculations are as folows

Palladium $H_{4d} = -8.5$ eV
$H_{5s} = -6.4$ eV
$H_{5p} = -3.2$ eV
Arsenic $H_{sp^3} = -11.2$ eV from $H_{4s} = -17.6$ eV
$H_{4p} = -9.05$ eV
Chlorine $H_h = -16.0$ eV (see the Appendix)
$H_{3p} = -13.7$ eV

The ionization potentials for chlorine and arsenic have been taken from references [20–21], H_{4d} for the palladium ion from reference, [13] and H_{5s}, H_{5p} using the ratios $H_{nd}/H_{(n+1)s}/H_{(n+1)p}$ for Ni^{2+} ($3d^8$) ion. [20]

The molecular energies (Eigenvalues) obtained by solving the secular equations by means of a double diagonalization subroutine in FORTRAN-IV for an IBM/360 computer, are as follows : Molecular energies (eV)

$$\Gamma_{Ag}\ \sigma_1 A_g(h) = -16.364$$
$$\sigma_2 A_g(sp^3) = -12.095$$
$$\sigma_3^* A_g(4d_{z^2}) = -8.040$$
$$\sigma_4^* A_g(4d_{x^2-y^2}) = -4.470$$
$$\sigma_5^* A_g(5s) = +35.070$$

$$\Gamma_{B_{1g}}\ \pi_1 B_{1g}(3p_{Cl}) = -13.732$$

$$\pi_2\, B_{1g}(d_{xy}) = -8.482$$

$$\Gamma_{B_{2g}}\ n_1 B_{2g}(d_{xz}) = -8.500$$

$$\Gamma_{B_{3g}}\ \pi_1 B_{3g}(3p_{Cl}) = -13.732$$

$$\pi_2^* B_{3g}(d_{yz}) = -8.482$$

$$\Gamma_{B_{1u}}\ \pi_1 B_{1u}(3p_{Cl}) = -13.708$$

$$\pi_2\, B_{1u}(5p_z) = -2.706$$

$$\Gamma_{B_{2u}}\ \sigma_1 B_{2u}(h) = -16.451$$

$$\sigma_2^*\, B_{2u}(5p_y) = +2.365$$

$$\Gamma_{B_{3u}}\ (\pi + \sigma)_1\, B_{3u}\, (3p_{Cl}) = -13.720$$

$$(\sigma + \pi)_2\, B_{3u}(sp^3) = -11.815$$

$$(\sigma^* + \pi^*)_3 B_{3u}(5p_x) = +4.319,$$

where σ, π show the bond type, the asterisk the antibonding state and "n" the nonbonding state.

By means of the molecular wave functions obtained by solving the secular equations, the 24 electrons, i.e. Pd^{2+} (8) ; 2 × As (2) ; 2 × Cl (6), have been redistributed on the molecular centres according to Mulliken's electron population analysis [22-23] and for the ground molecular state of the complex $\psi^2\,(\sigma_1 B_{2u})$

$$\psi^2\,(\sigma_1 A_g)\,\psi^4\,(\pi_1\,(B_{1g} + B_{3g}))\,\psi^2\,((\pi + \sigma)_1\, B_{3u}\psi^2\,(\pi_1\, B_{1u})\,\psi^2\,(\sigma_2\, A_g)$$

$$\psi^2\,((\sigma + \pi)_2.\, B_{3u})\,\psi^2\ (nB_{2g})\ \psi^4\,(\pi_2^*(B_{1g} + B_{3g}))\,\psi^2\,(\sigma_3^*\, A_g).$$

As may be later seen, the two uncoupled electrons of the free Pd^{2+} ($4d^8$) ion will be paired in the antibonding molecular state $\psi^2(\sigma_3^*\, A_g)$, in other words the complex behaves as a low spin complex.

The electron population analysis leads to the following distribution of electronic densities and net charges on the atoms

$$Pd^{+1.004}\,[(4d)^{8.206}\ (5s)^{0.388}\,(5p)^{0.401}]$$

$$As\ [(sp^3)^2]$$

$$Cl^{-0.499}\ [(3p)^{3.982}\ h^{1.519}]$$

[22] R. S. Mulliken, *J. Chem. Phys.*, **23**, 1833, 1841 (1955).
[23] R. S. Mulliken, *J. Chem. Phys.*, **36**, 3428 (1962).

As may be observed, the net charge on the palladium ion is reduced to $+1$ as a consequence of the σ (π) chemical bond formation. The chloride ions become more positive (from -1 to ~ -0.5) and the arsenic atoms have no formal charges mainly due to the neighbouring chloride ions, via the molecular quantum state described by the wave function ψ ($\sigma_1 A_g$), which compensates the transfer of electron densities in "σ" As $\rightarrow$ Pd bonds. The upper 5s and 5p orbitals of the central metal ion are involved in chemical bonding to a considerable extent, in spite of the assertion reported in literature[13] about the chemical inadequacy of these orbitals. The $5p_z$ palladium orbital which forms "π" bonds with 3p chlorine orbitals ($\Gamma_{B_{1u}}$), does not substantially participate in chemical bonding (electronic density $(5p_z)^{0.014}$).

Nevertheless, this metal orbital could play an essential role in the SN_2 attack of the reagents which may, from sterical reasons, come along the "z" axis. The approach of the reagents will primarily weaken the "π" Pd—Cl bonds, and will favour the removal of the chloride ion from the complex. This conclusion is very important in explaining the formation mechanism of active coordination centres in the homogeneous catalysis, where square-planar complexes are frequently used as catalysts. Another surprising fact is the mixing of $4d_{z^2}$ and 5s palladium orbitals in the molecular state described by ψ ($\sigma_3^* A_g$), which has been previously suggested by Jørgensen.[9] It may be stated, in this context, that a d_{z^2} — s hybridization would take place. Since the 5s orbital has a very great radial extension, its mixing with $4d_{z^2}$ will enlarge the radial extension of the last orbital, thus leading to a decreased repulsion between the donor electron pair of the incoming reagent along the "z" axis, and that of the molecular level $\sigma_3^* A_g(4d_{z^2})$. The approach of the reagent will therefore labilize to an almost equal extent the "σ" Pd—Cl and Pd—As bonds and facilitates the ligand rearrangement in the coordination sphere of the intermediate 5-coordinate complex with the most probable coordination geometry, trigonal bipyramid (D_{3h}) (the molecular orbital stabilization energy of each coordination point in D_{3h} geometry in a square-planar complex[24]). The decrease of the repulsion between the electron pair in the $\sigma_3^* A_g(4d_{z^2})$ level and that of the reagent may be also achieved if electronic densities from $\sigma^*{}_3 A_g(4d_{z^2})$ are transferred in the upper 5d levels of the arsenic atoms involved in the "π" back-donation bonds metal $\rightarrow$ ligand.

From these considerations it follows that the catalytic properties of the square-planar complexes depend on the existence of a direction suitable for the attack of the reagents ("z" axis), as well as on the presence of "π" metal-halide bonds which favour the formation of active coordination centres, and, finally, on the "π" back-donation metal-arsenic bonds which facilitate the incoming of the reagent.

EXPERIMENTAL

Materials. Palladium (II) and platinum (II) chlorides were purchased from Reanal (Budapest). All other chemicals were reagent grade or equivalent.

Analyses were carried out by micromethods : C, H, N were determined by microcombustion, Pd metal gravimetrically by ignition.

---

[24] C. I. Lepădatu, *J. Cryst. Mol. Structure (London)*, **1**, 397 (1971).

Measurements. The uncorrected melting points were measured in sealed tube immersed in silicon oil.

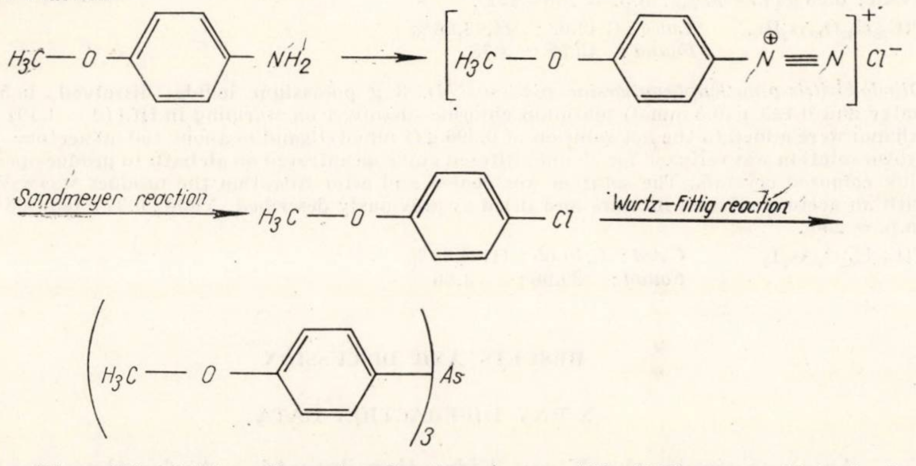
The X-ray diffraction data were obtained by Debye-Scherrer powder technique, using the X-ray source TuR_M -60 (GDR). The procedure involved the Cu $K_\alpha(\lambda = 1.5418$ Å) radiation filtered on nickel (at 30 kV and 19 mA) and a 57.3 mm diameter camera.

The electronic absorbiton spectra were run at room temperature on a VSU-2 C. Zeiss Jena spectrophotometer. In the u.v. range (220 − 360 mμ) $0.25\ 10^{-4}$ M and $0.5.10^{-4}$ M absolute ethanol solutions for the compounds and for the ligand respectively, were employed. In the visible range (350 − 8007 m μ) acetone solutions were used. The low solubility of the compounds in most of the usual solvents, did not allow to obtain solutions of proper concentration in order to cover the whole range.

The i.r. spectra of the ligand and of all the complexes were recorded on potassium bromide pellets, by means of a UR 10 C. Zeiss Jena spectrophotometer in the 400 − 4000 cm^{-1} range.

The ligand tris(p-methoxyphenyl)arsine. The title compound was obtained in a Wurtz-Fittig type reaction, allowing the *p*-chloroanisole to react with arsenic trichloride in absolute diethyl ether and in the presence of sodium metal.[25]

p-chloro-anisole was prepared via *p*-anisidine diazotization, strongly acidifying with hydrochloric acid. The resulted diazonium salt yielded the *p*-chloro-anisole in a Sandmeyer type reaction[25]



The white tris(*p*-methoxyphenyl)arsine (m.p. = 156 − 157°) was obtained from *p*-chloro-anisole, the yield being about 15%.

The coordination compounds were prepared in acetone, in the molar ratio M/L = 1/2 (M = Pd (II), Pt(II) ; L = tris(*p*-methoxyphenyl)arsine) and were formulated on the basis of the elemental analysis. In order to obtain some further data concerning the nature of the complexes investigated and to assign their most probable structure, their X-ray, vibration and electronic spectra (in u.v. and visible range) have been recorded.

Dichloro-bis(tris-p-methoxyphenyl) arsine palladium (II). A solution obtained by dissolving 0.0886 g (0.5 mmol) $PdCl_2$ in 25 ml hot water in the presence of 1 ml HCl (d = 1.19), was added to 150 ml warm solution of 0.3960 g (1 m mol) ligand. The resulting yellow solution was refluxed about 1 hour on a steam bath, until orange crystals appeared. After stirring for 5 min the orange microcrystals were filtered and washed with warm acetone. The product recrystallized from acetone was dried in vacuo over P_4O_{10}. Yield 0.35 g (75 − 80%) ; m.p. = 215 − 218°

		Pd	C	H
$PdC_{42}H_{42}O_6As_2Cl_2$	*Calcd* :	10.97 ;	52.03 ;	4.33 %
	Found :	11.43 ;	51.63 ;	4.34

Dibromo-bis(tris-p-methoxyphenyl)arsine palladium(II). To a hot solution of 0.600 g (1.6 mmol) ligand in about 130 ml acetone, 20 ml aqueous solution of 0.134 g (0.75 mmol) $PdCl_2$ and 1.6 g KBr previously dissolved in 5 ml water was added. An orange fluffy compound separated immediately. The mixture was warmed on a steam bath and stirred continuously for 10 min. The orange crystalline powder was then filtered off and washed with acetone. The product recrystallized from acetone was dried in vacuo over P_4O_{10}. Yield : 1.2 g (35–40 %) ; m.p. = 217–219°

Found : 10.11 ; 47.70 ; 4.22

Diiodo-bis(tris-p-methoxyphenyl)arsine palladium(II). To the hot solution of 0.396 g (1 mmol) ligand in about 150 ml acetone, a brown suspension of potassium iodide and palladium iodide (1.0 g KI in 5 ml water and 0.088 g, 0.5 mmol $PdCl_2$) was added gradually. The mixture was refluxed about 1 hr 45 min on a steam bath. After cooling, brown crystals separated which were filtered and washed with acetone. The recrystallization and drying were as described above. Yield : 0.226 g (40–45 %) ; m.p. = 228–230°.

$PdC_{42}H_{42}O_6As_2I_2$ *Calcd* : Pd, 9.22 ; C, 43.79 ; H, 3.64 %
Found : 9.22 ; 43.28 ; 3.89

Dibromo-bis(tris-p-methoxyphenyl)arsine platinum(II). A solution of 3.0 g sodium bromide in 5 ml water and 0.133 g (0.5 mmol) $PtCl_2$ dissolved on warming in a mixture of hydrochloric acid and ethanol were added to the hot solution of 0.396 g (1 mmol) ligand in about 150 ml acetone. The mixture was refluxed 15–20 min and then cooled. The lemon-yellow coloured crystals were filtered, washed with an acetone-ethanol mixture and dried in vacuo over P_4O_{10}. Yield : 0.25 g (45–50 %) ; m.p. = 230–232°.

$PtC_{42}H_{42}O_6As_2Br_2$ *Calcd* : C,43.98 ; H, 3.66 %
Found : 43.58 ; 3.75

Diiodo-bis(tris-p-methylphenyl)arsine platinum(II). 3 g potassium iodide dissolved in 5 ml water and 0.133 g (0.5 mmol) platinum chloride dissolved on warming in HCl (d = 1.19) and ethanol were added to the hot solution of 0.396 g (1 mmol) ligand in about 150 ml acetone. The brown solution was refluxed for 45 min, filtered and concentrated on air bath to produce peach-pink coloured crystals. The solution was cooled and after filtration the product was washed with an acetone-ethanol mixture and dried as previously described. Yield : 0.37 g (60–65 %) ; m.p. = 250°.

$PtC_{42}H_{42}O_6As_2I_2$ *Calcd* : C,40.65 ; H, 3.38 %
Found : 39.96 ; 3.66

RESULTS AND DISCUSSION

X-RAY DIFFRACTION DATA

As an example, the X-ray diffraction data (d = Å) for the complex $[PdBr_2\,(As\,(p-CH_3O-C_6H_4)_3)]$ and the starting materials ($PdCl_2$ and Ars) are comparatively summarized in Table 2.

It can be seen, that the values of the diffraction lines of the complex differ from those of the starting reagents. This may indicate a new unitary compound with characteristic diffraction lines. The mean intensity of these values, along the whole range of the angles measured, suggests an ordered structure of low symmetry.

VIBRATIONAL SPECTRA

The i.r. spectra of the ligand and of the 5 new compounds exhibit an unusual similarity in the whole measured range (400–4000 cm $^{-1}$). This fact is not surprising, because the expected dissimilar vibrations ν_{M-L}(L = Cl, Br, I) and ν_{M-As} (M = Pd (II), Pt (II)) appear only below 400 cm^{-1}, which is out of our measurement possibilities. The remarkable similarity of the spectra mentioned above, indicates the presence of the

arsine ligand in all the complexes investigated. The most probable assignments [26−27] of the i.r. spectral bands of the free ligand and of the two representative complexes are shown in Table 3.

ELECTRONIC SPECTRA

In Figs. 2−6 the electronic spectra of the complexes and of the ligand are shown. In the u.v. range, they exhibit the characteristic bands for the $\pi-\pi^*$ transitions in the phenyl groups of the arsine. The additional band, characteristic of the compounds will be thoroughly discussed bellow.

The molecular energy levels calculated for *trans*-[Pd (II) Ars$_2$Cl$_2$], are schematically shown in Fig. 7.

As may be observed in Fig. 7, the antibonding effects are stronger than the bonding ones, which is to be expected in the case of heteropolar chemical bonds. In spite of all this, the complex is stable. The molecular orbital stabilization energy of each coordination point (Bonds Stabilization Energy) [24, 28] calculated for the electronic configuration, as represented in Fig. 7, assumes a value of −0.96 eV (−22.16 kcal/mol).

According to the energy diagram (Fig. 7), the following electric dipole allowed transitions are to be expected :

$$\nu_1 = \sigma_1 B_{2u}(h_{Cl}) \rightarrow \sigma_4^* A_g(4d_{x^2-y^2})$$

$$\nu_2 = \pi_1 B_{1u}(3p_{Cl}) \rightarrow \sigma_4^* A_g(4d_{x^2-y^2})$$

$$\nu_3 = (\pi + \sigma)_1 B_{3u}(3p_{Cl}) \rightarrow \sigma_4^* A_g(4d_{x^2-y^2})$$

$$\nu_4 = (\sigma + \pi)_2 B_{3u}(sp^3_{As}) \rightarrow \sigma_4^* A_g(4d_{x^2-y^2})$$

where ν_2, ν_3 are quasi-degenerate. Since the electric dipole projections M_x, M_y, M_z belong to B_{3u}, B_{2u}, B_{1u} symmetry classes of the group D_{2h}, it is not difficult to see that ν_3 and ν_4 are *x* — ν_2 "z" — and ν_1 "y" —

allowed transitions. These transitions might occur in the electronic spectrum as very intense absorption maxima ; they may be regarded as charge-transfer ligand → metal bands, since the bonding molecular energy levels are practically located on the ligands and the antibonding levels on the central metal ion.

The theoretical estimation of these CT-transitions is very difficult to be made, because of the many-centre molecular integrals involved, [9–10] the evaluation of which constitutes so far a difficult task. For these reasons, we shall present, in the following pages, only a qualitative assignment of these CT-bands, resulted by comparing this kind of transitions, occurring in the spectra of the $[Pd\ (II)\ Ars_2X_2]$ complexes, where $X = Cl^-$, Br^- and I^- (see Table 4).

Taking into account that the "σ" antibonding effects produced by the halide ions are approximately the same, [29–30] and neglecting the bonding ones which generally are small for heteropolar chemical bonds, it results that $\nu_4\ (sp^3_{As} \rightarrow 4d_{x^2-y^2})$ must occur in the electronic spectra of the three compounds, approximately at the same wavenumbers (see Table 4). Since $3p_{Cl}$ level is placed below the sp^3_{As} level, it follows that $3p_{Cl} \rightarrow 4d_{x^2-y^2}$ must occur at higher wavenumbers in the complex where $X = Cl^-$, but the transition $^4p_{Br} \rightarrow 4d_{x^2-y^2}$ is shifted towards lower wavenumbers, because the $4p_{Br}$ level lies approximately at 1.2 eV above[21] the $3p_{Cl}$ level. The transitions $5p_y \rightarrow 4d_{x^2-y^2}$ and $sp^3_{As} \rightarrow 4d_{x^2-y^2}$ are

[29] C. I. Lepădatu, *Z. Physik. Chemie (Frankfurt)*, **60**, 202 (1968).

[30] C. I. Lepădatu, Ph. D. Thesis, University of Bucharest, 1969.

inverted in the complex [Pd (II) Ars_2I_2], because the $5p_y$ shell has an energy of about [31] 10.5 eV and therefore placed above the sp^3_{As} level in the energy diagram, as shown in Fig. 7.

Table 4

Assignments of electronic transitions in [Pd(II) Ars_2 X_2]

X	Absorption maxima (cm^{-1}) (intensity ε_{mol})	Assignment
Cl^-	I 30,700 (4500)	$3p_{Cl} \rightarrow 4d_{x^2-y^2}$
	II 27,000 (25000)	$sp^3_{As} \rightarrow 4d_{x^2-y^2}$
	III 23,530 (~2000)	d–d
Br^-	I 29,850 (7800)	$4p_{Br} \rightarrow 4d_{x^2-y^2}$
	II 25,650 (19500)	$sp^3_{As} \rightarrow 4d_{x^2-y^2}$
	III 22,220 (1400)	d–d
I^-	I 27,100 (17100)	$sp^3_{As} \rightarrow 4d_{x^2-y^2}$
	II 22,370 (15500)	$5p_I \rightarrow 4d_{x^2-y^2}$
	III 17,540 (~200)	d–d

Besides the electric dipole allowed CT-transitions, in the electronic spectra of the palladium (II) complexes a further absorption band of lower intensity ($\varepsilon_{mol} \approx 200-2000$) is observed at higher wavelengths (Table 4). This absorption band could be assigned to an electron transition between the antibonding molecular levels $\sigma_3^*A_g(4d_{z^2}) \rightarrow \sigma_4^*A_g(4d_{x^2-y^2})$. Since these molecular states belong to a total symmetric class A_g, and the projections of the electric dipole belong to *"u"* (ungerade) classes of the D_{2h} point group, this transition must take place only through a vibronic coupling. This kind of transition may be considered as being of d–d type, the antibonding molecular levels $\sigma_3^*A_g$ and $\sigma_4^*A_g$ being practically localized on the central metal ion.

To facilitate the discussion, we adopt the following notations for the metal orbitals, familiar in the ligand field theory [32]

$$\psi\,(nB_{2g}\,;\,d_{xz}) = \eta$$

$$\psi\,(\pi_2^*B_{3g}\,;\,d_{yz}) = \xi$$

$$\psi\,(\pi_2^*B_{1g}\,;\,d_{xy}) = \varphi$$

$$\psi\,(\sigma_3^*A_g\,;\,d_{z^2}) = u$$

$$\psi\,(\sigma_4^*A_g\,;\,d_{x^2-y^2}) = v$$

[32] N. WATANABE, "Operator Methods in Ligand Field Theory", Prentice Hall, Inc., Englewood Cliffs, New Jersey, 1966.

Considering all the bonding levels as being included in the molecular core, the eigenfunctions of the spectral terms between which the u → v transition can take place, are

Singlet states

$$ {}^1A_g(I) \qquad \eta^2\ \xi^2\ \varphi^2\ u^2 $$

$$ {}^1A_g(II) \qquad \frac{1}{\sqrt{2}}(\eta^2\ \xi^2\ \varphi^2\ u^+\ v^- - \eta^2 \xi^2\ \varphi^2\ u^- v^+) $$

$$ {}^1A_g\ (III) \qquad \eta^2\ \xi^2\ \varphi^2\ v^2 $$

Triplet state

$$ {}^3A_g : \eta^2\ \xi^2\ \varphi^2\ u^+ v^+\ (\text{or}\ \eta^2\ \xi^2\ \varphi^2\ u^- v^-) $$

If the relativistic effects (spin-orbit coupling) were neglected, using MO's truncated to orbitals having the highest mixing coefficients, the spectral term energies are

$$ \begin{array}{c|c|c|c|} & {}^1A_g(I) & {}^1A_g(II) & {}^1A_g(III) \\ {}^1A_g(I) & W + 2\varepsilon(u) - E & 0 & 4B + C \\ {}^1A_g(II) & 0 & W + \varepsilon(u) + \varepsilon(v) - 4B - C - E & 0 \\ {}^1A_g(III) & 4B + C & 0 & W + 2\varepsilon(v) - E \end{array} = 0 $$

$$ E\ ({}^3A_g) = W + \varepsilon(u) + \varepsilon(v) + 12B + 3C $$

where

$$ W = E^{core} + 2\ \varepsilon(\eta) + 2\varepsilon(\xi) + 2\varepsilon(\varphi) + 28A - 22B + 24C $$

E^{core} being the core energy, ε-one-electron energies (levels in figure 7), A, B, and C – The Racah parameters for the interelectronic repulsion energies.

From these equations, one obtains

$$ E\ [{}^1A_g\ (I)] = W + \varepsilon(u) + \varepsilon(v) - \sqrt{[\varepsilon(u) - \varepsilon(v)]^2 + (4B+C)^2} $$

$$ E\ [{}^3A_g] = W + \varepsilon(u) + \varepsilon(v) + 12B + 3C $$

$$ E\ ({}^1A_g(II)] = W + \varepsilon(u) + \varepsilon(v) - 4B - C $$

$$ E\ ({}^1A_g(III)] = W + \varepsilon(u) + \varepsilon(v) + \sqrt{[\varepsilon(u) - \varepsilon(v)]^2 + (4B+C)^2} $$

where the singlet $^1A_g(I)$ corresponds to the low spin electron distribution and the triplet ^3A_g to the high spin one, the other spectral terms corresponding to a single electron jump $u \rightarrow v(^1A_g(II))$ or to a double electron jump $u^2 \rightarrow v^2\ (^1A_g(III))$. In order to establish which of the electronic configurations becomes ground state in our complexes, we must compare the energy expressions of the $^1A_g(I)$ and ^3A_g terms. Assuming that the low spin state is fundamental, and neglecting the configuration interaction one obtains

$$E[^1A_g(I)] < E\,(^3A_g), \text{ or}$$

$$\varepsilon\,(u) - \varepsilon\,(v) < 12B + 3C$$

where the left-hand of the inequality represents the difference between orbital energies, i.e. $\varepsilon\,(\sigma_4^* A_g) - \varepsilon\,(\sigma_3^* A_g)$ in Fig. 7, and the right-hand the spin-pairing energy.[33] With $B = 826\ cm^{-1}$ and $C = 2620\ cm^{-1}$ for the palladium ion,[34] the condition is fulfilled, the complex *trans*- [Pd(II) Ars_2Cl_2] being therefore in the low spin state, as has been earlier assumed in the electron population analysis.

The spin-allowed d-d transitions between singlet terms, will be

$$\nu_1\,[^1A_g(I) \rightarrow {}^1A_g(II)] = \sqrt{[\varepsilon\,(u) - \varepsilon(v)]^2 + [4B + C]^2} - 4B - C$$

$$\nu_2\,[^1A_g(I) \rightarrow {}^1A_g\,(II)] = 2\sqrt{[\varepsilon(u) - \varepsilon(v)]^2 + (4B + C)^2}$$

or numerically

$$\nu_1 = 23{,}474\ cm^{-1}\ (\text{exp. } 23530\ cm^{-1})$$

$$\nu_2 = 58{,}796\ cm^{-1}\ (\text{out of measurement})$$

As may be seen from Table 4, the *d—d* transition is shifed towards smaller wavenumbers going from Cl^- to Br^- and I^-, the "σ" antibonding effects of the halide ions being progressively diminished [29-30] in the series Cl^-, Br^-, I^-.

In the electronic spectrum of the complex [Pt (II) $Ars_2\,Br_2$] (see experimental) besides the absorption bands due to the $\pi - \pi^*$ transitions of the arsine phenyls, two absorption bands occur at 3000 Å ($33{,}300\ cm^{-1}$) and 4000 Å ($25{,}000\ cm^{-1}$). Since the ionization potential value of 5d platinum shell is approximately [31] 9 eV and therefore close to that of 4d palladium shell (8.5 eV), by analogy with the similar palladium complex, these last bands can be described as being due to CT-transitions, $4p_{Br} \rightarrow 5d_{x^2-y^2}$ and $sp^3_{As} \rightarrow 5d_{x^2-y^2}$, respectively.

APPENDIX

The participation of 3s chlorine orbital to "σ" bonding has been estimated from the minimization condition [35]

$$\theta = \frac{\lambda^2 E(3p) + (1-\lambda^2)E(3s)}{\lambda S_\sigma(3p_{Cl}, \varphi_{Pd}) + \sqrt{1-\lambda^2}\, S_\sigma(3s_{Cl}, \varphi_{Pd})}$$

where φ_{Pd} represents the metal orbital, S_σ the diatomic overlap integral, λ — the mixing coefficient from the linear combination

$$h_{Cl} = \lambda | 3p > + \sqrt{1-\lambda^2}\, | 3s >$$

With [21] E (3p) = 13.7 eV and E (3s) = 25.3 eV, for the 4d, 5s and 5p Palladium orbitals, one finds $\lambda \simeq 0.9$.

MÉCANISME DE L'ACTIVITÉ CATALYTIQUE DES MÉTAUX DE TRANSITION DÉPOSÉS SUR UN SUPPORT ACTIF

ANTONI SWINARSKI et ANNA ZYTKOWICZ
Institut de Chimie de l'Université Nicolas Copernic
Toruń, Pologne

Reçu le 28 octobre 1974

On a déposé d'une solution diluée de nitrates les cations des métaux de structure d^3 à d^{10} sur du charbon activé. Sur la surface du charbon on a formé préalablement une concentration élevée d'oxydes superficiels de caractère acide. Les cations des métaux de transition ont été fixés sur la surface du charbon par chémosorption sous forme d'aquo-complexes. On a appliqué trois températures différentes de séchage des échantillons du charbon ainsi dopé. La température de 60° n'a pas détruit l'aquo-complexe déposé. La température de 100° a partiellement changée l'aquo-complexe en oxyde, cette opération étant nettement plus avancée à 150°. Par la réaction d'oxydation de l'hydrogène sulfuré on a pu constater une différence très nette entre l'activité catalytique des échantillons dopés séchés aux températures de 60°—100°—150°. On a pu observer que l'activité catalytique du cation déposé dépendait directement de l'énergie d'activation dans la réaction S_N2 de l'aquo-complexe formé dans le cas du séchage à 60°. Cette activité catalytique change nettement avec la destruction thermique de l'aquo-complexe formé. Plus la température de séchage est haute, plus l'activité catalytique de l'échantillon tend à devenir proportionnelle au pouvoir oxydant de l'oxyde formé sur la surface du charbon.

Sur la surface du charbon activé on peut faire développer une concentration élevée des oxydes superficiels de caractère acide par une activation appropriée[1]. On a préparé plusieurs échantillons de ce charbon qui ont eu la même surface spécifique et la même répartition des pores. Par l'immersion prolongée du charbon dans des solutions diluées de nitrates de Cr^{3+}, Mn^{2+}, Fe^{3+}, Co^{2+}, Ni^{2+}, Zn^{2+}, Hg^{2+}, Ag^{+}, on arrive à déposer sur la surface du charbon par chémosorption des quantités définies de cations. Le cation étant lié à la surface du carbon, l'anion qui l'accompagne —le nitrate — se laisse facilement éliminer par simple lavage avec de l'eau distillée.

Les échantillons ont été séchés à 60° pendant 84 heures. En mesurant l'acidité initiale du charbon et celle qui a subsistée après l'adsorption du cation déposé on a pu évaluer le nombre des protons qui ont été remplacés par le cation appliqué. Les résultats sont présentés sur le tableau 1.

Les cations liés à la surface du charbon par chémosorption y remplacent le nombre de protons équivalents à la valence du cation. Ce n'est

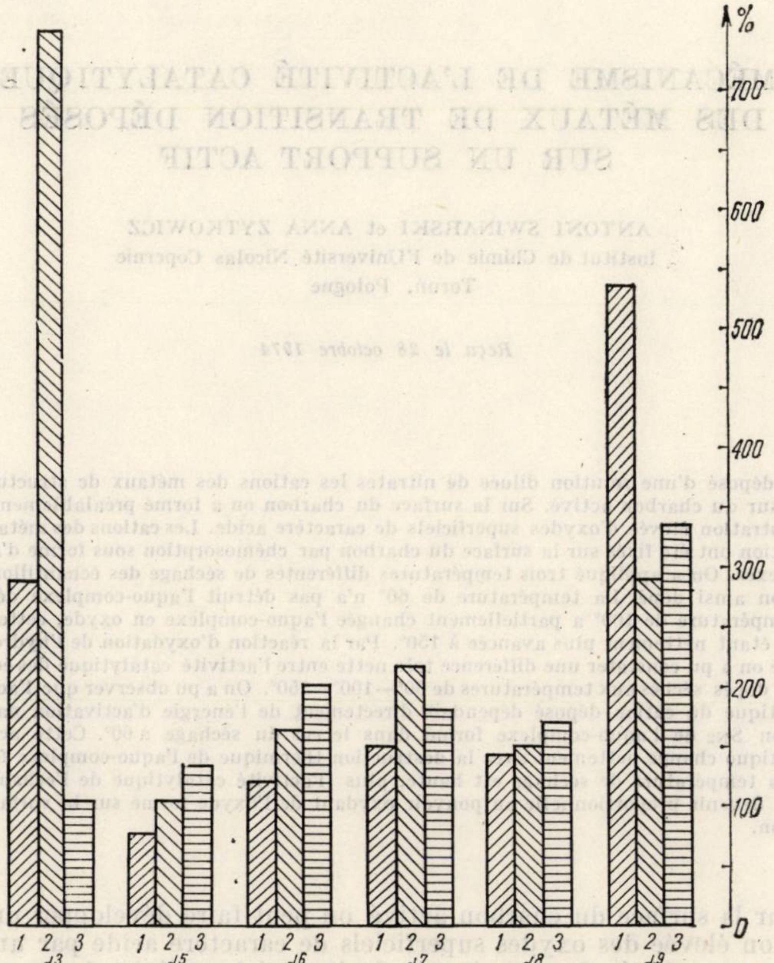

Fig. 1. — L'activité catalytique des échantillons de charbon dopé par les cations de métaux de transition.

1, température de séchage 60° ; *2*, température de séchage 100° ; *3*, température de séchage 150°.

que l'ion Fe^{3+}, et l'ion Hg^{2+} qui au cours de l'adsorption sont réduits à l'état de Fe^{2+} et Hg_2^{2+}.

L'activité catalytique des échantillons dopés et séchés à la température de $60^{\circ 1}$, de $100^{\circ 2}$ et $150^{\circ}C^{3}$ est présentée par rapport à l'activité de l'échantillon non dopé mis comme 100% sur la figure 1.

Les résultats laissent voir un changement considérable de l'activité catalytique suivant la température de séchage appliquée à l'échantillon.

En comparant l'activité catalytique des échantillons dopés par différents métaux et séchés à la même température de 100 et 150° on trouve une dépendance régulière entre l'activité catalytique et la chaleur de formation des oxydes correspondants.

Tableau 1

L'échange des ions sur la surface du charbon activé sous l'influence des cations de métaux de transition

Cation déposé	Nombre de protons sur un m^2 de la surface du charbon	Nombre de cations sur un m^2 de la surface du charbon	Nombre de protons remplacés par un cation
Cr^{3+}	$4{,}99.10^{17}$	$0{,}97.10^{17}$	3
Mn^{2+}	5,72	1,17	2
Fe^{3+}	6,10	0,85	2
Co^{2+}	5,44	1,05	2
Ni^{2+}	5,79	0,51	3
Cu^{2+}	5,99	0,86	2
Zn^{2+}	6,55	0,63	2
Hg^{2+}	6,23	1,61	1
charbon non dopé	7,70		

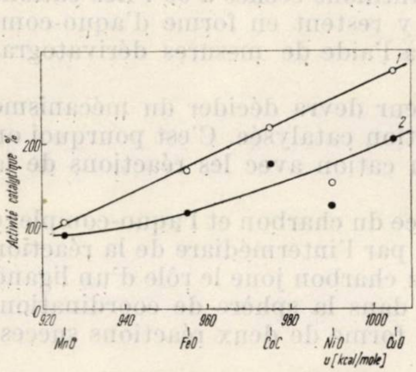

Fig. 2. — L'activité catalytique des échantillons de charbon dopé par les cations de métaux de transition en fonction de la chaleur de formation de leurs oxydes correspondants.

1, température de séchage 100° ; *2*, température de séchage 150°.

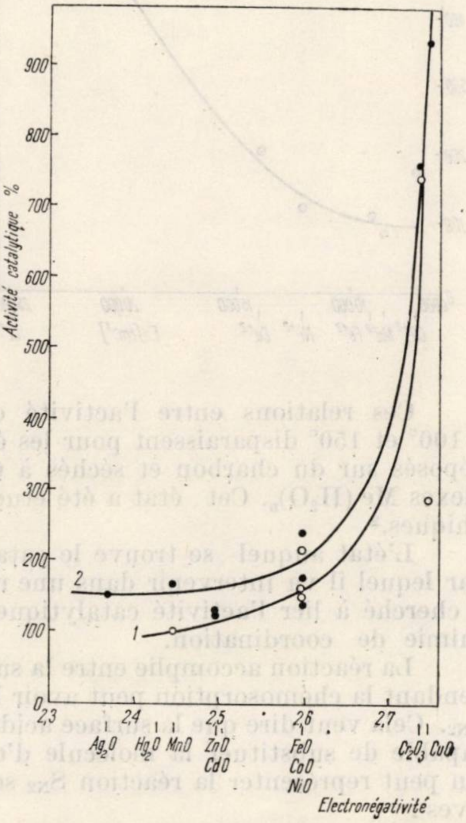

Fig. 3. — L'activité catalytique des échantillons de charbon dopé par les cations de métaux de transition en fonction de l'électronégativité moyenne de leurs oxydes correspondants.

1, température de séchage 150° ; *2*, température de séchage 100°.

Une autre dépendance régulière est à signaler entre l'activité catalytique des échantillons séchés à 100 et 150° et l'électronégativité moyenne des oxydes correspondants. L'électronégativité moyenne d'après Pauling peut être considérée comme une valeur représentative de la capacité du cation considéré à lier l'oxygène. Cette dépendance est présentée sur la figure 3.

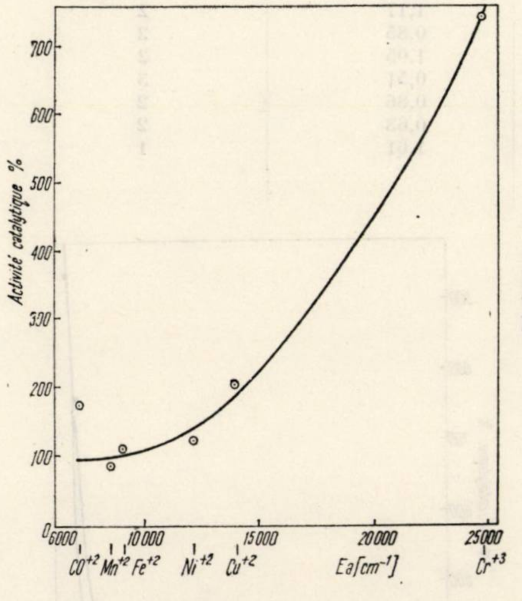

Fig. 4.—L'activité catalytique des échantillons de charbon dopé par les cations de métaux de transition d^3-d^9 en fonction de l'énergie d'activation de la réaction S_{N2}. Température de séchage 60°.

Ces relations entre l'activité catalytique des échantillons séchés à 100° et 150° disparaissent pour les échantillons séchés à 60°. Les cations déposés sur du charbon et séchés à 60° y restent en forme d'aquo-complexes $Me(H_2O)_n$. Cet état a été étudié à l'aide de mesures dérivatographiques.[2]

L'état auquel se trouve le catalyseur devra décider du mécanisme par lequel il va intervenir dans une réaction catalysée. C'est pourquoi on a cherché à lier l'activité catalytique du cation avec les réactions de la chimie de coordination.

La réaction accomplie entre la surface du charbon et l'aquo-complexe pendant la chémosorption peut avoir lieu par l'intermédiare de la réaction S_{N2}. Cela veut dire que la surface acide du charbon joue le rôle d'un ligand capable de substituer la molécule d'eau dans la sphère de coordination. On peut représenter la réaction S_{N2} sous forme de deux réactions successives :

$$Me(H_2O)_6 + C_xO_y = Me(H_2O)_6 \cdot C_xO_y$$

$$Me(H_2O)_6 \cdot C_xO_y = Me(H_2O)_5 \cdot C_xO_y + H_2O$$

[2] A. Swinarski et A. Zytkowicz, *Chemia Stosow.*, sous presse 1974.

La première réaction fait apparaître un complexe à sept ligands. Ce complexe étant instable se décompose en libérant l'eau.

A l'aide des valeurs de l'énergie d'activation, nécessaire pour accomplir le passage indiqué par la réaction S_{N2} [3], on trouve que l'activité catalytique reste en dépendance régulière de cette énergie pour chacun des cations mis en jeu (fig. 4).

Les résultats obtenus nous permettent de tirer quelques conclusions générales :

1. Le charbon activé se comporte comme un support actif pour les cations des métaux de transition utilisés comme catalyseurs d'oxydation.
2. La chémosorption sur la surface du charbon augmente sensiblement l'activité catalytique du cation déposé.
3. La température de séchage de l'échantillon dopé par les métaux permet d'obtenir le cation déposé soit sous forme d'aquo-complexe (temp. 60°), soit sous forme d'oxyde, au moins partiellement (100 et 150°).
4. L'activité catalytique du cation sous forme d'aquo-complexe est définie par la valeur de l'énergie de stabilisation.
5. Cette activité dans le cas des oxydes est proportionnelle à la facilité de l'oxyde à libérer l'oxygène. Cette faculté peut être quantitativement mise en évidence en présentant l'activité catalytique en fonction de la chaleur de formation des oxydes correspondants soit en fonction de l'électronégativité moyenne de l'oxyde.

COORDINATION COMPOUNDS WITH CHOLINE PERCHLORATE

MARIA BREZEANU and IOANA JITARU

University of Bucharest, Inorganic Chemistry Laboratory, Splaiul Independenţei, 87,
Bucharest, Romania

Received April 29, 1974

This paper reports the preparation of a series of perchlorate complexes of some 3d metals with choline perchlorate, which belong to two general types: $[ML_4^+(ClO_4)_2](ClO_4)_4$ (M^{II}=Ni, Co) and $[ML_4^+](ClO_4)_6$ (M^{II} = Mn, Cu, Zn), in which $L^+ = (CH_3)_3^+N-C_2H_4-OH$, behaves as a cationic ligand. The compounds obtained were characterized by elemental chemical analysis, molecular weight determinations, molecular electrical conductivity, electronic and vibrational spectra. The data obtained were used in establishing the probable structure of these compounds and also the coordination of choline and of perchlorate anion.

The literature has recently reported several papers concerned with the synthesis and characterization of some complex compounds with cationic ligands. The largest number of papers in this field report the coordination capacity of cationic ligands derived from diamines (primary, secondary or tertiary), tertiary diphosphines, aminophosphines and tertiary diarsines.[1–14]

The study of the coordination capacity of cationic ligands is of particular interest for several reasons. In the first place, new aspects may be revealed in such systems with regard to electronic interaction in the coordination sphere of a complex compound, which may affect the stoichiometry and the stereochemistry of the respective compound. On the other hand, compounds containing cationic ligands whose complex ion is characterized by a high positive charge, i.e. water-soluble compounds, play an important role in biochemical reactions.

In the frame of a more general research concerning the coordination capacity of aminoalcohols, we have considered of interest to study the donor properties of some quaternary ammonia ions of aminoalcohols, for which the donor atom is the oxygen of the hydroxyl group. Consequently, we undertook a study on the coordination ability of choline, the quaternary ammonium ion derived from monoethanolamine.

Depending on the nature of the anion, a different behaviour of choline is expected, i.e. as a cationic ligand or as an uncoordinated ion, stabilizing a series of complex anions.

In the presence of anions with a relatively high coordination capability (halogens, pseudohalogens, etc.), choline behaves as a free uncoordinated ion, in the ionization sphere of some complex compounds of the $L_2^+[MX_4]$ type.

In the presence of anions with a reduced coordination ability (acetate, perchlorate, etc.) complex compounds in which choline behaves as a cationic ligand could be obtained.

Owing to this fact, we first used choline perchlorate and acetate in our study.

The present paper reports the results obtained in the synthesis and characterization of complex compounds of some 3d metal perchlorates with choline perchlorate. These compounds belong to the following general types: $[ML_4^+(ClO_4)_2](ClO_4)_4$ ($M^{II} = Ni$, Co; $L^+ = (CH_3)_3^+N-C_2H_4-OH$) and $[ML_4^+](ClO_4)_6$ ($M^{II} = Mn$, Cu, Zn).

Attempts to obtain complex compounds of other 3d elements (Cr^{III}, Fe^{III}) with choline perchlorate under similar experimental conditions failed.

RESULTS AND DISCUSSION

Mn(II), Co(II), Ni(II), Cu(II) and Zn(II) perchlorates react in alcoholic solution (see the Experimental section) with choline perchlorate, leading to complex compounds of the $ML_4^+(ClO_4)_6$ type.

Molecular weight determinations have established the monomer nature of the latter.

Based on electronic and vibrational spectra, it could be established that these compounds, with the same empirical formula, belong to two structurally different types, i.e. octahedral $[ML_4^+(ClO_4)_2](ClO_4)_4$ ($M^{II} = Co$, Ni) and tetrahedral $[ML_4^+](ClO_4)_6$ ($M^{II} = Mn$, Cu, Zn).

As it can be seen, in the case of compounds of the first type, hexacoordination is achieved by the coordination of two perchlorate ions.

These compounds are air-stable, practically insoluble in most organic solvents (ethyl alcohol, methyl alcohol, isopropyl alcohol, ethyl ether, petroleum ether, acetone, carbon tetrachloride, chloroform); they decompose in water or undergo solvation (with colour change) by dissolution in solvents with good donor properties (dimethyl formamide, dimethylsulphoxide). In acetonitrile, the obtained compounds are rather easily dissolved without colour change.

Electronic spectra. Two absorption bands of a relatively low intensity appear in the spectrum of compound $CoL_4^+(ClO_4)_6$, the first in the visible range (530 mm) assigned to $^4T_{1g}(P) \leftarrow {}^4T_{1g}$ transition, and the second in the near infrared range (1100 nm) assigned to $^4T_{2g} \leftarrow {}^4T_{1g}$ transition.

The spectrum of this compound may be thus satisfactorily interpreted in terms of an octahedral configuration, which leads to the following formulation $[CoL_4^+(ClO_4)_2](ClO_4)_4$.[15]

In the spectrum of compound $NiL_4^+(ClO_4)_6$, there appear also two absorption bands, one in the visible range (740 nm) assigned to $^3T_{1g}(F) \leftarrow {}^3A_{2g}$ transition for d^8 ion in octahedral symmetry field, the second in the near infrared range (1240 nm) assigned to $^3T_{2g} \leftarrow {}^3A_{2g}$ transition. The shoulder in the range of higher frequencies may be assigned to $^3T_{1g}(P) \rightarrow {}^3A_{2g}$ transition. Based on these data and on molecular electrical conductivity determinations, the compound was formulated as $[NiL_4^+(ClO_4)_2](ClO_4)_4$.[16]

An extremely broad band, of a relatively low intensity, present in the spectrum of compound $CuL_4^+(ClO_4)_6$ indicates a tetrahedral configuration, compatible with formulation $[CuL_4^+](ClO_4)_6$ (fig. 1).[17]

Vibrational spectra. In order to establish the function of the perchlorate anion (ionic, mono, or bidentate ligand) and also of choline, vibrational spectra of compounds obtained within the 400–3600 cm^{-1} range were obtained.

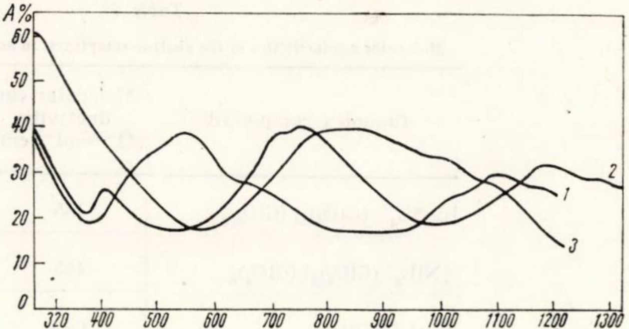

Fig. 1. — Electronic spectra of compounds: *1.* $[CoL_4^+(ClO_4)_2](ClO_4)_4$; *2.* $[NiL_4^+(ClO_4)_2](ClO_4)_4$; *3.* $[CuL_4^+](ClO_4)_6$

Spectra of compounds $[ML_4^+](ClO_4)_6$ and $[ML_4^+(ClO_4)_2](ClO_4)_4$ reveal small differences in the domain of vibration modes of ClO_4^- ion. In this respect, mention could be made of the greater width and additional splitting of the band at 1100 $cm^{-1}(\nu_3)$ and also of intensification and band splitting at 900 $cm^{-1}(\nu_1)$ in the spectra of compounds $[ML_4^+(ClO_4)_2](ClO_4)_4$ compared to those of compounds $[ML_4^+](ClO_4)_6$.

These results suggest that in the first type of compounds, at least part of perchlorate ions is coordinated.

It is difficult to make a definite assignment of the absorption bands of the perchlorate ion, since some bands characteristic of choline itself, also appear in this region.[18]

Choline coordination as a positive ligand does not induce basic changes in its vibration spectrum (the symmetry of cation $(CH_3)_3^+N-$$-C_2H_4-OH$ does not seem to be significantly affected by the formation of the M$-$O bond) except for the OH stretching vibration frequency (ν_{OH}), which shifts towards smaller values.[19,20]

In free choline, the ν_{OH} frequency appears at $\sim$3450 cm^{-1} as a result of some inter—or intramolecular hydrogen bonds. In the spectra of compounds $ML_4^+(ClO_4)_6$ this frequency appears at lower values (3300 cm^{-1} or 3265 cm^{-1}), this shift indicating choline coordination by oxygen.

Molecular conductivity determinations. The formulation suggested for the studied compounds was confirmed by molecular electrical conductivity determinations performed in acetonitrile solution.

Data referring to the conductivity of acetonitrile solutions are unfortunately extremely scarce in the literature.

Assignments made according to the existing data, lead, however, to the conclusion that while Ni(II) and Co (II) complex perchlorates are 1 : 4 electrolytes, the complex perchlorates of the other metals (Mn(II), Cu(II), Zn(II)) are 1 : 6 electrolytes (see table 1).

Table 1

Molecular conductivities of the choline complexes, in acetonitrile solution

Complex compound	Molecular conductivity ($\Omega^{-1}mol^{-1}cm^2$)	Type of electrolyte
$[Co^*L_4^+ (ClO_4)_2](ClO_4)_4$	485	1 : 4
$[NiL_4^+ (ClO_4)_2](ClO_4)_6$	465	1 : 4
$[CuL_4^+[(ClO_4)_6$	690	1 : 6
$[ZnL_4^+](ClO_4)_6$	710	1 : 6
$[MnL_4^+][(ClO_4)_6$	690	1 : 6

* $L+ = (CH_3)_3+N-C_2H_4-OH$ solution 10^{-3} M, t = 25°, solvent-acetonitrile.

$[ZnL_4^+)] (ClO_4)_6$	240	1078.76	1095.00

EXPERIMENTAL

I. *Synthesis of complexes.* Mn(II), Co(II), Ni(II), Cu (II) and Zn(II) complex choline perchlorates were obtained by mixing hot ethanol solutions of metal perchlorates with a hot ethanol solution of choline perchlorate, in a M(II) : choline = 1 : 5 molar ratio.

Crystalline compounds are separated from ethanol solutions by concentration on a water bath at 70–80° ; their colour is light-pink for Mn(II), violet-pink for Co(II), light-blue for Ni(II), blue-green for Cu (II), and white for Zn(II).

Compounds are filtered, washed with hot ethyl alcohol and then with cold ethyl alcohol.

A similar type of compounds is also obtained at higher values of the M(II) : choline ratio (example 1 : 7).

Elemental analysis data are listed in table 3.

II. Molecular Conductivities. Molecular conductivity measurements were made at 25° on freshly prepared acetonitrile solutions with a Conductometer II (Czechoslovakia) with a unit cell $K = 0.52$.

III. Molecular Weights. Molecular weights of the compounds studied were determined by means of the Rast micromethod, using camphor as solvent.

IV. Electronic Spectra. The electronic spectra in the range 320–1300 nm were recorded at room temperature, on a VSU_1 spectrophotometer, C. Zeiss, Jena using magnesium oxide as reference.

V. *Vibrational Spectra.* The IR spectra in the range 400–3600 cm^{-1} were measured on a UR-20 spectrophotometer C. Zeiss, Jena using the KBr disks technique.

COMBINAISONS COMPLEXES DU Mn(III) ET DU Mn(IV).I

LE SYSTÈME Mn(III, IV)–ACIDE ANILINE-4 SULPHONIQUE

NICOLAE CALU, ADINA POPA-RANG et MARIA CALENCIUC
Faculté de Chimie, Université « Al.I. Cuza », Jassy, 11 str. 23 august

Reçu le 24 juin 1974

On a étudié par spectrophotométrie, polarographie et chromatographie sur papier les complexes formés en solution pour les rapports 1 Mn (IV) : 2 L et 1 Mn (IV) : 4 L, où L est l'acide aniline-4 sulphonique. Les complexes du Mn (IV) sont obtenus aussi par la disproportion du Mn(III) de l'ion $[Mn(H_2P_2O_7)_3]^{3-}$ en présence de l'acide aniline-4 sulphonique, d'après une réaction du premier ordre avec $k = 2,13.10^{-2}$ sec^{-1} pour 21° et $E_a = 19,84$ kcal/mole. Le spectre champ cristallin du complexe $Mn\,L_4$ du système MnO_2–L a le paramètre $D_q = 1130$ cm^{-1} et celui néphélauxétique $\beta_{35} = 0.63$.

Les sels de Mn(III) et de Mn(IV) sont caractérisés par une petite stabilité et dans des solutions aqueuses celle-ci est influencée par le p_H, la nature des anions, la présence des ligands et par d'autres facteurs.

Dans la figure 1 on voit le domaine d'existence de certains composés du manganèse dans différents états d'oxydation, en fonction du p_H. On constate que, dans un milieu acide, l'ion Mn^{3+} peut subir un processus de disproportion et d'hydrolyse, avec la formation de MnO_2 et de Mn^{2+}.

Souvent, les cations Mn(III) et Mn(IV) sont stabilisés par le processus de coordinence. On connaît, ainsi, des complexes du Mn(III) et du Mn(IV)

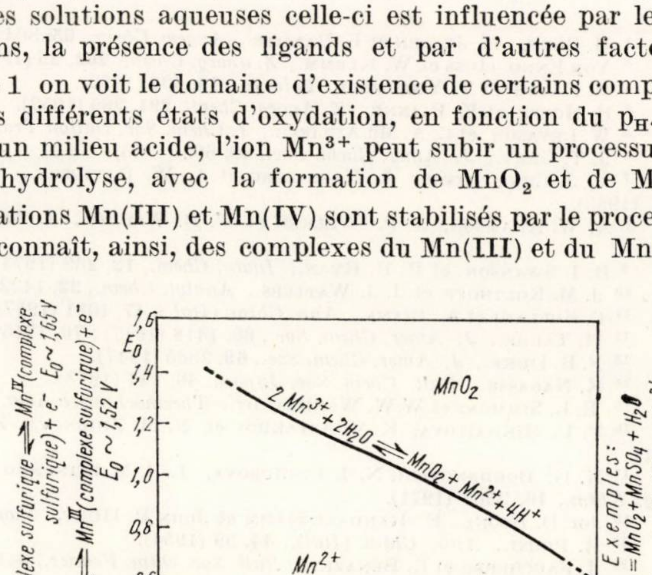

Fig. 1. — Données concernant les propriétés de certains composés du Mn(III, IV).

avec différents ligands, comme : les anions halogènes [1-6] et pseudo-halogènes, [7-9] les anions de certains acides polybasiques, [10-15] les ligands à fonctions mixtes comme des amines tertiaires avec des fonctions alcool ou acide,[16-22] l'acétylacétone,[23] les bases Schiff [24-25] et d'autres. [26,27]

Nos recherches ont comme but les combinaisons complexes du Mn(III) et du Mn(IV) avec des ligands à fonctions mixtes de la classe des acides aminosulphoniques aromatiques, etc. Ces ligands dissolvent (grâce à leur fonction SO_3H) des oxydes de manganèse, comme le MnO_2 et le Mn_2O_3, avec la formation de complexes ; ils provoquent parfois la disproportion du Mn(III) dans le Mn(IV) et le Mn(II) ou ils réduisent le Mn(IV) dans le Mn(III) et le Mn(II).

Ces recherches ont un intérêt pratique dans l'étude des minerais contenant des oxydes supérieurs de manganèse.

Dans ce travail, on présente les résultats obtenus dans l'étude du système Mn(III, IV)-acide aniline-4 sulphonique dans lequel les complexes avec Mn(IV) sont stables.

RÉSULTATS ET DISCUSSION

A) RÉACTIFS

Le Mn(III) a été utilisé sous forme de Mn_2O_3 et du complexe $[Mn^{III}(H_2P_2O_7)_3]^{3-}$ en solution aqueuse de concentration autour de 2.10^{-2} moles/l. Cet ion complexe a été obtenu en solution à partir de Mn_2O_3, $K_4P_2O_7$ et H_2SO_4 au pH$\sim$2,5. Il est suffisamment stable en solution aqueuse au pH de l'obtention.

Le Mn(IV) a été employé comme le MnO_2.

Le ligand : l'acide aniline-4 sulphonique (L) a été utilisé comme des solutions aqueuses de concentration environ 2.10^{-2} moles/l.

En solution, ce ligand existe comme amphion selon l'équilibre :

$$H_2N - C_6H_4 - SO_3^{\ominus} + H^{\oplus} \rightleftharpoons H_3N^{\oplus} - C_6H_4 - SO_3^{\ominus}$$

ainsi que pour la concentration 2.10^{-2} moles/l le pH est 2,5.

B) RÉACTION ENTRE LES COMPOSÉS DU Mn(III, IV) ET L'ACIDE ANILINE-4 SULPHONIQUE

Les composés Mn_2O_3 et $[Mn(H_2P_2O_7)_3]^{3-}$ réagissent avec l'acide aniline-4 sulphonique et les équilibres sont déplacés vers les complexes du Mn(IV) et l'ion Mn^{2+}.

Le bioxyde de manganèse forme avec le ligand utilisé des complexes de Mn(IV).

Ces réactions et les produits obtenus ont été étudiés par plusieurs voies.

Par les études spectrophotométriques, on a suivi l'identification des complexes du Mn(III) et du Mn(IV) et on a déterminé la composition et la stabilité des ions complexes du Mn(IV). On a obtenu, en même temps, des épreuves sur le processus de disproportion du Mn(III) en Mn(IV) et l'ion Mn^{2+}, à l'aide de la polarographie et de la chromatographie sur papier.

C) COMPOSITION ET STABILITÉ DES IONS COMPLEXES DU SYSTÈME Mn(III, IV)—ACIDE ANILINE-4 SULPHONIQUE

1) Déterminations spectrophotométriques

Dans les figures 2 et 3, on représente les spectres d'absorption, dans le domaine visible, de quelques solutions contenant le système Mn(III, IV)$-L$.

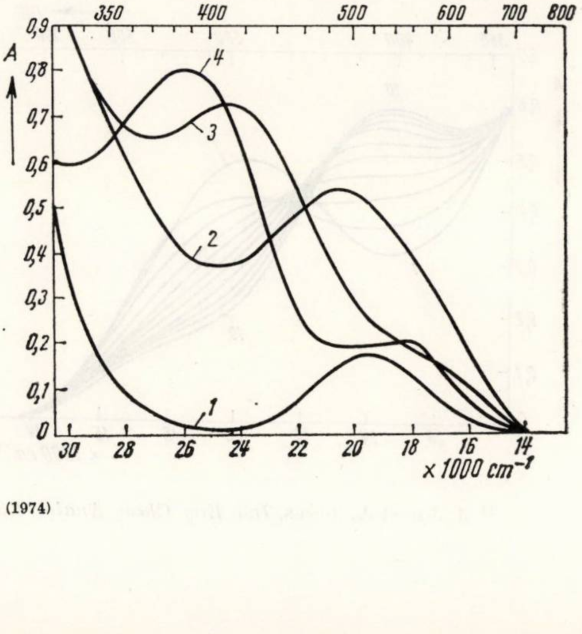

Fig. 2. — Spectres d'absorption dans le domaine visible des solutions du système Mn (III, IV) — L. *1*, Ion $[Mn(H_2P_2O_7)_3]^{3-}$; conc. 2.10^{-2} moles/l ; cuve 0.1 cm. *2*, Système $[Mn(H_2P_2O_7)_3]^{3-}-L$; $t = 0$; conc. Mn (III) ; $6,6.10^{-3}$ moles/l ; cuve 0,1 cm. *3*, Système (2) pour $t = 80'$. *4*, Système MnO_2-L ; conc. Mn(IV) :$3,3.10^{-4}$ moles/l ; cuve 1 cm. Dans les mélanges 2,3 et 4, le ligand est en excès.

L'ion $[Mn(H_2P_2O_7)_3]^{3-}$, contenant le Mn(III), un cas d^4, présente une seule bande champ cristallin (fig. 2, courbe *1*,), bande qui correspond à la transition spin permis ${}^5T_{2g} \leftarrow E_g$, dans le champ faible O_h. Cette bande est fortement affectée dans la réaction de l'ion $[Mn(H_2P_2O_7)_3]^{3-}$ avec l'acide aniline-4 sulphonique. Ainsi, au début de la réaction, la bande devient plus grande et elle est déplacée vers des longueurs d'onde plus petites (fig. 2, courbe 2). A la longue, à sa place apparaissent 3 bandes : deux en visible et une au-dessus de 800 nm (fig. 2, courbe 3), modification qui peut être due à plusieurs causes. Celle qui se vérifie cependant, expérimentalement, est la disproportion du Mn(III) et la formation du Mn(IV), auquel on peut attribuer ces bandes.

En effet, théoriquement, ces complexes du Mn(IV), un cas d^3, dans la symétrie O_h présentent 3 bandes d'absorption champ cristallin, correspondant aux transitions ${}^4T_{2g} \leftarrow {}^4A_{2g}$, ${}^4T_{1g}(F) \leftarrow {}^4A_{2g}$ et ${}^4T_{1g}(P) \leftarrow$ $\leftarrow {}^4A_{2g}$.

Le Mn_2O_3 est dissous dans la solution de l'acide aniline-4 sulphonique et présente un spectre ressemblant à celui des complexes du Mn(IV), preuve de la disproportion du Mn(III) dans ces conditions.

Le Mn O_2, dissous dans la solution de l'acide aniline-4 sulphonique, présente le spectre caractéristique des complexes du Mn(IV) — fig. 2, courbe *4* — preuve que, dans cette réaction, le manganèse ne change pas d'état d'oxydation.

Pour les spectres enregistrés, à la longue, sur une solution avec le système $[Mn(H_2O_2O_7)_3]^{3-}—L$, on observe un point isosbestique qui marque la disproportion du Mn(III) en Mn(IV) et l'ion Mn^{2+} (fig. 3).

Dans le cas d'éventuels complexes du Mn(II), dans la symétrie O_h, les transitions sont Laporte et spin interdites et, selon les tests effectués, leurs spectres ne sont pas perceptibles dans les systèmes étudiés.

La composition des complexes du Mn(IV) des systèmes Mn(III, IV)—L a été établie par spectrophotométrie et les résultats obtenus par la méthode des rapports molaires [28] sont présentés sur les figures 4 et 5.

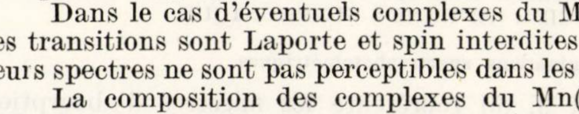

Fig. 3. — Spectres enregistrés à la longue sur le système 1 $[Mn(H_2P_2O_7)_3]^{3-}$ — 2L, conc. Mn(III) : $6{,}76.10^{-3}$ moles/l. *1*, $t = 2'$; 10 — t = 66' ; cuve 0,1 cm ; temp. = 21°.

---

[28] J. Joe et A. Jones, *Ind. Eng. Chem. Analyt. Ed.*, **16**, 11 (1944).

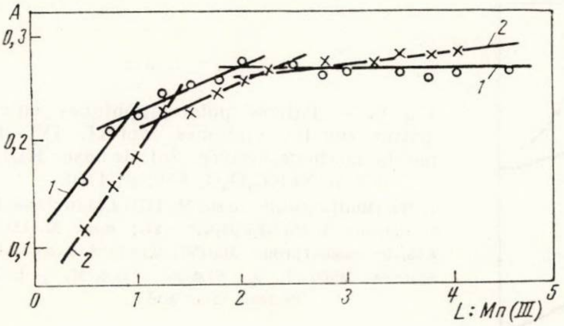

Fig. 4. — Composition des ions complexes du système $[Mn(H_2P_2O_7)_3]^{3-}$ — — L par la méthode des rapports molaires; conc. Mn(III) : 1,6.10^{-3} moles/l ; conc. Mn(IV) : 0,80.10^{-3} moles/l ; cuve 0,2 cm.
1, t = 5' ; λ = 490nm ; 2, t = 120' ; λ=411 nm.

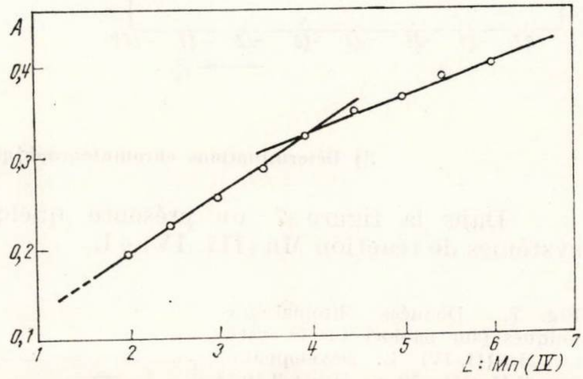

Fig. 5. — Composition de l'ion complexe du système MnO_2—L par la méthode des rapports molaires; conc. Mn (IV) : 8,33.10^{-4} moles/l ; cuve 0,5 cm ; λ=396 nm ; t=72 h.

Dans le cas des réactifs avec le Mn(III), la concentration des complexes avec le Mn(IV)- obtenus par disproportio—nest la moitié de celle totale en manganèse. On a fait abstraction de l'ion Mn^{2+}.

Ainsi, dans le premier système (fig. 4), on admet les complexes pour les rapports : 1 Mn(IV) : 2L et 1 Mn (IV) : 4L.

Dans le système avec MnO_2 comme réactif, (fig. 5), le complexe pour le rapport 1 Mn(IV) : 4L, noté MnL_4, est évident.

La stabilité de ce dernier complexe a été déterminée par la méthode Edmonds-Birnbaum [29] et on a obtenu $\beta_4 = 2{,}80.10^{16} 1/mole^{-1}$.

2) Déterminations polarographiques

Dans la figure 6, on représente quelques polarogrammes enregistrés par la méthode dérivée, sur des solutions de l'ion $[Mn(H_2P_2O_7)_3]^{3-}$, de même que sur des solutions des systèmes de réaction Mn(III, IV)—L.

On constate que, à l'addition du ligand, le palier caractéristique de l'ion $[Mn(H_2P_2O_7)_3]^{3-}$ avec $E_{1/2} = -1{,}08$ v subit des modifications. À sa place, apparaîssent 2 paliers : l'un pour —0,27 v, commun avec celui du complexe obtenu dans le système MnO_2—L et l'autre pour —1,24 v, commun avec l'ion Mn^{2+}.

Ces résultats confirment le processus de disproportion susmentionné.

---

[29] S. Edmonds et N. Birnbaum, *J. Amer. Chem. Soc.*, **63**, 1471 (1941).

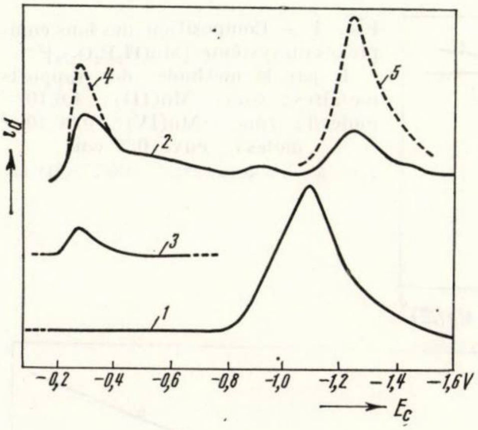

Fig. 6. — Paliers polarographiques enregistrés sur les systèmes Mn(III, IV)—*L* par la méthode dérivée. Sol. de base : KOH 6M et $NaKC_4H_4O_6$ 6M ; s : 1/10.

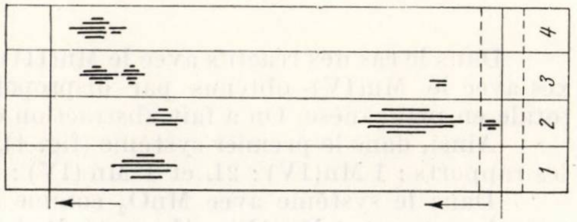
1, Ion $[Mn(H_2P_2O_7)_3]^{3-}$; conc. Mn(III) : $4,35.10^{-3}$ mole/l. *2*, Système 1 $[Mn(H_2P_2O_7)_3]^{3-}-2L$; conc. Mn(III) : $4,35.10^{-3}$ moles/l ; conc. Mn(IV) : $2,18.10^{-3}$ moles/l. *3*, Système MnO_2-L. *4*, Système (2) + MnO_2-L. *5* Système (2) + Mn^{2+}

3) Déterminations chromatographiques (sur papier)

Dans la figure 7 on présente quelques chromatogrammes des systèmes de réaction Mn (III, IV)—L.

Fig. 7. — Données chromatographiques (sur papier) sur le système Mn(III, IV)—L. Développant : 50p. C_2H_5OH+50 p. H_2SO_4 2.10^{-2} moles/l. Papier Whatman n° 1.

1, Mn^{2+} ; $R_F \sim 0,80$; KOH + H_2O_2 ; brun ; *2*, Mn^{2+} + $[Mn^{III}(H_2P_2O_7)_3]^{3-}$; Mn^{2+} : $R_F \sim 0,75$; KOH + H_2O_2 ; brun ; Mn(III) : $R_F \sim 0,20$ rouge ; KI (H+) et amidon : bleu. *3*, 1 $[Mn(H_2P_2O_7)_3]^{3-} -2L$ (2h) ; Mn^{2+} = R_F 0,83 ; KOH + H_2O_2 : brun ; Mn(IV) : $R_F \sim 0,90$ rouge. *4*, $1MnO_2-4L$; Mn^{2+} ; $R_F \sim 0,85$; KOH + H_2O_2 : brun (traces) ; Mn (IV) : $R_F \sim 0,90$; rouge-orange.



On constate que le spot caractéristique de l'ion $[Mn(H_2P_2O_7)_3]^{3-}$ avec $R_F \sim 0,20$ est presque effacé dans le système de réaction $[Mn(H_2P_2O_7)_3]^{3-}$ — L. À sa place apparaissent deux spots : l'un avec $R_F \sim 0,90$, commun avec celui du complexe obtenu dans le système MnO_2—L et l'autre avec $R_F \sim 0,83$, commun avec l'ion Mn^{2+}.

Les spots sont en grande mesure superposables, mais différenciés à l'aide d'une réaction de couleur. Les identifications des composés du Mn(IV) et du Mn(II) constituent, de même, des arguments en faveur du processus de disproportion.

D) LA CINÉTIQUE DU PROCESSUS DE DISPROPORTION DU Mn(III)

Dans le tableau 1 on présente les données cinétiques, obtenues dans l'étude du processus de disproportion du Mn(III) dans le système $[Mn(H_2P_2O_7)_3]^{3-}$ — L.

La variation, à la longue, de la concentration des composés du Mn(IV) et du Mn(III) a été déterminée sur la base des relations [30]:

$$A_1 = x\varepsilon_{\mathrm{Mn(III)}}\lambda_1 + y\varepsilon_{\mathrm{Mn(IV)}}\lambda_1$$

$$A_2 = x\varepsilon_{\mathrm{Mn(III)}}\lambda_2 + y\varepsilon_{\mathrm{Mn(IV)}}\lambda_2$$

où A_1 et A_2 = les absorbances du système pour λ_1 et respectivement λ_2; ε Mn(III) λ_1 et ε Mn(IV) λ_1 = les coefficients molaires d'absorption pour λ_1 et pour λ_2; x=la molarité en Mn(III) et y=la molarité en Mn(IV).

Le processus de transfert électronique suit donc une loi de vitesse du premier ordre et la voie de la réaction passe par un complexe activé qui contient les réactifs.

E) LE SPECTRE ÉLECTRONIQUE DU COMPLEXE $[MnL_4]$

Dans les complexes du Mn(IV), se réalise une configuration octaédrique, configuration qu'on admet aussi pour le complexe $[MnL_4]$, obtenu par la dissolution du MnO_2 dans l'acide aniline-4-sulphonique. Dans ce cas, le ligand est coordiné par des groupements $-NH_2$ et $-SO_3H$, et la microsymétrie de l'ion complexe est inférieure à celle O_h. Elle peut être D_{4h}, C_{2v}, etc.

Malgré cela, le complexe a un spectre champ cristallin caractéristique de la microsymétrie O_h, ce qui prouve que, dans la symétrie plus basse, la scission des niveaux dégénérés est petite et n'apparaît pas dans le spectre.

Dans les tableaux 2 et 3, on présente les données caractéristiques des bandes d'absorption du spectre électronique du complexe MnL_4, obtenu dans le système MnO_2-L.

Dans la région étudiée en UV, l'acide aniline-4 sulphonique présente 3 bandes d'absorption, notées ν_1, ν_2, et ν_3. Les bandes ν_1 et ν_2 sont dues à des transitions $\pi^* \leftarrow \pi$ et celle ν_3 est due à une transition $\pi^* \leftarrow n$. Les mêmes bandes d'absorption sont retrouvées dans le complexe $[MnL_4]$, avec de très petits déplacements hypsochromiques ou batochromiques. Pour $\lambda \sim 283$ nm, il se précise un point isosbestique.

Donc, dans le spectre UV du complexe $[MnL_4]$, les bandes d'absorption caractéristiques du ligand sont dominantes.

Dans le domaine visible, apparaissent les bandes de type cristallin du complexe $[MnL_4]$. Elles sont interprétées sur la base du diagramme des niveaux énergétiques propres au cas d^3 dans la symétrie O_h.[31]

Les valeurs des coefficients molaires d'absorption pour les bandes champ cristallin du complexe $[MnL_4]$ sont plus élevées que celles communes à des spectres champ cristallin. Cela est dû, entre autres, à l'état élevé d'oxydation du générateur de complexe.

Le paramètre champ cristallin 10 D_q et celui néphélauxétique β_{35} ont été calculés par une méthode graphique,[31] à la base des représentations :

$$\nu_m/\nu_n = f(Dq/B) \quad \text{et}$$

$$\nu_3/\nu_n = f(E\nu_3/B)$$

où $m = 2,3$; $n = 1,2$; $E\nu_3$ = l'énergie de la bande avec $\lambda_{max} = 25600$ cm^{-1}; B = le paramètre Racah.

CONCLUSIONS

— Les composés $[Mn(H_2P_2O_7)_3]^{3-}$, Mn_2O_3 et MnO_2 réagissent avec la solution de l'acide aniline-4-sulphonique et forment certains composés du Mn(IV). Dans le cas des réactifs avec le Mn(III), les complexes sont obtenus à la suite d'un processus de disproportion du Mn(III) en Mn(IV) et l'ion Mn^{2+}.

L. MITTEILUNG.

POTENTIOMETRISCHE BESTIMMUNG DER ACIDITÄTSKONSTANTEN VON 4-HYDROXY-6-OXIMINTETRAHYDROTRIAZINYL-2-FORMALDOXIM

EUGENIA GAVRILĂ und ION CĂDARIU
Lehrstuhl für physikalische Chemie der Babeş-Bolyai Universität
Cluj-Napoca, str. Arany János 11

Eingegangen 13. Mai 1974

Die potentiometrische Titration von 4-Hydroxy-6-oximintetrahydrotriazinyl-2-formaldoxim zeigt, daß eine tribasische Säure vorliegt, deren Ionisierungsstufen sich überlappen. Aus der Titrationskurve wurden durch nacheinanderfolgende Näherungen unter Verwendung zweier Rechenmethoden (nach Ong und nach Bjerrum) die thermodynamischen Aciditätskonstanten erhalten, deren Werte bei Zimmertemperatur $pK_{a2} = 7{,}7$, $pK_{a3} = 9{,}9$ und $pK_{a4} = 10{,}9$ betragen. Mit Hilfe dieser Konstanten konnten die Extinktionskoeffizienten der entsprechenden Ionen berechnet werden; es wurden auch – unter Verwendung der Daten aus einer früheren Mitteilung – die Punkte der spektrophotometrischen Titrationskurve neu berechnet.

ALLGEMEINES

Für die spektrophotometrische Untersuchung des Eisen(III)-Komplexes von 4-Hydroxy-6-oximintetrahydrotriazinyl-2-formaldoxim (Kurzbezeichnung: Dioxim) war die Kenntnis der Aciditätskonstanten notwendig. Da die Substanz schwer löslich ist, hofften wir, daß die spektrophotometrische Methode zu genügend genauen Ergebnissen für die Werte dieser Konstanten führen wird.

Das UV-Spektrum des Dioxims ändert sich in Abhängigkeit von der Art des Mediums [1]; die graphische Darstellung der Abhängigkeit der Extinktion vom pH-Wert ergibt eine Kurve mit 3 Stufen bzw. Bereichen, in denen die Extinktion pH-unabhängig ist. In diesen Bereichen existiert die Substanz in einer einzigen Form:

$$\begin{array}{lll} \text{protoniertes Dioxim} & \text{bei pH} \cong 0 & \\ & & pK_{a1} = 1{,}6 \\ \text{neutrales Dioxim} & \text{bei pH} = 3 \text{ bis } 7{,}5 & \\ & & pK_{a2} = 9{,}2 \\ \text{Dioximanion} & \text{bei pH} > 11 & \end{array}$$

[1] I. CĂDARIU, E. GAVRILĂ und G. NIAC, *Z. phys. Chem.* (*Leipzig*), **242**, 391 (1969).

Es hat uns überrascht, daß eine zweite Säurefunktion des Oxims nicht in Erscheinung trat, um so mehr als A. Ostrogovich und I. Cădariu das Dinatriumsalz des Oxims isolieren konnten.[2]

Wir kamen zu der Vermutung, daß die zwei anionischen Formen wahrscheinlich bei derselben Wellenlänge absorbieren, oder aber die zwei verschiedenen Wellenlängen sehr dicht beieinander liegen, und dementsprechend auch die Werte der Aciditätskonstanten sich nur minimal unterscheiden.

Allerdings, das Einsetzen der Spektraldaten in die lineare Gleichung des Ausdruckes $\log \frac{\alpha}{1-\alpha}$ in Abhängigkeit von pH, wobei die erhaltene Steigung die Zahl der aus der Dissoziation entstandenen H^+-Ionenen ergibt, führt zu einem Wert von 0,8, und die einzelnen Punkte zeigen eine relativ große Streuung. Diese Tatsachen berechtigen die Annahme, daß der spektrophotometrisch bestimmte Wert für pK_{a2} eine zusammengesetzte Größe ist.

Für den Fall, in dem mittels Spektrum die molekularen Spezies nicht einzeln identifizierbar sind, ist es üblich, elektrometrische Methoden zu benutzen. Wir haben in unserem Fall potentiometrische Messungen durchgeführt.

EXPERIMENTELLER TEIL

Die Dioximlösung—mit einer Konzentration von $1{,}8436.10^{-3}$ M—wurde durch Lösen der Festsubstanz (auf Mikrowaage gewogen) in bidestilliertem, CO_2-freiem Wasser, hergestellt. Um die protonierte Form zu erhalten, wurde die Dioximlösung mit einer 0,103 M $HClO_4$-Lösung titriert; dann wurde diese mit einer 0,1037 M NaOH-Lösung und zum Schluß wieder mit $HClO_4$-Lösung zurück titriert.

Die $HClO_4$- bzw. NaOH-Lösungen wurden durch Verdünnen der 70%-igen $HClO_4$-Lösung p.a. bzw. einer — aus NaOH p.a. hergestellten gesättigten NaOH-Lösung mit bidestilliertem, CO_2-freiem Wasser erhalten.

Die EMK-Kette bestand aus einer gesättigten Kalomel-Bezugselektrode und einer Wasserstoff-Meßelektrode. Die EMK wurde mit einem Potentiometer QLK-Metra gemessen. Die Messungen wurden bei 24—24,5°C durchgeführt.

Zur Titration wurden 10 ml Dioximlösung vorgelegt. Es wurde eine Mikrobürette verwendet, die gegen CO_2- Eintritt aus der Luft geschützt wurde.

Die Messungen wurden auch mit einer Glaselektrode durchgeführt, und die Ergebnisse waren identisch mit denen, die mit der Wasserstoffelektrode erhalten wurden. Für die Diskussion der Ergebnisse wurden die mit der Wasserstoffelektrode durchgeführten Messungen vorgezogen, weil für die spektrophotometrischen Bestimmungen auch die Wasserstoffelektrode verwendet wurde, und außerdem sind mit der H_2-Elektrode größere pH-Werte zugänglich.

DISKUSSION UND ERGEBNISSE

Aus der Tirationskurve —Abb. 1 — ist ersichtlich, daß das protonierte Dioxim vier Ionisierungsstufen aufweist. Die Ionisierung des ersten Protons ist vollständig, und die erste Stufe ist deutlich ausgebildet, so wie auch aus den spektrophotometrischen Messungen hervorgeht[1]. Die anderen Ionisierungsstufen überlappen sich, da die folgenden Ionisierungskonstanten sich wenig unterscheiden.

Wenn man die umgekehrte Titration durchführt (Titration des dreiwertigen Dioximanions mit $HClO_4$), stellt man fest, daß die erhaltene

Kurve sich nicht mit der Kurve der Direkttitration deckt; es besteht also eine Hysteresis, die wahrscheinlich den tautomeren Umwandlungen im alkalischen Medium zuzuschreiben ist. Infolgedessen sind die Konstanten K_{a2}, K_{a3} und K_{a4} mit einem Bestimmungsfehler von etwa 0,4 pK_a-Einheiten behaftet.

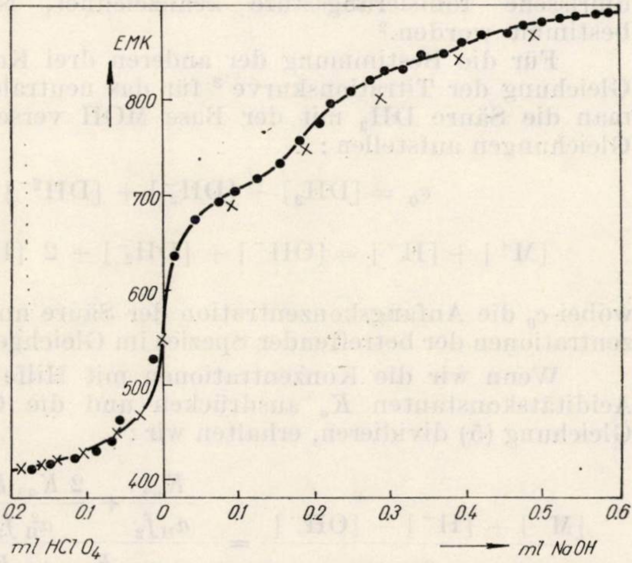

Abb. 1. — Änderung der EMK in Abhängigkeit von dem Titrierlösungsvolumen. $c_0 = 1{,}84 \cdot 10^{-3}$ M, (●) — 0,1 N NaOH-Lösung, (×) — 0,1 N HClO$_4$-Lösung.

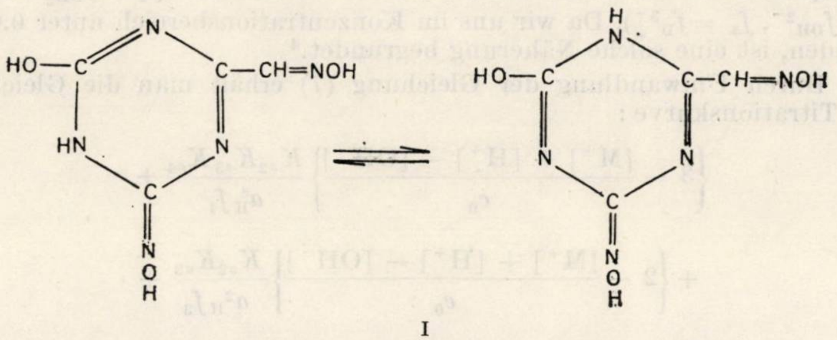
Wenn man annimmt, daß die Oxo-Gruppe des Dioxims im alkalischen Medium enolisiert (I), existieren drei ionisierbare H-Atome, und wir werden dementsprechend das Dioxim kurz DH_3 bezeichnen (und nicht DH_2 wie in der Mitteilung[1]).



I

Das Dioxim ist also eine poliprotische Säure, die folgende Gleichgewichte aufweisen kann:

$$DH_4^+ \xrightleftharpoons{K_{a1}} DH_3 + H^+ \tag{1}$$

$$DH_3 \xrightleftharpoons{K_{a2}} DH_2^- + H^+ \tag{2}$$

$$DH_2^- \xrightleftharpoons{K_{a3}} DH^{2-} + H^+ \tag{3}$$

$$DH^{2-} \xrightleftharpoons{K_{a4}} D^{3-} + H^+ \tag{4}$$

Die thermodynamische Konstante K_{a1}, die die erste, deutlich umrissene Ionisierungsstufe kennzeichnet, ist spektrophotometrisch bestimmt worden.[2]

Für die Bestimmung der anderen drei Konstanten werden wir die Gleichung der Titrationskurve [3] für das neutrale Dioxim ableiten. Wenn man die Säure DH_3 mit der Base MOH versetzt, lassen sich folgende Gleichungen aufstellen :

$$c_0 = [DH_3] + [DH_2^-] + [DH^{2-}] + [D^{3-}] \tag{5}$$

$$[M^+] + [H^+] = [OH^-] + [DH_2^-] + 2\ [DH^{2-}] + 3\ [D^{3-}] \tag{6}$$

wobei c_0 die Anfangskonzentration der Säure und die Klammer die Konzentrationen der betreffender Spezies im Gleichgewicht bedeuten.

Wenn wir die Konzentrationen mit Hilfe der thermodynamischen Aciditätskonstanten K_a ausdrücken und die Gleichung (6) durch die Gleichung (5) dividieren, erhalten wir :

$$\frac{[M^+] + [H^+] - [OH^-]}{c_0} = \frac{\dfrac{K_{a2}}{a_H f_2} + \dfrac{2\ K_{a2} K_{a3}}{a_H^2 f_3} + \dfrac{3\ K_{a2} K_{a3} K_{a4}}{a_H^3 f_4}}{1 + \dfrac{K_{a2}}{a_H f_2} + \dfrac{K_{a2} K_{a3}}{a^2_H f_3} + \dfrac{K_{a2} K_{a3} K_{a4}}{a_H^3 f_4}} \tag{7}$$

wobei a_H die Protonenaktivität und f der für die Ionenstärke am Halbstufenpotential berechnete Aktivitätsfaktor bedeutet ($f_2 \equiv f_{DH_2^-} \equiv f_{H^+}$, $f_3 \equiv f_{DH^{2-}}$, $f_4 = f_{D^{3-}}$). Da wir uns im Konzentrationsbereich unter 0,01 M befinden, ist eine solche Näherung begründet.[4]

Durch Umwandlung der Gleichung (7) erhält man die Gleichung der Titrationskurve :

$$\left\{3 - \frac{[M^+] + [H^+] - [OH^-]}{c_0}\right\} \frac{K_{a2} K_{a3} K_{a4}}{a_H^3 f_4} +$$

$$+ \left\{2 - \frac{[M^+] + [H^+] - [OH^-]}{c_0}\right\} \frac{K_{a2} K_{a3}}{a^2_H f_3} +$$

$$+ \left\{1 - \frac{[M^+] + [H^+] - [OH^-]}{c_0}\right\} \frac{K_{a2}}{a_H f_2} = \frac{[M^+] + [H^+] - [OH^-]}{c_0} \tag{8}$$

[4] "Physical Methods in Heterocyclic Chemistry", vol. I, cap. I, Ed. A. R. Katritzky, Academic Press, New York, 1963.

wobei der Ausdruck $\frac{[M^+] + [H^+] - [OH^-]}{c_0} = h^*$ die Anzahl der von der mehrbasischen Säure in Freiheit gesetzten Protonen und das Verhältnis $\frac{[M^+]}{c_0} = \bar{h}$ die mittlere theoretische Anzahl der von der zugesetzten Base verbrauchten Protonen bedeutet.

Die Titrationskurve des unprotonierten Dioxims, die aus der Gleichung : $h^* = f(-\log[H^+])$ hervorgeht, ist im Abb. 2 wiedergegeben.

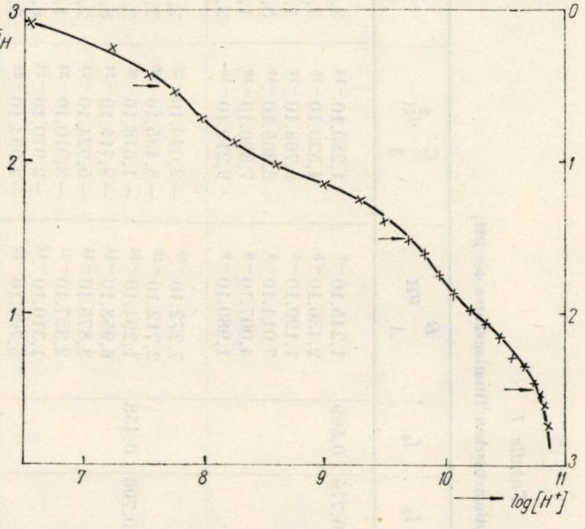

Abb. 2. — Titrationskurve des DH_3 in h^*, $\bar{n}_H$-Koordinaten, in Abhängigkeit vom $-\log$ $[H^+]$.

Gekürzt kann die Gleichung (8) in folgender Form geschrieben werden :

$$A\, K_{a2}K_{a3}K_{a4} + B\, K_{a2}K_{a3}\, a_H + C\, K_{a2}\, a_H^2 = D\, a_H^3 \tag{9}$$

wobei :

$$A = \{(3 - \bar{h})\, c_0 - [H^+] + [OH^-]\}\, \frac{1}{f_4} = \frac{(3 - h^*)}{f_4} \tag{10}$$

$$B = \{(2 - \bar{h})\, c_0 - [H^+] + [OH^-]\}\, \frac{1}{f_3} = \frac{(2 - h^*)}{f_3} \tag{11}$$

$$C = \{(1 - \bar{h})\, c_0 - [H^+] + [OH^-]\}\, \frac{1}{f_2} = \frac{(1 - h^*)}{f_2} \tag{12}$$

$$D = \bar{h}\, c_0 + [H^+] - [OH^-] = h^* \tag{13}$$

Für Säuren mit mehr als zwei ionisierbaren H-Atomen—und besonders für solche, deren Ionisierungsstufen sich überlappen—ist die Gleichung sehr schwer aufzulösen.

Ong (^{3} s 227) berechnet unter Anwendung nacheinanderfolgender Näherungen aus der Titrationskurve die Konstanten der Pyridin-pentacarboxylsäure. Wir verwendeten ein analoges Verfahren.

Die einzelnen Daten (auch die berechneten) für die Titrationskurve sind in der Tabelle 1 enthalten.

Aus dem Endabschnitt der Titrationskurve ermittelt man einen ungefähren Wert für die Konstante K_{a4}. Für diesen Abschnitt (die Bestimmungen 21 — 18) ist die H^+ - Ionenaktivität klein, und die Größen a_H^2 und a_H^3 können vernachlässigt werden; die Gleichung (9) nimmt dann die Form an:

$$K_{a3} K_{a4} + \frac{B}{A} K_{a3}\, a_H \approx 0 \qquad (14)$$

Es ergibt sich:

$$K_{a4} \approx -\frac{B}{A} a_H \qquad (15)$$

Den so erhaltenen Wert K_{a4} führen wir in die Gleichung (14) ein, die diesmal für den nächstfolgenden Abschnitt der Titrationskurve (Bestimmungen 17 — 15) angewandt wird; wir erhalten somit einen ersten Wert für K_{a3}. Diesen K_{a3} - Wert führen wir in die Gleichung (14) ein, die wieder für den Endabschnitt der Titrationskurve geschrieben wird, und wir erhalten einen K_{a4} - Wert in der zweiten Näherung.

Mit den so erhaltenen Werten für K_{a3} und K_{a4} bestimmen wir einen ersten Wert für K_{a2} (Bestimmungen 6—4). Die Näherungen für die Berechnung der Konstanten werden—vom Endabschnitt zum Aufangsabschnitt der Titrationskurve ausgehend — weiter fortgesetzt, bis die erhaltenen Werte konvergieren. Wir haben festgestellt, daß die Streuung der berechneten Werte in folgenden $\bar{h}$-Bereichen am kleinsten sind: 0,5 — 1 für K_{a2}, 1,5 — 2 für K_{a3} und 2,5 — 3 für K_{a4}.

Die erhaltenen Daten sind in Tabelle 2 zusammengefaßt; die stark abweichenden Werte wurden zur Ermittlung des Mittelwertes nicht berücksichtigt.

Tabelle 2

Werte der Säurekonstanten des DH_3

	K_{a2}	K_{a3}	K_{a4}
Ong Methode	$1{,}9.10^{-8}$	$1{,}3.10^{-10}$	$1{,}0.10^{-11}$
Bjerrum Methode	$1{,}7.10^{-8}$	$1{,}1.10^{-10}$	$1{,}2.10^{-11}$
Mittelwerte	$1{,}8.10^{-8}$	$1{,}2.10^{-10}$	$1{,}1.10^{-11}$

Einen anderen Rechnungsweg bietet die Methode nach Bjerrum; die Bezugssubstanz ist in diesem Falle die total unprotonierte Form D^{3-}.

Man rechnet mit der Bildungsfunktion $\bar{n}_H$, deren Wert die mittlere Anzahl der durch die mehrbasische Säure gebundenen Protonen ausdrückt:

$$\bar{n}_H = \frac{3\,c_0 - [H^+] + [OH^-] - [M^+]}{c_0} \tag{16}$$

Durch die Darstellung von $\bar{n}_H$ in Abhängigkeit von $(-\log[H^+])$ erhält man dieselbe Titrationskurve — Abb. 2 — wie im Falle der Darstellung von h^* in Abhängigkeit von $(-\log[H^+])$, lediglich der Nullpunkt ist verschoben, da die Beziehung $\bar{n}_H = 3 + h^*$ gilt.

Die Halbstufenpotentiale liefern die ersten ungefähren Werte für die Aciditätskonstanten, die—mittels Konzentrationen bei der entsprechenden Ionenstärke ausgedrückt—folgendes ergeben:

$$(K_2)_{\bar{n}=0,5} = 2.10^{-8} \quad (K_3)_{\bar{n}=1,5} = 2.10^{-10} \quad (K_4)_{\bar{n}=2,5} = 1,7.10^{-11}$$

Wenn wir diese ersten Werte in die Konstantenausdrücke [5]:

$$K_2 = \left(\frac{1}{[H^+]}\right)_{\bar{n}=0,5} \frac{1}{1 + 3\,K_3\,[H^+]_{\bar{n}=0,5} + 5\,K_2 K_3 [H^+]^2_{\bar{n}=0,5}} \tag{17}$$

$$K_3 = \left(\frac{1}{[H^+]}\right)_{\bar{n}=0,5} \frac{1 + \dfrac{3}{K_2\,[H^+]_{\bar{n}=0,5}}}{1 + 3\,K_4\,[H^+]_{\bar{n}=1,5}} \tag{18}$$

$$K_4 = \left(\frac{1}{[H^+]}\right)_{\bar{n}=2,5} \left(1 + \frac{3}{K_3[H^+]_{\bar{n}=2,5}} + \frac{5}{K_2 K_3\,[H^+]_{\bar{n}=2,5}}\right) \tag{19}$$

einführen, erhalten wir die ungefähren Konstantenwerte, die wieder in die obigen Ausdrücke eingeführt werden. Das Verfahren wird wiederholt, bis die erhaltenen Werte konvergieren; in unserem Fall ist die Konvergenz bei folgenden Werten erreicht:

$$K_2 = 1,9.10^{-8} \; K_3 = 1,5.10^{-10} \; K_4 = 2,2.10^{-11}$$

Unter Verwendung folgender Beziehungen:

$$K_{a2} = K_2 f_2^2 \; K_{a3} = K_3 f_3 \text{ und } K_{a4} = K_4 \frac{f_4 f_2}{f_3} \tag{20}$$

können dann die thermodynamischen Aciditätskonstanten berechnet werden; die erhaltenen Werte sind in Tabelle 2 zusammengefaßt, und sie sind in befriedigender Übereinstimmung mit den nach der Methode von Ong berechneten Werten.

---

[5] C. Luca und O. Enea, "Determinarea constantelor analitice", Ed. didactică şi pedagogică, Bukarest, 1971, S. 46.

Um die Ergebnisse zu überprüfen, haben wir die Extinktionskoeffizienten (ε) aller Dioximspezien und daraus die spektrophotometrische Titrationskurve im alkalischen Medium berechnet.

Da die Extinktion (E) additiv ist, kann man folgende Gleichung aufstellen :

$$\frac{E}{\mathrm{d}} = [\mathrm{DH_3}]\ \varepsilon_1 + [\mathrm{DH_2^-}]\ \varepsilon_2 + [\mathrm{DH^{2-}}]\ \varepsilon_3 + [D^{3-}]\ \varepsilon_4 \qquad (21)$$

Wenn man die Konzentrationen durch die Konstanten K_2, K_3 und K_4 bei der gegebenen Ionenstärke ausdrückt und die Beziehungen (20) berücksichtigt, wandelt sich die Gleichung (21) zu :

$$\frac{E}{\mathrm{d}} = [\mathrm{DH_3}]\left[\varepsilon_1 + \frac{K_2}{[\mathrm{H^+}]}\varepsilon_2 + \frac{K_2K_3}{[\mathrm{H^+}]^2}\varepsilon_3 + \frac{K_2K_3K_4}{[\mathrm{H^+}]^3}\varepsilon_4\right] \qquad (22)$$

Gleichung (22) dividiert durch die Gleichung (5) und zweckmäßig umgeordnet führt zu der Gleichung :

$$\frac{E}{\mathrm{d}\,c_0}\left([\mathrm{H^+}]^2 + K_2[\mathrm{H^+}] + K_2K_3 + \frac{K_2K_3K_4}{[\mathrm{H^+}]}\right) - \varepsilon_1\ [\mathrm{H^+}]^2 - \frac{K_2K_3K_4\,\varepsilon_4}{[\mathrm{H^+}]} = \qquad (23)$$

$$= K_2\varepsilon_2\ [\mathrm{H^+}) + K_2K_3\ \varepsilon_3$$

wobei d die Küvettendicke darstellt.

Die Werte der Extinktionskoeffizienten für das neutrale Dioxim — ε_1 und für das völlig unprotonierte Dioxim — ε_4 können aus der Extinktion der waagerechten Abschnitte der Kurve $E = f(\mathrm{pH})$ [1] berechnet werden ; mit d $= 2{,}003$ cm und $c_0 = 4 . 10^{-5}$ Mol/1 erhält man folgende Werte :

$\lambda = 280$ nm $\quad \varepsilon_1 = 3250 \quad \varepsilon_4 = 18750$ l.mol^{-1}. cm^{-1}
$\lambda = 350$ nm $\quad \varepsilon_1 = 3150 \quad \varepsilon_4 = \quad 1337$ ”

Mit Hilfe dieser Werte und denen der Aciditätskonstanten bei der Ionenstärke $J = 0{,}3$:

$$K_2 = 3{,}57 . 10^{-8} \quad K_3 = 4{,}72 . 10^{-10} \quad K_4 = 8{,}57 . 10^{-11}$$

kann man das erste Glied der Gleichung (22) berechnen.

Diese Funktion, die von $[\mathrm{H^+}]$ linear abhängig ist, werden wir mit F bezeichnen. Die den zwei Wellenlängen entsprechenden Daten sind in der Tabelle 3 zusammengefaßt.

Tabelle 3

Ergebnisse bezüglich der berechneten spektrophotometrischen Titrationskurve

pH	$[H^+]$	$\lambda = 280$ nm F.10^{13}	 E_{exp}	 E_{ber}	$\lambda = 350$ nm F.10^{13}	 E_{exp}	 E_{ber}
8,32	$6{,}75.10^{-9}$	22,4	(0,630)	0,666	6,9	0,220	0,206

Received April 16, 1974

A new series of Cu(II) coordination compounds with biguanide derivatives of the type: [Cu $(RBig)_2$] $(SeCN)_2$ and $CuRBig(SeCN)_2$ where RBig = N^1-dimethylbiguanide, N^1-morpholinbiguanide, N^1-phenylbiguanide, N^1-*p*-chlorophenylbiguanide, N^1-*p*-tolylbiguanide, N^1-*p*-chlorophenyl-N^5-isopropylbiguanide, have been studied. The compounds were characterized by chemical elementary analysis, IR and electronic spectra, electric conductivity measurements, magnetic susceptibility and EPR spectra. From these data and by correlating the electronic spectral parameters with those of the EPR spectra, information on the structure and the chemical bonding was obtained.

I. INTRODUCTION

The study of Cu(II) selenocyanate complexes is of a special interest due to the fact that the SeCN group can function as a monodentate bifunctional ligand. The literature mentions rather few papers on the Cu(II) selenocyanate complexes. The first indications signal out [Cu en_2] $(SeCN)_2$ formations.[1,2] In 1964, $[Cu(NH_3)_4]$ $(SeCN)_2 . H_2O$ was obtained.[3] Subsequently [4–6] other compounds of the type: $[CuA_2](SeCN)_2$ and CuA_2SeCNX where A = substituted diamines, and X = NO_3^-, ClO_4^-, were also studied. With the $CuMBen_2(SeCN)$ (NO_3) it was signalled out that the SeCN group will be in a bridge. There are also indications about the existence of $CuHg(SeCN)_4$ [7].

We considered interesting to extend the study on the Cu(II) selenocyanate complexes, using as ligands, biguanide derivatives π donors, which can stabilize transition metals in the high valence states.

In the present paper we continue our study concerning Cu(II) coordination compounds with substituted biguanides [8-10] presenting the synthesis and the study by electronic, IR, and EPR spectra, magnetic and conductometric measurements on some new Cu(II) selenocyanate complexes of the type: $[Cu(RBig)_2](SeCN)_2$ and $Cu(RBig)(SeCN)_2$.

II. EXPERIMENTAL

a. Chemical procedures. We used $CuCl_2 \cdot 2H_2O$ Merck *p.a.*,KSeCN prepared by the method indicated by literature [11] and the following biguanide derivatives (RBig):
N^1-dimethylbiguanide ($C_4H_{11}N_5$), Me_2Big;
N^1-morpholinbiguanide ($C_6H_{13}N_5O$), MorBig;
N^1-phenylbiguanide ($C_8H_{11}N_5$), PhBig;
N^1-*p*-chlorophenylbiguanide ($C_8H_{10}N_5Cl$), ClPhBig;
N^1-tolylbiguanide ($C_9H_{13}N_5$), TolBig;
N^1-*p*-chlorophenyl-N^5-isopropylbiguanide ($C_{11}H_{16}N_5Cl$), Pald.

$[Cu(RBig)_2](SeCN)_2$ compounds could be obtained by 3 methods: either by a direct method in aqueous medium, at pH = 8, from $CuCl_2 \cdot 2H_2O$, RBig and KSeCN in a molar ratio 1 : 2 : 2, or by the exchange reaction between $[Cu(RBig)_2]Cl_2$ and KSeCN in aqueous or alcoholic medium, or by mixing $Cu(RBig)Cl_2$ with KSeCN molar ratio 1 : 2, 1 in acetone or DMF medium, at pH = 8. By these 3 methods, the same pink products noted with 1—6 in table 1, hardly soluble in water, ethanol, and partly soluble in acetone and DMF, were obtained.

Table

$CuRBig(SeCN)_2$ compounds were obtained by the action of KSeCN on $Cu(RBig)Cl_2$, molar ratio 2,1 : 1, in ethanol or DMF medium. Filtered solutions were immediately treated with alkalinized water (pH = 7.5) when brown precipitates were separated. They were filtered, washed with water after which they were dried in vacuum. The brown selenocyanates noted with 7—11 in table 1 are hardly soluble in water, ethanol, ether, and very slightly soluble in DMF and DMSO.

b. Instrumentation.

IR spectra were recorded in the range 3400—400 cm^{-1} with a spectrophotometer UR—10 Zeiss Jena, using the pelleted powder method.

Electronic spectra of DMF solutions in visible and UV were recorded with a VSU_1 Universal spectrophotometer (Zeiss Jena).

Reflectance spectra were recorded with the same apparatus either on pure compounds or on dilutions with MgO.

EPR spectra were obtained by using an X band spectrograph with high frequency field modulation (100 kHz).

Polycrystalline powder, samples magnetically diluted with $[Zn(RBig)_2](SeCN)_2$ and $PdRBig(SeCN)_2$ as well as DMF solution were used. In order to determine the g values, DPPH and Mn^{2+} were used as standard.

Conductance measurements were effected in DMF solutions with a conductometer type OK 102/1 Radelkis with the measure range 0.1μs—0.5s, the apparatus constant being calculated by using NaCl solutions of different normalities. The results are given in table 1.

III. RESULTS

1. IR SPECTRA (400—3400 cm^{-1})

In table 1 are given the values of vibration frequency $\nu_{C\equiv N}$ for the considered selenocyanate complexes. The pink dibiguanide compounds, noted from 1 to 6, present for $\nu_{C\equiv N}$ values of about 2070 cm^{-1} very close to the recorded value in KSeCN ($\nu_{C\equiv N} = 2072$ cm^{-1}). This would indicate that in these complexes, the SeCN group would be ionically bound. With the brown monobiguanide compounds, noted 7—11, values higher than 2120 cm^{-1} were recorded for $\nu_{C\equiv N}$. Inasmuch as $\nu_{C\equiv N}$ shifts usually by coordination towards higher values of the wavenumbers, this behaviour indicates the fact that in this compounds we meet Cu-SeCN bonding. It is known that if the SeCN group is bound by selenium an increase of $\nu_{C\equiv N}$ takes place and a diminution of ν_{C-Se} by comparison to vibration modes proper to the non-coordinated ion. If the coordination takes place by nitrogen then ν_{C-Se} increases and $\nu_{C\equiv N}$ diminishes slightly.

In Cu(RBig) (SeCN)$_2$ both SeCN groups are equivalent, because in the spectrum only a single band corresponding to the $\nu_{C\equiv N}$ vibration mode appears without any splittings.

2. ELECTRONIC SPECTRA

In table 1 are given the values of absorption maxima from the reflectance spectra of the considered compounds and, for dibiguanide complexes, from the absorption spectra of DMF solutions as well. In fig. 1., typical spectra of these compounds are given as examples.

In the reflectance spectra of pink dibiguanide compounds only a maximum observable at values above 19000 cm^{-1} was pointed out. The absorption spectra of the same complexes in DMF present maxima at values close enough to those from the reflectance spectra except for the compound noted with 6, indicating that, by solving, important changes do not occur. These bands are similar to those observed at a series of Cu(II) planar complexes as for example the complexes with aldimine,[12] with the pyrrole derivatives with succinimide [13] with *o*-alkyl-1-amidinourea, [14] and so on.

The reflectance spectra of monobiguanide complexes present two bands, the one with the maximum at about 11 000 cm^{-1} and the other, at about 27 500 cm^{-1}. It should be mentioned that the former is large, flattened, rendering difficult the accurate determination of the values corresponding to the maxima. The band from 27 500 cm^{-1} originates in the electronic transitions proper to coordinated SeCN (in the free ion it appears at 42500 cm^{-1}) as well as in Δ_{xz} transition. A band proper to the ligand (the aryl derivative of biguanide) situated at about 39000cm^{-1}

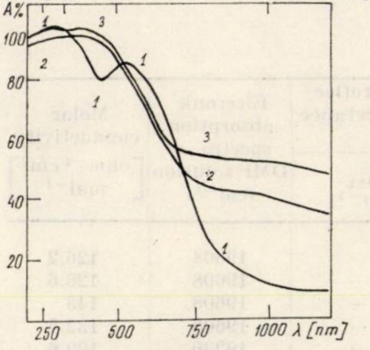

Fig. 1. Reflectance spectra of complexes :

[12] R. E. Clarke and J. H. Weber, *J. Inorg. Nuclear Chem.*, **30**, 1837 (1968).

[13] S. Yamada and S. Miki, *Bull. Chem. Soc. Japan*, **36**, 680 (1963).

[14] J. R. Wasson and C. Trapp, *J. Phys. Chem.*, **73**, 3763 (1969).

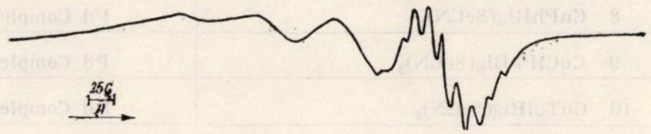
appears also in the spectra of the compounds noted with 3–6 and 8–11. The other band proper to the non-coordinated ligands ranging between 41000–43000 cm^{-1} is shifted in far UV due to the conjugated system characteristics of the cycles formed after complexation.

3. EPR SPECTRA ANALYSIS

With dibiguanide complexes, EPR spectra of DMF solutions are recorded. Under these conditions, at room temperature, isotropic spectra which present a hyperfine structure with 4 components corresponding to the interaction of the unpaired electron with the nuclear spins of ^{63}Cu and ^{65}Cu $\left(\text{both equal with } I = \frac{3}{2}\right)$, were obtained (fig. 2).

In this case, a resolving of the splittings from ^{63}Cu and ^{65}Cu was not observed, perhaps due to the line broadening. On the hyperfine components of the spectra located at higher fields, a supplementary superhyperfine structure was observed resulting from the interaction of Cu unpaired electron with the nuclear spins of ligand atoms forming the bond. In fig. 3, the superhyperfine structure recorded on the hyperfine components located at high field of $[Cu(PhBig)_2](SeCN)_2$ are given as an example.

Fig. 2. EPR spectrum of $[Cu(PhBig)_2](SeCN)_2$ solution in DMF recorded at room temperature.



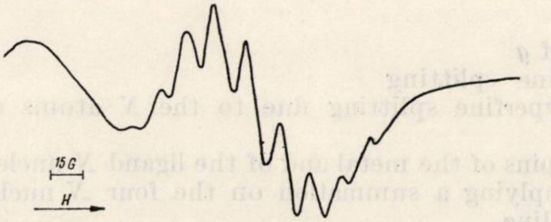


Fig. 3. Superhyperfine structure of $[Cu(PhBig)_2](SeCN)_2$ in DMF at room temperature.

The analysis of the superhyperfine structure pattern in these complexes showed it to present 9 components with a splitting of 14–15 G and the intensities ratio very close to 1 : 4 : 10 : 16 : 19 : 16 : 10 : 4 : 1. This pattern was assigned to the Cu unpaired electron interaction with 4 equivalent N nuclei ($I = 1$). The EPR spectra of these solutions can be well interpreted by means of a spin Hamiltonian of the type :

$$H_{Sp} = g_0 \beta H + A_0 SI + \sum_n A_0^N SI^N \qquad (1)$$

Table

Values and Hyperfine Structure Constants

where

g_0 — isotropic value of g
A_0 — isotropic hyperfine splitting
A_0^N — isotropic superhyperfine splitting due to the N atoms of the ligand.

I and I^N refer to the nuclear spins of the metal and of the ligand N nuclei, respectively, the last term implying a summation on the four N nuclei which participate in the bonding.

From these spectra we could determine the isotropic values of the spectroscopical splitting factors g_0, of the hyperfine structure constant A_0 and of the superhyperfine structure constants A_0^{λ} (table 2).

We recorded also the EPR spectra of DMF solutions of these complexes, frozen at 77 K. These spectra consist of two sets of hyperfine lines corresponding to $g_{||}$ and $g_{\perp}$ tensors (fig. 4).

The hyperfine structure with 4 components corresponding to $g_{||}$ is well resolved but the one corresponding to $g_{\perp}$ is not, the latter overlapping the components of $g_{||}$ located at high field. Moreover, these spectra also present a superhyperfine structure which is observed on the high field components rendering the spectrum analysis difficult in this range.

We recorded also the EPR spectra of these complexes in powders magnetically diluted with $[Zn(RBig)_2](SeCN)_2$ (ratio 1 : 100) at room temperature as well as 77 K. The obtained spectra are similar to those of the frozen DMF solutions (at 77 K).

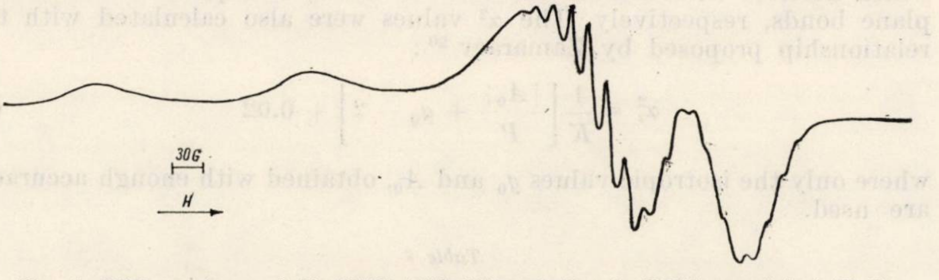

Fig. 4. EPR spectrum of $[Cu(PhBig)_2](SeCN)_2$ solution in DMF recorded at 77 K.

From these spectra we could determine with accuracy $g_{\parallel}$ and $A_{\parallel}$ values which are summarized in table 2. In the same table are given also the $g_{\perp}$ and $A_{\perp}$ values determined with a lower accuracy from the spectra of diluted powders or of DMF frozen solutions, as well as the values of these parameters, obtained by using Kivelson [15] and McConnell's [16] relationships:

---

[15] D. Kivelson, *J. Chem. Phys.*, **33**, 1094 (1960).

[16] H. M. McConnell, *J. Chem. Phys.*, **25**, 709 (1956).

$$3g_0 = g_{\|} + 2g_{\perp} \tag{2}$$

$$3A_0 = A_{\|} + 2A_{\perp} \tag{3}$$

From this table, some differences between the parameter values obtained in DMF solutions and those from the magnetically diluted powders can be observed. They can be assigned to the used solvent effect.

Concerning the monobiguanide complexes, inasmuch as they are not soluble in usual solvents, we recorded the spectra of the powders magnetically diluted with $PbRBig(SeCN)_2$ [17] (ratio 1 : 100). From these spectra, $g_{\|}$, $A_{\|}$, $g_{\perp}$ and $A_{\perp}$ values were determined and then the g_0 and A_0 values were obtained by means of these values using Kivelson and McConnell's relationships (table 2). Inasmuch as $g_{\perp}$ and $A_{\perp}$ cannot be obtained with a great accuracy, due to the overlapping with the hyperfine components corresponding to $g_{\|}$, the g_0 and A_0 values will also be affected by this lack of precision. With these complexes one also observes a superhyperfine structure on the high field components but due to the superpositions, it is difficult to precisely state the ligand nuclei with which the unpaired Cu electron interacts.

In order to calculate the molecular orbital parameters of the dibiguanide complexes on the basis of EPR and electronic spectra characteristics the approximate M.O. theory of Kivelson and Neiman [18] and Gersman and Swallen [19] was used. We preserved the same notations as in our previous works.[1,9,10] Thus, by using the wavefunctions defined in,[8] making the same approximations and considering Δ_{xy} from table 1 as ΔE_{xy} we calculated the values of α^2 coefficients and with these ones the α'^2 and β^2 values for the considered complexes. α, β and δ are coefficients which describe the covalent character of the σ, π in-plane and π out-of-plane bonds, respectively. The α^2 values were also calculated with the relationship proposed by Zamaraev [20]:

$$\alpha_z^2 = \frac{1}{K}\left[\frac{|A_0|}{P} + g_0 - 2\right] + 0.02 \tag{4}$$

where only the isotropic values g_0 and A_0, obtained with enough accuracy, are used.

Table 3

LCAO – MO parameters

Compound	α^2	α'^2	α_z^2	β^2
1 $[Cu(Me_2Big)_2](SeCN)_2$	0.79_6	0.294	0.78_8	0.68_7
2 $[Cu(MorBig)_2](SeCN)_2$	0.82_6	0.260	0.79_8	0.65_4

The obtained values for the considered complexes are very near to those calculated with the Kivelson [18] and Gersman [19] relationships, the differences being comprised between 0.01 and 0.03. The obtained results are summarized in table 3.

As regards δ^2 values, we could not calculate them since ΔE_{xz} values from the electronic spectra could not be accurately determined.

With the monobiguanide complexes, we did not calculate these coefficients since, being insoluble, we could not obtain the isotropic EPR spectra which would have indicated us the manner in which the Cu atom is bound with the ligands.

III. DISCUSSION

A number of 11 new Cu(II) selenocyanate complexes belonging to two types : $[Cu(RBig)_2](SeCN)_2$ dibiguanide complexes and $Cu(RBig)(SeCN)_2$ monobiguanide complexes, were synthetized.

The stable, pink-coloured dibiguanide complexes were prepared either by a substitution reaction between the respective chlorocompounds $[Cu(RBig)_2]Cl_2$ and KSeCN, using ethanol as a solvent, either by a direct method, or by using the monobiguanide compound in acetone or DMF medium. In the last method, the following reaction is considered to take place :

$$2\ Cu(RBig)Cl_2 + 2\ KSeCN \rightarrow [Cu(RBig)_2](SeCN)_2 + K_2[CuCl_4]$$

If the development of the reaction by this mechanism was not admitted, a formation of hardly soluble products, $Cu(SeCN)_2$ brown and CuSeCN white, respectively, which would impurify the synthetized compounds should be supposed. The chemical and physicochemical deteminations are arguments attesting the formation of only pink-coloured, hardly soluble dibiguanide selenocyanates; as for the $CuCl_4^{-2}$ ion, it passes into solution (table 1).

The physico-chemical methods used provide valuable information on the Cu valence state and the bonding manner of the SeCN and biguanide groups, in these complexes. Thus, the molar conductance determinations effected on the DMF solutions of these complexes present values in the range of 117–143 $ohm^{-1}\ cm^2\ mol^{-1}$ (table 1) which shows that they are electrolytes of 1:2 type.

Magnetic susceptibility measurements led to values of $\mu_{ef} = 1.6 - - 1.68$ MB showing that these complexes are paramagnetic, copper being divalent (d^9). It results that in the formation reactions of these selenocyanate complexes, in the above mentioned conditions, redox reactions between Cu(II) and $SeCN^-$ did not take place.

IR spectra showed that, with these complexes, the vibration frequency $\nu_{C\equiv N}$ (table 1) does not practically shift towards the corresponding value from KSeCN which pleads for an ionic bonding of selenocyanate group, supporting the conclusions obtained from conductance determinations.

The results obtained from electronic spectra fall into the same category. Thus it was pointed out that the substitution of halogen ions from $[Cu(RBig)_2]X_2$ with $SeCN^-$ does not lead to a sensible shift of the adsorption band located at about 19800 cm^{-1}, band which is encountered in all the pink dibiguanide complexes studied,[1,9,10] suggesting a structure similar to these.

On the basis of the above mentioned facts, these complexes can be formulated $[Cu(RBig)_2](SeCN)_2$.

EPR spectra supplied information concerning the Cu(II) bonding with the biguanide ligand, showing that the bonding is performed by 4 equivalent or almost equivalent N atoms coming from the two biguanide molecules. The calculus of parameters using the EPR spectral data, also showed that with the dibiguanide complexes, the α^2 values ranging between 0.80—0.83 (table 3), σ bondings present a moderate covalency degree. It should also be mentioned that there are no marked differences between these values for compounds with different derivatives of substituted biguanide, values somewhat higher being, however, recorded for the compounds with N^1-*p*-chlorophenyl-N^5-izopropylbiguanide and with tolylbiguanide.

The β constant describes the covalent character of the in-plane π bonds. From table 3 it results that with the dibiguanide compounds, β^2 has values in the range 0.65—0.75 indicating a more accentuated covalent character for the π in-plane bands. This is especially found in the $[Cu(MorBig)_2](SeCN)_2$ and $[Cu(Me_2Big)_2]$ $(SeCN)_2$, the β^2 values of which are sensibly smaller than for the other compounds considered.

Generally, as in the case of other dibiguanide compounds studied,[1,9,10] the β^2 values for these complexes are more differentiated than the α^2 values, which allows us to consider them as being a more sensible indication of the covalent bonding character.

The brown monobiguanide compounds $Cu(RBig)$ $(SeCN)_2$ were prepared by the reaction between the chlorocompounds $Cu(RBig)Cl_2$ and KSeCN, molar ratio 1 : 2, using ethyl alcohol or DMF as solvent. The separation in the solid state of these compounds was made by direct treatment with cold water lightly alkalinized ($pH = 7.5$). The syntheses of all these selenocyanates obtained present a certain degree of difficulty in that they are sensitive to pH-variations below 7, decomposing with red selenium separation.

The monobiguanide selenocyanates present a light brown colour, more intensive than that of the analogous thiocyanates. They are stable in solid state, hardly soluble in water and in other usual solvents. The aryl-radical from the biguanide derivative confers to these compounds a greater stability than the alkyl-radical.

Similar to the dibiguanide compounds, in this case, too, susceptibility measurements showed that these compounds are paramagnetic, the paramagnetism coming from an unpaired electron (d^9) which of course is due to the Cu(II) existing in the complex.

IR spectra of these complexes showed a strong shift of the vibration frequency $\nu_{C\equiv N}$ towards higher values, over 2120 cm^{-1} (table 1). This would indicate, on the one hand, that the selenocyanate group is coordinated at Cu and, on the other hand, it would suggest that coordination would take place through Se, inasmuch as it is known from literature [21-22] that coordination through Se leads to a sensible increase of $\nu_{C\equiv N}$ towards the value of 2072 cm^{-1} from KSeCN.

An attempt was made to determine the corresponding ν_{C-Se}, ν_{Cu-Se}, and δ_{SeCN} from the spectra which would provide supplementary information on the manner in which the selenocyanate group is bonding, but the overlapping with the biguanide ligand bands did not allow their determination.

Important shifts are also recorded in the band positions of the electronic spectra. Thus, with these complexes we do not observe the band from 19000 cm^{-1} as we signalled out for the corresponding pink complexes, but a large band with a maximum at about 11000 cm^{-1} and another at 27500 cm^{-1} were observed.

If we consider that in monobiguanide compounds of the type $Cu(RBig)X_2$, where $X = NO_3$, NCS, NCO, N_3 previously studied [1,9,10] (in which the coordination was supposed to occur through N), absorption bands at values about 15000—17000 cm^{-1} were recorded, the lower value recorded in the case of Cu(RBig) $(SeCN)_2$ would suggest a coordination through Se, this fact being due to the strong, distorting character of the SeCN group, leading to a planar structure.

The EPR spectral parameters of these compounds are different from those corresponding to the dibiguanide complexes. Thus, isotropic g_0 factors have greater values while the A_0 values are somewhat smaller than those recorded in the pink compounds. Similarly, higher $g_{||}$ values and lower $A_\perp$ values were recorded for the brown compounds. The $g_\perp$ and $A_\perp$ values which do not differ sensibly proved to be less sensitve to the transition from one category of complexes to the other.

Unfortunately, the EPR spectra of these compounds could not supply additional information as these compounds were not soluble in usual solvents so that it was not possible to obtain the isotropic spectra from which we could have observed how the selenocyanate group is coordinated. From anisotropic spectra obtained on magnetic dilution with Pd(RBig) $SeCN)_2$ it is difficult to state if the coordination takes place through N or through Se because the superhyperfine structure corresponding to $g_\perp$, which is obserwed, results from the overlapping of a relatively great number of lines and, in addition, there is an overlapping with the lines from the hyperfine structure corresponding to $g_{||}$ as well. Due also to the fact that the monobiguanide compounds are not soluble, the molar conductivity and the molecular mass could not be determined.

Nevertheless, on the basis of the synthesis of the data of chemical analysis as well as from those obtained by I.R., electronic and EPR spectra these compounds can be formulated as Cu(RBig) $(SeCN)_2$ the biguanide ligand being coordinated by 2 nitrogen atoms and the selenocyanate group being, presumably linked with copper by selenium.

would take place through Se, inasmuch as it is known from literature [21–22] that coordination through Se leads to a sensible increase of ν_{CN} towards the value of 2072 cm^{-1} from KSeCN.

An attempt was made to determine the corresponding ν_{C-Se}, ν_{Cu-Se}, and δ_{SeCN} from the spectra which would provide supplementary information on the manner in which the selenocyanate group is bonding, but the overlapping with the biguanide ligand bands did not allow their determination.

Important shifts are also recorded in the band positions of the electronic spectra. Thus, with these complexes we do not observe the band from 19000 cm^{-1} as we signalled out for the corresponding pink complexes, but a large band with a maximum at about 11000 cm^{-1} and another at 27500 cm^{-1} were observed.

If we consider that in monobiguanide compounds of the type Cu(RBig)X_2, where X = NO_3, NCS, NCO, N_3 previously studied [14–16] (in which the coordination was supposed to occur through N), absorption bands at values about 15000–17000 cm^{-1} were recorded, the lower value recorded in the case of Cu(RBig) $(SeCN)_2$ would suggest a coordination through Se, this fact being due to the strong, distorting character of the SeCN group, leading to a planar structure.

The EPR spectral parameters of these compounds are different from those corresponding to the dibiguanide complexes. Thus, isotropic g_0 factors have greater values while the A_0 values are somewhat smaller than those recorded in the pink compounds. Similarly, higher $g_\parallel$ values and lower $A_\parallel$ values were recorded for the brown compounds. The $g_\perp$ and $A_\perp$ values which do not differ sensibly proved to be less sensitive to the transition from one category of complexes to the other.

Unfortunately, the EPR spectra of these compounds could not supply additional information as these compounds were not soluble in usual solvents so that it was not possible to obtain the isotropic spectra from which we could have observed how the selenocyanate group is coordinated. From anisotropic spectra obtained on magnetic dilution with Pd(RBig) $(SeCN)_2$ it is difficult to state if the coordination takes place through N or through Se because the superhyperfine structure corresponding to $g_\perp$, which is observed, results from the overlapping of a relatively great number of lines and, in addition, there is an overlapping with the lines from the hyperfine structure corresponding to $g_\parallel$ as well. Due also to the fact that the monobiguanide compounds are not soluble, the molar conductivity and the molecular mass could not be determined.

Nevertheless, on the basis of the synthesis of the data of chemical analysis as well as from those obtained by I.R., electronic and EPR spectra these compounds can be formulated as Cu(RBig) $(SeCN)_2$ the biguanide ligand being coordinated by 2 nitrogen atoms and the selenocyanate group being presumably linked with copper by selenium.

SUR LES COMPOSÉS DU TRICHLORURE DE L'ÉTHOXYTITANE AVEC DES BASES SCHIFF

D. NEGOIU, ANGELA KRIZA et MARTHA NASTA
Université de Bucarest, Faculté de Chimie, chaire de Chimie inorganique, 89, Splaiul Independenței

Reçu le 9 mars 1974

On a obtenu et étudié cinq nouveaux composés du titane (IV) avec des bases Schiff aromatiques, à partir du trichlorure d'éthoxytitane. La structure des composés obtenus a été établie à l'aide des spectres IR et électroniques.

INTRODUCTION

Les recherches actuelles sur la chimie du titane sont dirigées vers les composés de ce métal avec des ligands dont la molécule comprend des atomes d'oxygène et d'azote. Parmi ceux-ci les salicylaldimines occupent une place importante. Lorsque les bases Schiff contiennent le groupement hydroxyle dans une position proche à la condensation, par réaction avec des ions métalliques elles peuvent former des cycles chélates, à nombre variable de membres.

Le nombre des composés du titane avec des salicylaldimines est très petit par rapport à d'autres métaux transitionnels. Ceci n'est pas surprenant si l'on tient compte des conditions extrêmement difficiles que réclament la synthèse et, d'autant plus, l'étude de tels composés du titane.

Les premiers composés du titane (IV) avec des salicylaldimines ont été obtenus en 1960.[1]

En 1967, pendant des recherches entreprises au Laboratoire de Chimie inorganique à la Faculté de Chimie de Bucarest on a abordé le problème de la synthèse des complexes du titane avec des bases Schiff dérivées du salicyl- et benzaldéhyde et des amines aliphatiques et aromatiques.

Pendant ces recherches on a remarqué que les bases Schiff dérivées d'orto-oxyaldéhydes peuvent former avec le tétrachlorure de titane, en certaines conditions, des complexes moléculaires du type $TiCl_4(SB)_2$.[2] Des complexes internes, du type « chélate », n'ont pas été obtenus par réaction directe du tétrachlorure de titane avec les bases Schiff mais seulement via alcoxydes de titane. Les composés obtenus de cette manière ont les formules suivantes : $Ti(OR)_2SB$ et $Ti(SB)_2$.[3,4]

---

[1] Chijuan-Ya, Ui, I. A. Savichi, A. V. Lapitzkii, V. P. Samorukov et L. G. Titov, *Vestnik. Mosk. Univ.*, **3**, 40 (1960).

[2] D. Negoiu et A. Kriza, *Anal. Univ. Buc.*, **20**, 39 (1971).

Nous précisons qu'en 1969, Bradley et ses collaborateurs[5] ont obtenu et étudié quelques chélates du titane (IV) : $Ti(SB)_4$, composés obtenus à partir du tétra(diméthylamino)titane: $Ti(NMe_2)_4$. Mais les substances nécessaires à la synthèse, c'est-à-dire le tétra(diméthylamino)titane, tout comme les alcoxydes du titane, ont été obtenues en conditions très difficiles.

Pendant nos recherches nous avons essayé d'obtenir des complexes du type $TiCl_2(SB)_2$. Nous n'avons pas réussi d'obtenir de tels composés unitaires par réaction directe du tétrachlorure de titane et des azométhynes dérivées d'amines aromatiques et aliphatiques, moins volumineuses.

Conformément à des remarques ultérieures, à savoir que les atomes de chlore tout comme les groupements alcoxydes chloroalcoxydes du titane peuvent être remplacés par réaction avec des ligands bidentés, nous avons essayé à obtenir de cette manière des chélates du titane avec des salicylaldimines.

C'est ainsi que, par réaction du trichlorure de l'éthoxytitane avec des salicylaldimines aromatiques, nous avons obtenu cinq nouveaux composés (tabl. 1).

(SA) = salicylal-aniline ; SPT = salicylal-*p*-toluidine ; SOT = salicylal-*o*-toluidine ; SPA = salicylal-*p*-anisidine ; SOA = salicylal-*o*-anisidine.

RÉSULTATS ET DISCUSSIONS

Par réaction par rapport molaire 1 : 2 on remplace le groupement alcoxy ainsi qu'un atome de chlore du chlorure d'éthoxytitane par deux molécules de base Schiff. La structure de ligand bidenté des bases Schiff indique la possibilité de la formation d'une liaison Ti-O. Pour vérifier cette hypothèse on a étudié les déplacements des fréquences caractéristiques des groupements azométhyne et phénoxy dans les spectres IR des composés par rapport aux spectres IR des ligands. Dans le tableau 2 on remarque les maxima d'absorption du spectre IR, déterminé dans les domaines 1100 et 1700 cm^{-1} et 2800 et 3600 cm^{-1}, pour les composés et les salicylaldimines correspondantes.

[3] D. Negoiu et A. Kriza, *Anal. Univ. Buc.*, **18**, 113 (1969).

[4] D. Negoiu et A. Kriza, *Anal. Univ. Buc.*, **19**, 31 (1970).

[5] D. C. Bradley, M. B. Hurthouse et J. F. Rendall, *Chem. Comm.*, **12**, 672 (1969).

Si des chélates s'étaient formés, on aurait dû remarquer un déplacement de la fréquence de vibration $\nu_{C=N}$ vers des valeurs plus petites et, à la fois, un déplacement de la bande caractéristique du groupement phénoxy vers des fréquences plus élevées.

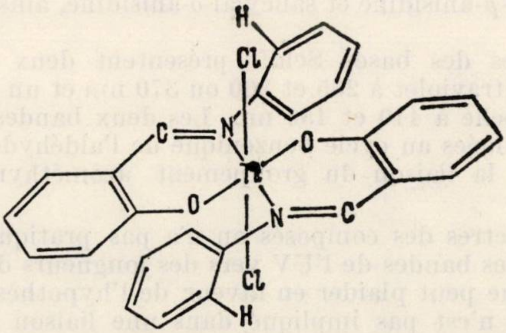
Tableau 2

Spectres IR des composés $TiCl_2(SB)_2$

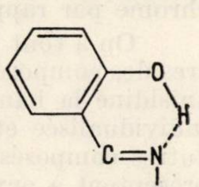
Composé	ν_{Ph-O} (cm^{-1})		$\nu_{C=N}$ (cm^{-1})	
	ligand	composé	ligand	composé
$TiCl_2(SA)_2$	1278	1285	1625	1645
$TiCl_2(SPT)_2$	1280	1290	1625	1645
$TiCl_2(SOT)_2$	1280	1290	1630	1645
$TiCl_2(SPA)_2$	1278	1290	1630	1647
$TiCl_2(SOA)_2$	1280	1287	1625	1647

Parmi les données du tableau 2 on remarque vraiment une augmentation de la fréquence du groupement phénoxy. Cette remarque tout comme l'absence de la fréquence caractéristique du groupement hydroxyle chélaté par liaisons hydrogène dans les spectres des composés par rapport aux spectres des ligands atteste la présence des liaisons Ti—O.

On remarque aussi une augmentation du $\nu_{C=N}$ ce qui ne concorde pas avec la formation d'un cycle quasi aromatique comprenant l'atome de titane ainsi qu'il est représenté par la formule :

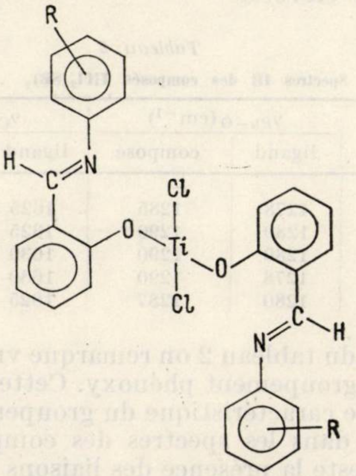


La liaison hydrogène qui apparaît entre l'hydrogène de l'hydroxyle et l'azote de l'azométhyne ferme un cycle conjugué de six membres. Dans ce type de systèmes conjugués l'énergie de la liaison hydrogène est due 90% à la conjugaison $\pi - \pi$. La contribution des électrons *p* de l'azote à la formation de la liaison hydrogène est assez insignifiante. Par formation des composés, la liaison hydrogène est détruite. La libération du groupement azométhyne de cette conjugaison mène à l'augmentation de la fréquence de ce groupement dans le spectre IR des composés.



La remarque que $\nu_{C=N}$ n'est pas déplacée vers de valeurs plus petites nous permet donc de supposer que le cycle comprenant l'atome de titane ne se ferme pas, à cause des empêchements stériques, et la liaison donneur-accepteur ne se forme pas.

Les composés obtenus pourraient être formulés de cette manière :



On a déterminé aussi les spectres électroniques des salicylaldimines et des composés dans le domaine 250—600 nm. La figure 1 représente les spectres électroniques des composés obtenus à partir de : salicylal-*p*-toluidine, salicylal-*p*-anisidine et salicylal-*o*-anisidine, ainsi que les spectres de ces ligands.

Les spectres des bases Schiff présentent deux bandes intenses dans le domaine ultraviolet à 265 et 360 ou 370 nm et un point d'inflexion dans le visible proche à 440 et 450 nm. Les deux bandes de l'ultraviolet peuvent être attribuées au cycle benzénique de l'aldéhyde aromatique et, respectivement, à la liaison du groupement azométhyne conjuguée au cycle benzénique.

Dans les spectres des composés on n'a pas pratiquement remarqué de déplacements des bandes de l'UV vers des longueurs d'onde plus grandes. Cette remarque peut plaider en faveur de l'hypothèse que le groupement azométhyne n'est pas impliqué dans une liaison avec l'atome de titane (l'apparition d'une liaison donneur-accepteur par l'intermédiaire du doublet électronique libre de l'azote aurait déterminé un effet bathochrome par rapport aux bandes de 360 ou 370 nm).

On a tout de même remarqué que dans le domaine visible des spectres des composés obtenus à partir de la salicylal-*p*-toluidine et salicylal-*p*-anisidine la bande de 440 ou 450 nm est déplacée à 460 nm, très bien individualisée et un peu élargie. Dans le même domaine du spectre, les autres composés et surtout celui obtenu à partir de la salicylal-*o*-anisidine présentent à environ 520 nm une bande moins précisée. On ne peut pas faire de précisions sur les déplacements des bandes dues, probablement, à des transitions internes des ligands. La littérature ne présente pas de spectres électroniques des composés analogues à ceux préparés par nous ; on ne peut donc faire aucune corrélation. Quand même on ne peut pas totalement exclure une transition de transfert de charge.

PARTIE EXPÉRIMENTALE

Bases Schiff. Les salicylaldimines ont été obtenues par des méthodes indiquées dans la littérature, par réaction directe du salicylaldéhyde et de l'amine aromatique (rapport molaire 1 : 1) dans de l'acool éthylique anhydrisé. Après l'ébullition on sépare les bases Schiff du tableau 3. Toutes les bases Schiff ont été purifiées par cristallisation.

Le trichlorure d'éthoxytitane a été obtenu dans une installation pourvue de tous les accessoires nécessaires aux synthèses dans l'atmosphère inerte. On ajoute de l'alcool éthylique dissous dans du chloroforme à un excès de tétrachlorure de titane, dans du chloroforme anhydrisé, sous agitation et à 0°. On porte à l'ébullition pendant huit heures, jusqu'au complet écartement de l'acide chlorhydrique. Après 24 heures, le composé solide formé a été séparé et distillé sous pression atmosphérique. A 185—186° distille un liquide jaune, qui se transforme dans un solide jaune. Les données de l'analyse élémentaire pour $TiCl_3(OC_2H_5)$ sont celles du tableau 3 (p.f. 80—81°).

Salicylal-*o*-anisidine	SOA	59,5	jaune	6,12	6,10

$TiCl_3(OC_2H_5)$ Calc. : 24,03% Ti 53,25% Cl Det. : 24,11% Ti 53,97% Cl.

Réaction du trichlorure de l'éthoxytitane avec des bases Schiff aromatiques. Les composés ont été synthétisés dans des conditions d'élimination totale de l'humidité atmosphérique. Les composés obtenus présentent une remarquable stabilité dans l'air, mais lorsqu'ils se trouvent encore sous forme de solution ils sont vulnérables à l'humidité. Par conséquent, toutes les opérations nécessaires à la synthèse et à la séparation des composés ont été accomplies sous atmosphère d'azote.

Les composés ont été obtenus par réaction du trichlorure d'éthoxytitane et de la base Schiff, par rapport molaire 1 : 2, dans du tétrachlorure de carbone anhydrisé, sous agitation. Après 24 heures on sépare le solide formé : les composés ont été lavés au tétrachlorure de carbone et à l'éther, dans un extracteur Soxhlet. Le solvant a été écarté par évaporation sous vide.

Received November 13, 1974

Isographs and isographic transformations are defined as graph-theoretical correspondents to topological (constitutional) isomers, and to topological isomerizations, respectively. In graph theoretical language, isographs are labelled graphs with the same partition of their vertex degrees. The nonvariant graph of a family of isographs is defined as the common spanning subgraph of the constitutional graphs of two (or more) topological isomers. Topological isomerizations can be rigorously and conveniently classified by relating them to the connectivity of the nonvariant graph.

INTRODUCTION

In a previous paper,[2] the definition of rearrangements and isomerizations was discussed. The present paper is concerned with isomerizations. Isomerization processes are usually classified as shown in table 1. In degenerate processes (automerizations or topomerizations), enantiomerizations and diastereomerizations, the constitutional formula, or constitutional graph, remains unchanged. Therefore topological (constitutional) isomerizations, or for short isomerizations, are those chemical processes which conserve the molecular formula of the reagent but modify its constitutional formula, which indicates the connectivities between atoms.

Table 1

Classification of various types of isomerizations by noting modified or conserved properties (conformational changes involving rotations around single bonds are ignored)

Name of the molecular transformation	Constitutional formula	Stereochemical formula	
	Topology of atoms	Distances between non-bonded atoms	Tridimensional orientation of atoms
Automerization[2, 3] (topomerization[4])	Conserved	Conserved	Conserved
Enantiomerization	Conserved	Conserved	Modified
Diastereomerization	Conserved	Modified	Modified
Constitutional (topological) isomerization	Modified	Modified	Modified

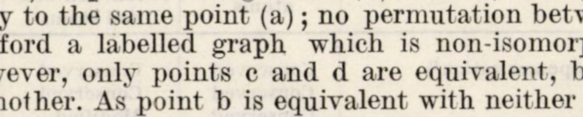
The authors' impression that there is, as yet, no systematic classification of isomerizations, and that the graph theory may be useful as a basis for such a classification, is expressed in the present paper.

ISOGRAPHS

For an adequate graph-theoretical treatment of topological isomerizations the concept of *isographs* has to be introduced. In the following, we shall deal with general graphs (where loops and multiple bonds are allowed) which need not be connected. Isolated points, i.e. with degree equal to zero, shall not be discussed.

A family of isographs is defined as a set of p labelled points, the degree of each point remaining the same in all the graphs of the family; this means that the number q of lines connecting these points is the same for all the members of the family. Consequently, all members of a family of isographs have the same partition of their vertex degrees. Thus, as seen in figure 1, there exist three isographs with three points and partition $2q = 3 + 2 + 1$. Owing to labelling, a family of isographs is usually more numerous than the family of non-labelled graphs with the same partition. In non-labelled graphs, no distinction is made between points of the same degree: the permutation of two such points will always result in an isomorphic graph. In labelled graphs, however, only permutations between two equivalent points will result in an isomorphic graph. Equivalence of two points in a labelled graph means that they (i) have the same degree and (ii) are either isolated (possibly having loops) or are connected only to one and the same point, and/or to each other, by single or multiple bonds. In a labelled graph, any permutation between two non-equivalent points of the same degree will result in a non-isomorphic graph from the same family of isographs. Let us take as example the isographs with four points and partition $2q = 3 + 1 + 1 + 1$.



In graph I, all points of degree one (b, c and d) are equivalent, being connected only to the same point (a); no permutation between points b, c and d can afford a labelled graph which is non-isomorphic with I. In graph II, however, only points c and d are equivalent, being connected only to one another. As point b is equivalent with neither c, nor d, it will afford graphs III and IV, non-isomorphic with II, on permutation with c

2	2	3+1				2+2			3	2+1+1			4	1+1+1+1		
3	2	5+1				4+2				3+3			3	2+2+2				3+2+1				4+1+1			4	3+1+1+1				2+2+1+1		
Fig. 1. — The simplest families of possible isographs resulted from permutation of $q = 1$, 2 or 3 lines between $p=2$, 3 or 4 points.[a]

[a] Graphs which would be isomorphic in the absence of labelling are indicated by dotted lines.

[b] Multigraphs are defined as connected or disconnected graphs with single or multiple bonds, but without loops.

[c] General graphs are defined as under *b* but with loops allowed.

and d, respectively. All graphs I — IV are of course isographs from the same family, but II, III and IV would be isomorphic in the absence of labelling.

A family of isographs, thus, consists of all non-isomorphic labelled graphs having the same partition, with the degree of each vertex (point) being constant. As examples, some of the simplest families of isographs are enumerated in figures 1 — 4.

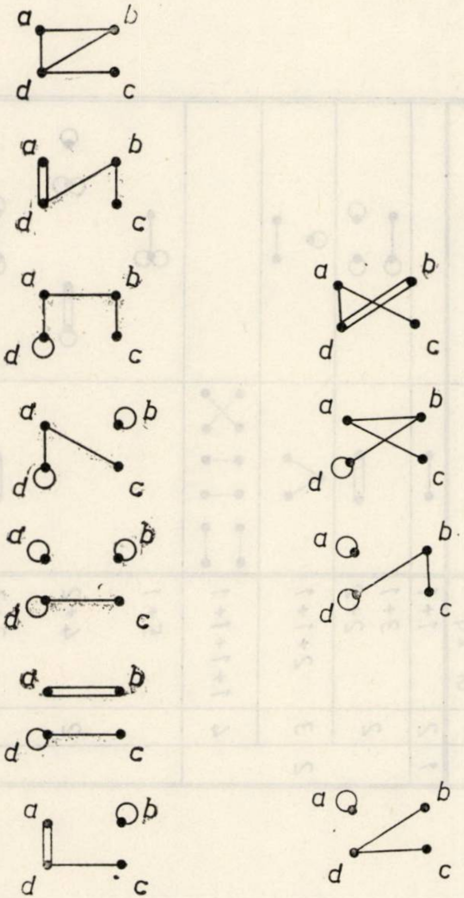

Fig. 3. – All isographs with the partition 2q = 3 + 2 + 2 + 1. Graphs which would be isomorphic without labelling are placed on the same line.

The enumeration of all n members of a family of isographs is interesting for finding out all topological isomers with the same molecular formula: these isomers correspond to the connected isographs of the given family. The labelled points correspond to atoms; points with the same degree may have the same, or different, chemical or isotopic [5] identities.

Such enumerations remain the main application of graph theory in chemistry. An appreciable amount of work has been done in this field,[6–10]

starting with Cayley's algorithm for the number of alkanes. In this paper, however, the concept of isographs will be used for a different purpose: classification of topological isomerizations on the basis of changes in the constitutional formula (graph) during that process.

ISOGRAPHIC TRANSFORMATIONS

The constitutional graphs of two topological isomers are isographs from the same family. Consequently, topological isomerizations may be regarded as isographic transformations, i. e.transformations of the constitutional graph G_1 into one of its n isographs $G_i(i = 2 \div n)$. Since, by definition, all isographs contain the same set of p points which conserve their degrees, isographic transformations will consist of permutations of a number of lines between these points. An isographic transformation which involves permutation of q' lines will alter the connections of only those p' points which were connected by the above q' lines in the original graph ($p \geqslant p' \leqslant 2q'$). The highest possible number of topological isomers obtainable from the molecule corresponding to G_1 by modifying only the connections of the p' atoms symbolized by the above subset of p' points will be equal to the number of possible isographs in the family g_i (subgraphs of G_i) consisting of the p' points and q' lines involved in the transformation.

Let us discuss the simplest examples, which are the only ones interesting for the chemist, consisting of the loop-free graphs from figures 1 and 2. Isographic transformations involving less than four lines are thus possible only in those cases from figures 1 and 2 which contain more than one multigraph for a given partition, namely $q = 2$, $p = 4$; $q = 3$, $p = 4$, 5 or 6. Commonly encountered isomerizations have $p = 2q$, and such cases can be described by the following two rules:

a) Permuting q lines between $p = 2q$ points, n isographs are formed, where $n = (p-1)\ (p-3)\ (p-5) \ldots 5.3.1$.

b) Between the n isographs described above, w isographic transformations implying permutation of 2, 3, ..., q lines are possible, w being the number of pairwise combinations of the n isographs. This second rule will apply, of course, also for cases where $p < 2q$.

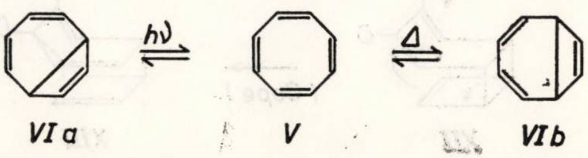
Detection of the p points and q lines taking part in the isographic transformation which describes a given topological isomerization may be useful in two respects:

(i) The enumeration of all possible n isomeric products and w isomerization processes will set the chemical problem in clearer terms.

(ii) Parameters q and p are closely related to the mechanism of the soimerization process under investigation. According to the Woodward —

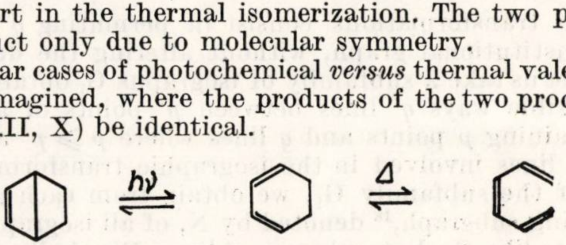
Hoffmann rules,[11] an isomerization characterized by $q = 2$, $p = 4$, will have a four-centre mechanism, generally allowed photochemically. On the other hand, an isomerization corresponding to an isographic transformation with $q = 3$, $p = 6$, will have a thermally allowed six-centre mechanism with an aromatic transition state.[12,13]

The usefulness of the graph-theoretical approach to topological isomerizations may be illustrated by the following example:[14] cycloöctatetraene (V) was observed to undergo valence isomerization photochemically [15] as well as thermally,[16] yielding in both cases bicyclo[4.2.0]octa-2,4,7-triene (VI). This is possible, without contradicting the Woodward — Hoffmann rules, if different atoms and bonds are involved in the two processes:



Only two bonds ($q = 2$) and four atoms ($p = 4$) are involved in the photochemical isomerization, whereas three bonds and six atoms ($q = 3$, $p = 6$) take part in the thermal isomerization. The two processes afford the same product only due to molecular symmetry.

Other similar cases of photochemical *versus* thermal valence isomerizations may be imagined, where the products of the two processes may (VI) or may not (VIII, X) be identical.



The formation of Nenitzescu's hydrocarbon (XIII) thermally from basketene (XI), which apparently could proceed by a retro 2 + 2 cycloreversion in disagreement with the Woodward – Hoffmann rules was shown by deuterium labelling to involve only thermally allowed steps, namely a retro-Diels-Alder reaction followed by a Cope rearrangement.[17]

NONVARIANT GRAPH OF A FAMILY OF ISOGRAPHS

Isographic transformations consist in permuting q lines between p points of a constitutional graph, without altering the degree of any of these points. Let us take a subfamily of isographs G_i obtained by permuting in all possible ways q' lines between p' points of a constitutional graph G_1 (containing p points and q lines where $p \geqslant p'$ and $q \geqslant q'$). By deleting the q' lines involved in the isographic transformations between the members of the subfamily G_i, we obtain from each graph the same common spanning subgraph,[18] denoted by N, of all isographs G_i. Graph N contains p points like G_1, but only $q - q'$ lines. We shall call this common spanning subgraph N of a family of isographs G_i, the *isographic nonvariant graph*, or briefly, the *nonvariant*. The nonvariant may be thought as the graph with those lines which are common to both reagent and product of reaction. On this basis, the reactions with six-membered cyclic transition state were discussed earlier.[12]

An example is given in figure 5 which illustrates the di-π-methane rearrangement [19] and the valence isomerizations between cyclopentene, vinylcyclopropane and bicyclo[2.1.0]pentane. In fig. 5, the same capital letters, plain or primed, designate graphs which would be identical in the absence of labelling. Figure 5 includes four (A – D) of the five possible[8] valence isomers of cyclopentene; the fifth one is bicyclo[1.1.1]pentane.

We will show in the following that the nature of an isographic transformation is a function of the connectedness of the nonvariant, and that topological isomerizations and cognate processes may be classified according to this criterion. Since we only relate initial to final products without regard to kinetics or mechanism, it is irrelevant if the process is concerted or not, rapid or slow.

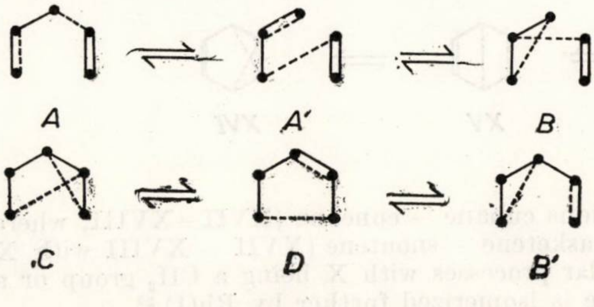

Fig. 5. — Isographic nonvariants (full line) in the di-π-methane rearrangement (above), and in valence isomerizations of cyclopentene (below). In both cases there are $q' = 2$ broken lines connecting $p' = 4$ points involved in the isographic transformation. In both cases the partition is the same $2q = 3 + 3 + 2 + 2 + 2$.

In the following discussion, for each category of nonvariant, two cases will be examined : A, $q' = 2$, $p' = 4$; B, $q' = 3$, $p' = 6$. For the sake of simplicity, only the p′ points in question will be shown explicitly ; the subgraphs connecting them, which together with the above p' points constitute the nonvariant, are drawn as curved full lines to differentiate them from covalent bonds which are drawn as straight lines. In other words, a straight line denotes a covalent bond, whereas a curved line denotes one or more covalent bonds.

TYPES OF NONVARIANT GRAPHS

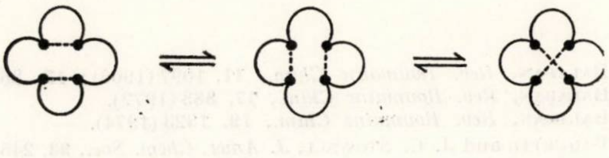
The following three possibilities may be differentiated.

1. THE NONVARIANT IS A CONNECTED GRAPH

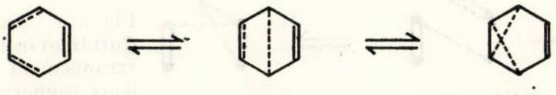
This is equivalent to say that none of the q' lines involved in the isographic transformations (drawn in fig. 5 and in the following formulae as broken lines) is a bridge [18] in any member of the subfamily G_i of isographs in question. Any two points of the constitutional graph may be linked by some path in all isographs of such a family, *via* the nonvariant.

1A. $q' = 2, p' = 4$

The known or possible examples involve either photochemical reactions, or catalyses by transition metal ions.

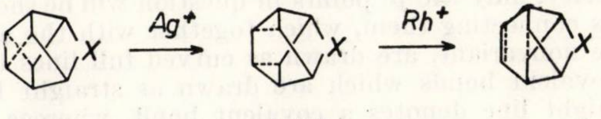


To this type of nonvariant belong the valence isomerizations of benzene (XIV), Dewar-benzene (XV) and benzvalene (XVI);



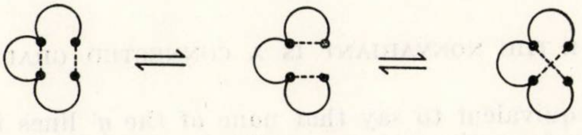
XIV XV XVI

also the valence isomerizations cubane – cuneane (XVII–XVIII, where X is a covalent bond), basketene – snoutene (XVII – XVIII with X being CH=CH), and similar processes with X being a CH_2 group or a heteroatom.[17,20–23] Snoutene is isomerized further by Rh(I).[24]

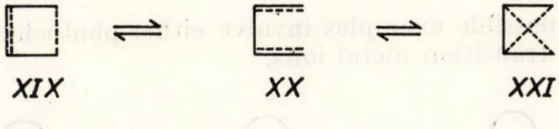


XVII XVIII

Another nonvariant of the same type is the following:



As examples for this nonvariant, are the interconversions C – D – B′ in fig. 5, and the valence isomerizations between cyclobutene (XIX), butadiene (XX) and bicyclobutane (XXI).



XIX XX XXI

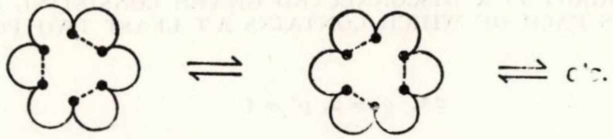
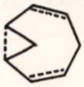
[24] A. de Meijere and L.-U. Meyer, *Tetrahedron Letters*, **1974**, 1849.

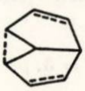
1B. $q' = 3,\ p' = 6$



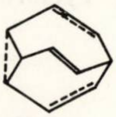
We shall illustrate this case of thermally allowed intramolecular reactions by degenerate rearrangements (automerizations or topomerizations): homotropylidene (XXII), semibullvalene (XXIII), bullvalene (XXIV), hypostrophene (XXV), snoutene (XXVI), lumibullvalene (XXVII) and 9,10-dihydronaphthalene (XXVIII).[17,20,21]



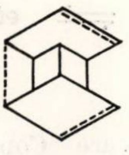
XXII



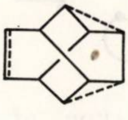
XXIII



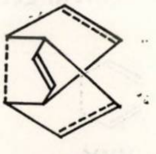
XXIV



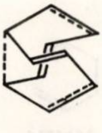
XXV



XXVI

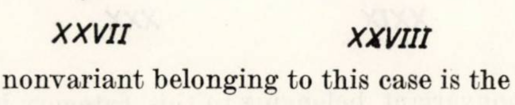


XXVII



XXVIII

Another type of nonvariant belonging to this case is the following:



Examples for this nonvariant are the valence isomerizations of 1,3,5-hexatrienes and 1,3-cyclohexadienes, or of 2,4-pentadien-1-ones (e. g. pyrylium pseudobases in the enolic form) and $2H$-pyrans. Such processes are illustrated by formulae IX and X.

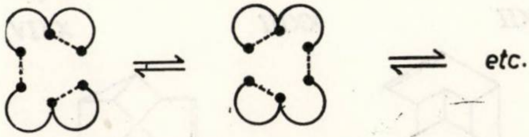
All isographic transformations characterized by a connected nonvariant correspond to topological isomerizations known in chemistry as valence isomerizations. The reverse is not true, however, since some valence isomerizations may have disconnected nonvariants, e. g. the degenerate Cope rearrangement of 1,5-hexadiene as will be shown in the next paragraph.

2. THE NONVARIANT IS A DISCONNECTED GRAPH CONSISTING OF TWO COMPONENTS EACH OF WHICH CONTAINS AT LEAST TWO POINTS

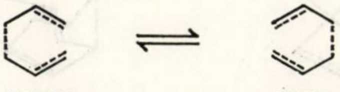
2A. $q' = 2$, $p' = 4$

Examples for this type of nonvariant are photochemical 2 + 2 cycloadditions and cycloreversions, and interconversions A – A′ – B in figure 5.

2B. $q' = 3$, $p' = 6$

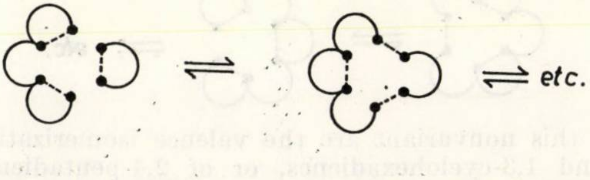


Examples for this type of nonvariant are Cope rearrangements XXIX – XXX, which according to substituents may be degenerate or non-degenerate. With heteroatoms, related rearrangements are possible (Claisen, oxy-Cope, etc.).

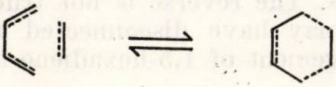


XXIX XXX

Another type of nonvariant belonging to this category is the following :

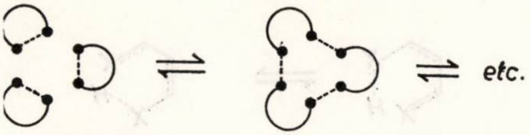


Examples for this nonvariant are the large class of thermal 4 + 2 cycloadditions (Diels-Alder reactions) and their reversions XXXI – XXXII with cyclic six-membered transition state.[12]

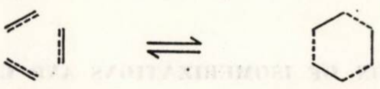


XXXI XXXII

Also in this category is the following nonvariant :



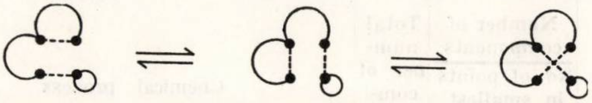
Examples are the thermal 2 + 2 + 2 cycloadditions and cycloreversions XXXIII — XXXIV.[12,13]



XXXIII XXXIV

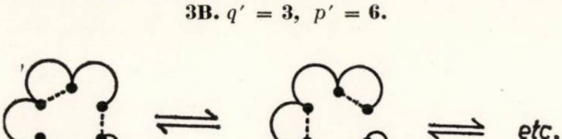
3. THE NONVARIANT IS A DISCONNECTED GRAPH CONSISTING OF TWO OR MORE COMPONENTS, SOME OF WHICH CONTAIN ONE POINT

3A. $q' = 2, p' = 4$

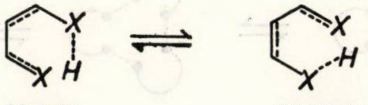


Examples for this type of nonvariant are the enolization of carbonyl derivatives (very rapid tautomeric equilibration) or the slower interconversions between allene (1,2-propadiene) and methylacetylene (propyne), which are both prototropic reactions. Also to this case belong 1,2-rearrangements such as the isomerizations butane — isobutane, or cyclohexane — methylcyclopentane ; or ring-chain isomerizations such as the formation of dichlorophthalide from phthaloyl chloride. All these processes are not concerted ; therefore their occurrence in thermal reactions under the influence of appropriate catalysts does not violate the Woodward — Hoffmann rules.

3B. $q' = 3, p' = 6.$



Examples for this case are the numerous thermal 1,5-hydrogen migrations, or the rapid interconversions between the two enolic forms of 1,3-diketones involving one or the other carbonyl group, XXXV — XXXVI, where X may be CR_2, NR, or O.



XXXV XXXVI

Similar processes are known where the migrating or reacting group is not a hydrogen atom : sigmatropic and cheletropic reactions.

CLASSIFICATION OF ISOMERIZATIONS AND COGNATE REACTIONS

According to the connectedness of the nonvariant and to the number of points in its components, isomerizations and cognate reactions may be classified as presented in table 2.

Table 2

Classification of isomerizations and related reactions according to the connectedness of the nonvariant and to the number of points in its components

Case	Number of components — No. of points in smallest component		Total number of components	Chemical process
	1	>1		
1	0	1	1	Valence isomerism
2	0	>1	$\geqslant 2$	Valence isomerism, cycloaddition, fragmentation
3	$\geqslant 1$	$\geqslant 1$	$\geqslant 2$	Prototropism, sigmatropism, cheletropism, isomerism

In conclusion, consideration of the nonvariant (i. e. of the graph containing those bonds which are common to the initial and final molecules) helps the systematization of chemical reactions, particularly of isomerizations.

STUDIES CONCERNING THE OPTIMISATION OF SEPARATIONS BY THIN LAYER CHROMATOGRAPHY ON SILICAGEL. I

SEPARATION OF SOME ETHANOLAMINES IN SEVERAL POLYCOMPONENT SOLVENT SYSTEMS

C. LITEANU and H. NAŞCU

Chair of Analytical Chemistry, "Babeş-Bolyai" University, Cluj-Napoca, Romania

Received August 19, 1974

The paper presents the thin layer chromatographic behaviour of some ethanolamines mixtures vs. solvent composition in three ternary solvent systems of the following type: proton donor or acceptor solvent: methanol: ammonia (d = 0.905). The optimum composition of the solvents is presented on Gibbs ternary diagrams while the R_f values are illustrated in graphs. The results may be qualitatively explained if we assume that the retention of these amines takes place through a donor-acceptor (Lewis) interaction.

A rather unusual method for the selection of solvent systems expected to perform a certain separation (besides that making use of solvent-solute interactions [1–4] or that of eluotropic series [5–9]) is the "universal solvent system" method adopted by some laboratories [10–12] on the basis of a long-term experience. Recently, Snyder [13] has introduced a new system for solvent classification which permits a logical selection of solvents both in terms of polarity and selectivity, proving theoretically the validity of such universal solvent systems. These systems permit the separation of a large number of components, on condition that the optimum ratio between the individual components of the mixture [10] be determined.

The simplest way for determining the optimum ratio in the case of polycomponent systems is that of using Gibbs diagrams and the graphical presentation of the results.[14-16]

The solvents so far proposed in literature for the separation of ethanolamines by paper and thin layer (TLC) chromatography,[17-26] generally contain an alcohol, and an aqueous solution of concentrated ammonia or acetic acid, when silicagel and cellulose (adsorbents with $-OH$ superficial groups) are used. Besides these solvents ammonia and methanol systems contain a secondary solvent too : ethanol,[17] ethyl acetate,[24] acetone,[25] or chloroform.[23] There are no references in the literature to the mechanism of retention in such solvents. The aim of the present paper is to fill in this gap and to find some guidelines for the selection of optimum solvent systems in the case of ethanolamines separation by TLC on silicagel.

MATERIALS AND METHODS

Glass plates 9 × 4.5 cm were used, on which thin layers of Silicagel H (Merck, Darmstadt, Germany) with 1 % starch as binder were spread with a manual device. After preparation the plates were air-dried for 24 hours. Developments were run at 5–6 cm distance from the starting point, immediately after solvent introduction in the tank (6 × 10 × 2 cm) After application of the spot (3–4 µl standard solution) at 1 cm distance from the inferior edge of the plate and after drying, the plate was introduced in the tank without any presaturation.

The solvents and concentrated ammonia (d = 0.905) were analytical grade reagents. The 1 % aqueous solutions of ethanolamines : monoethanolamine (MEA), diethanolamine (DEA), triethanolamine (TEA), and 2-N-dimethylaminoethanol (NDEA) were prepared by weighing, starting from analytical grade reagents (Merck, Darmstadt, Germany). The preparation of solvent mixtures and developments was carried out at 23 ± 1°C. In all cases 20 ml eluent were prepared with a measuring precision of 0.5 %. Two determinations were made for each solvent mixture.

The visualisation reagent used was 0.2 % ninhydrin in n-butanol containing 2 % acetic acid. The plates, dried and heated for 10 minutes at 120°C in an oven, were sprayed with the above reagent and again introduced for 10 minutes in the oven.

After a series of preliminary investigations the following solvent systems were selected :

1. MeEtCO : MeOH : NH_3 (d = 0.905)
2. $CH_3COOC_2H_5$: MeOH : NH_3 (d = 0.905).
3. $CHCl_3$: MeOH : NH_3 (d = 0.905)

These three systems differ only by their first component. In the first and second solvent system it is a proton acceptor while in the last case it is a proton donor. Acetone proved to be

less efficient than methyl-ethyl-ketone as component of the solvent mixture in the case of the studied ethanolamines. The tests were made within the region of total miscibility of the Gibbs triangle by taking equal size increments. In this respect, 36 equidistant points were set, as shown in fig. 1. The selected mixture tested had the same volume percent composition as these points.

RESULTS

The tested solvent systems are presented in figs. 2, 3 and 4. The hatched zones represent solvents which permit clear separations to be obtained i.e., compact, round and completely separated zones, at least for two of them, in the case of MEA, DEA and TEA mixtures. The separation of NDEA from TEA is not always complete but compact zones were also obtained in this case.

The R_f values obtained in these cases are graphically presented in figs. 5, 6 and 7.

By drawing a parallel line to one side of the triangle passing through the area containing the tested points, the effect of solvent composition on migration of solutes can be observed (figs. 8, 9 and 10).

DISCUSSION

By comparing the diagrams presented in figs. 8a, 8b and 8c it can be seen that in the case of a constant composition of methyl-ethyl-ketone the increase in water-ammonia content, detrimental to the methanol content leads to higher R$_f$ values. This proves that the main contributing factor to the eluent "strength" is the content of the first mixture.

Looking at the data and the chromatograms obtained with the tested solvent, one can see that in the great majority of cases, when good separations were obtained (i.e., a good resolution of MEA, DEA and TEA), the solvent mixture belonged to 60—80% (w/w) methanol in water range. When the concentration of methanol in water exceeds 80%, anomalies such as elongated spots, zone inversions or poor visualisation generally appear. However, in this case too, useful separations may be obtained, when the concentration of aqueous ammonia solution is over a given limit (10% in the case of methyl-ethyl-ketone, 11% in the case of ethyl acetate and 10% in the case of chloroform). Similarly, the concentration of the second organic solvent in the mixture must be higher than 2M, otherwise good selectivity and efficiency cannot be obtained. Although apparently these experimental data have not substantiated theoretical explanations and in spite of all the pessimism in the literature, regarding the mechanism of separation in such solvents, some qualitative theoretical proofs can be formulated. Thus, the studies of solvent effect on protonation constants in methanol-water mixtures [27,28] in the case of ammonia and some primary, secondary and tertiary amines and also of some polyamines and polyaminoalcohols evidence the fact that the protonation constants of these amines become smaller than the protonation constant of ammonia at 65% (w/w) methanol in water content. In addition, as can be seen from fig. 11, the variation of protonation constants for methylamine and ethylamine are identical both in value and aspect.[28]

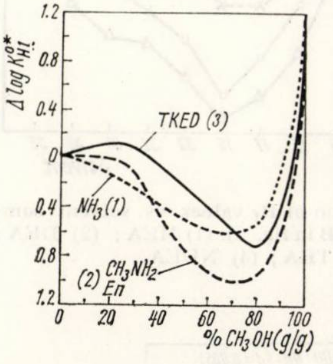

Fig. 11. —Variation of protonation constants for ammonia (1), ethylendiamine and methylamine (2) and N, N, N′, N′ tetrakis (2-hidroxyethyl)-ethylendiamine (3) vs. MeOH : H_2O mixture composition.[28]

The lowest value of the protonation constant differs from the primary to tertiary amino group, being slightly affected by the radical attached to this group.[28] This value is found for the tertiary amino group in the region above 80% methanol concentration as compared with the primary amino group (fig. 7). These facts partly explain the statement that in most cases the resolution is optimum when the concentration of methanol in water exceeds 60% (w/w). Since in our experiments the second organic solvent acts, with regard to the amino groups, as an inert diluent for methanol and the concentration of the first is generally low, as a first approximation, its action on the protonation constant of amines and ammonia can be neglected. When methanol concentration falls below 60% useful separations can be obtained only with high concentrations of ammonia (over 7 m), probably, due to a compensatory effect of higher ammonia concentration which adversely affects the stability of the adduct with the stationary phase. At higher concentrations of methanol in water (over 80%) the sudden rise of protonation constants leads, probably, to a low rate exchange kinetics and to an excessive zone broadening. The inversion in zone succession on the chromatograms may be explained by the fact that the minimum

values of the protonation constant appear at different concentrations of ammonia in water. As regards the second organic solvent it can be ascertained that when this is a proton donor only (group VIII after Snyder's classification [13]) solvent selectivity is higher.

CONCLUSIONS

The solvent composition regions in which efficient separations take place, greatly facilitate the selection of a solvent system for separating substances with primary, secondary and tertiary amino groups.

All these groups are probably retained by the stationary phase formed on silicagel through a mechanism of protonation via —OH superficial groups. Solvent selectivity is based, in this case, on the existing difference between protonation constants of solutes and ammonia.

Since with the solvent mixture used in the present study an efficient separation may be obtained, the solvent composition should be adjusted in such a way that the protonation constants of amines be lower then the corresponding value for ammonia and, at the same time, low enough for ensuring a quick mobile phase-stationary phase transfer kinetics. This leads to a minimum value for the mass transfer resistance.

The selection of a solvent from the hatched area in Gibbs triangles presented in figs. 2, 3 and 4 assures, in the majority of cases, the best conditions for efficient separations.

Taking into acount the fact that the "universal" solvents proposed [11,12] have a similar composition with those presented in this paper, the separation mechanism suggested here may be valid in other similar cases whenever the retention mechanism is based on an acid-base (Lewis) interaction.

SYNTHETIC SINGLE CRYSTAL PbSe ELECTRODE POTENTIOMETRIC TITRATION OF Cu(II) WITH Na_2EDTA

D. C. CÖRMÖŞ *, IOVANCA HAIDUC * and P. STEȚIU **
* Babeş-Bolyai University, Cluj, Chemistry Department, Chair of Analytical Chemistry, str. Arany J., 11, Cluj-Napoca, Romania
** Babeş-Bolyai University, Cluj, Physics Department, Isotopes and Solid State Laboratory, Cluj-Napoca, Romania

Received April 2, 1974

The characteristics of the synthetic single crystal PbSe electrode against Cu(II) ions were determined. The electrode function is 29 mV per pCu unit in the range of pCu = 1 to 6 at pH = 4. The reaction rate depends upon concentration and is 10 sec at pCu = 6 and 40 sec at pCu = 1. The electrode was used as indicating electrode in the titration of Cu(II) with Na_2EDTA. The influence of temperature, NH_3 concentration, amount of NH_4OH-NH_4Cl buffer and the NaCl concentration were investigated.

INTRODUCTION

Copper (II) ions are frequently determined potentiometrically. For titrations, several ion-selective electrodes have been proposed.[1–24]

In the present paper we describe the behaviour of the synthetic single crystal PbSe electrode in the potentiometric titration of Cu(II) with Na_2EDTA, with good results.

EXPERIMENTAL

The electrode. The PbSe single crystal was obtained from spectral pure selenium and lead. The single crystal was mounted without internal solution.

The solutions. All the solutions used were made from reagent grade substances and doubly distilled water. The constant ionic strength was achieved with a KNO_3 solution.

The apparatus. The PbSe electrode potentials were measured with a MV-11S potentiometer with a precision of ±2 mV and are referred to SCE.

RESULTS AND DISCUSSION

The electrode response for Cu(II). For the determination of the electrode response to Cu(II) ions, the potentials of the synthetic single crystal PbSe electrode were measured in solutions prepared by successive dilution of $Cu(NO_3)_2$ 10^{-1}M, at ionic strength J = 0.1. All the solutions were brought to pH = 4 with HNO_3 10^{-2}M. Measurements were made at pH = 4 since the electrode potential in 10^{-1} Cu(II) solution is constant for the pH range from 2.5 to 6.0. In fig. 1 the electrode response is depicted:

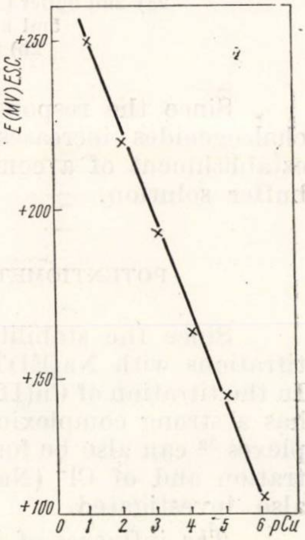

Fig. 1. – The PbSe single crystal electrode response to Cu(II).

The synthetic single crystal PbSe electrode has a nernstian response to Cu(II) in the range of pCu = 1–6. The reproducibility of potential values is very good and the electrode can be used both for the potentiometric titration of Cu(II) and for direct potentiometry.

Response rate. The response rate of the electrode investigated was determined for Cu(II) ions under the conditions of potentiometric titration with Na_2EDTA. For this purpose potential-time curves were plotted at pH = 10, on $2 \cdot 10^{-3}$ M Cu(II) solutions, at various concentrations of the buffer. These curves are given in fig. 2a:

The potential-time curves show changes which decrease with the increase of the buffer concentration used. To determine the buffer concentration at which the electrode potential is constant at t = 0, the PbSe electrode potential values in Cu(II) solutions were plotted at various buffer concentrations at t = 0 and t = 30 sec (the time at which the potential becomes constant). The straight lines obtained are shown in fig. 2b. Their intersection shows the buffer concentration for which the electrode response is constant with time.

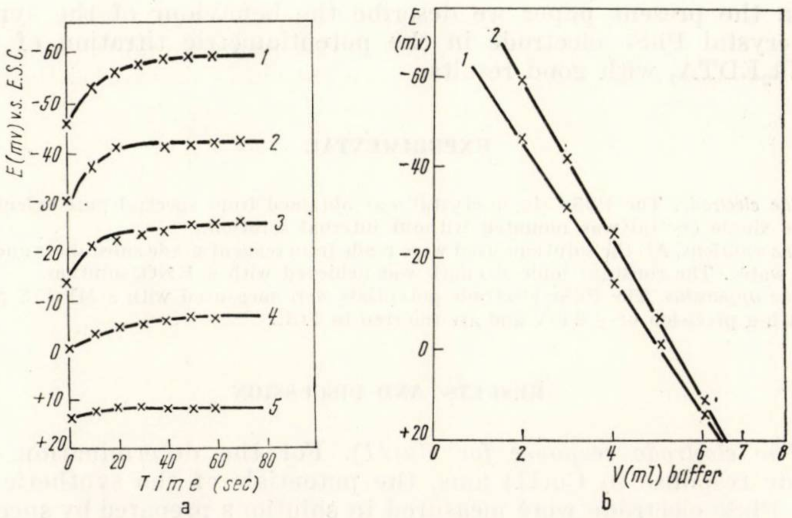

Fig. 2. — Response rate of PbSe single crystal electrode in $2 \cdot 10^{-3}$ M Cu(II) buffered solution (pH = 10 with $NH_4OH + NH_4Cl$) : 2a) 2ml buffer (curve *1*), 3ml buffer (curve *2*), 4ml buffer (curve *3*), 5ml buffer (curve *4*), 6 ml buffer (curve *5*). 2b) *t* = 0 (curve 1), t = 30 sec (curve *2*).

Since the response rate of the electrodes based on heavy metal chalcogenides increases with decreasing ion concentration, the rapid establishment of a constant potential is favoured by the addition of a buffer solution.

POTENTIOMETRIC TITRATION OF Cu(II) WITH Na_2EDTA

Since the stability of metal complexonates is a function of pH, titrations with Na_2EDTA are made in the presence of buffer solutions. In the titration of Cu(II) the NH_4OH/NH_4Cl buffer is used. Since ammonia has a strong complexing action upon Cu(II) and copper (II)-chlorocomplexes [32] can also be formed, the influence of ammonia, of buffer concentration and of Cl^- (NaCl) concentration upon the titration curve were also investigated.

The influence of NH_3 concentration. In order to determine the optimal concentration of ammonia several titrations of Cu(II) with Na_2EDTA were made at the following molar ratios between NH_3 and Cu(II) : 1, 2, 4, 6, 8 and 10.

In all solutions the molar concentration of Cu(II) was $2 \cdot 10^{-3}$ and the initial volume of the solution was 50 ml. The results of titrations are shown in fig. 3.

The increasingly negative value of the electrode potential with increasing $[NH_3]/[Cu]$ ratio is due to the complexation of Cu(II) by

---

[32] W. E. Hatfield and R. Whyman, *Transition Metal Chem.*, **5**, 123 (1969).

NH_3. The equivalence volume remains constant with ratios, but the shape of the titration curve and the potential jump around the equivalence vary. The titration curve 1 is very asymmetrical due to the instability of the Cu-EDTA complexes in the presence of the hydrogen ions resulted from the reaction, which are incompletely neutralized at the ratio $[NH_3]/[Cu] = 1$. After the equivalence (curves *3–6*) the potentials are not negativated according to the ammonia : copper ratio, because of the excess of ammonia, which destabilizes the Cu-EDTA complex. The titration curve *2* (corresponding to the ratio $[NH_3]/[Cu] = 2$) is the most symmetrical, and has a potential jump around the equivalence $\Delta E \pm 1\% = 110$ mV. For the $[NH_3]/[Cu] = 2$ ratio the two hydrogen equivalents released during the reaction are entirely neutralized by ammonia.

The titration of Cu(II) with Na_2 EDTA can also be performed in the following way : the Na_2EDTA solution is chosen so as to contain the ammonia concentration required to neutralize the H^+ ions resulted from the reaction. In this case the initial potentials will be determined by the Cu(II) concentration and the potential jump will be higher than in the case of Cu(II) – NH_3 solutions. In the titration of a Cu(II) M/50 solution with a Na_2EDTA M/50 solution in NH_4OH M/25 the potential jump observed is $\Delta E_{\pm 1\%} = 160$ mV.

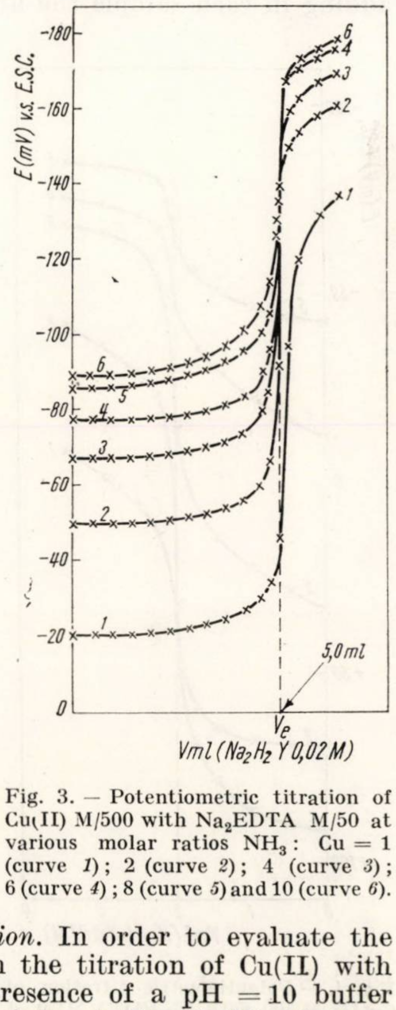

Fig. 3. – Potentiometric titration of Cu(II) M/500 with Na_2EDTA M/50 at various molar ratios NH_3 : Cu = 1 (curve *1*) ; 2 (curve *2*) ; 4 (curve *3*) ; 6 (curve *4*) ; 8 (curve *5*) and 10 (curve *6*).

The influence of the buffer concentration. In order to evaluate the influence of the buffer concentration upon the titration of Cu(II) with Na_2EDTA, a series of titrations in the presence of a pH = 10 buffer (with a ratio $[NH_3]/[NH_4^+] = 6.5$) were carried out. The Cu(II) solutions had a concentration of $4 \cdot 10^{-5}$ moles in 50 ml solution, and the buffer was added from 0.25 to 10.0 ml. The titration data are shown in Fig. 4

The figure shows that all the titration curves exhibit the same variation around the equivalence and the shape of the titration curve varies. The highest potential jump (70 mV) corresponds to curve *2*, fig. 4. By comparing the titration curves in fig. 3 with those in fig. 4 the influence of the presence of NH_4Cl is quite obvious. The concentration of NH_4Cl in the buffer solution should be 3 times lower than the concentration of copper.

The influence of NaCl concentration. In order to determine the influence of Cl^- ions upon the titration of Cu(II) with Na_2EDTA with PbSe electrodes, the titrations illustrated in fig. 3 were repeated by adding in each sample the amount of sodium chloride required to keep the molar ratio $[NH_3]/[NaCl]$ constant. For this purpose 50 ml samples of Cu(II) M/500 were titrated. The molar concentrations of these samples in NH_3 respectively in NaCl were: $2\cdot 10^{-2}$, $4\cdot 10^{-2}$, $8\cdot 10^{-2}$, 1.2×10^{-1}, 1.6×10^{-1} and 2.0×10^{-1}. The titrating reagent was a Na_2EDTA M/50 solution.

The titration data thus obtained are given in table 2.

By comparing the potential variation around the equivalence, we can notice wide variations in the titrations made in the presence of NaCl, up to ammonia concentration of $8\cdot 10^{-2}$ M, after which this variation remains constant. Therefore, the Cl^- ions (introduced in solution as NaCl) do not have a depressing effect upon the potential jump and in the case the NH_4OH-NH_4Cl buffer is used, the ammonia ions are the ones exhibiting a strong depressing effect. At high NaCl concentrations the potential jump around the equivalence is much decreased ($\Delta E_{\pm 1\%} = 20$ mV in the titration in the presence of NaCl compared to $\Delta E_{\pm 1\%} = 70$ mV in the absence of NaCl). The titration curves are shown in fig 5. In this case 50 ml of a M/500 Cu(II) solution, containing $2\cdot 7 \times 10^{-2}$ moles of ammonia and $1\cdot 76 \times 10^{-1}$ moles of NaCl.

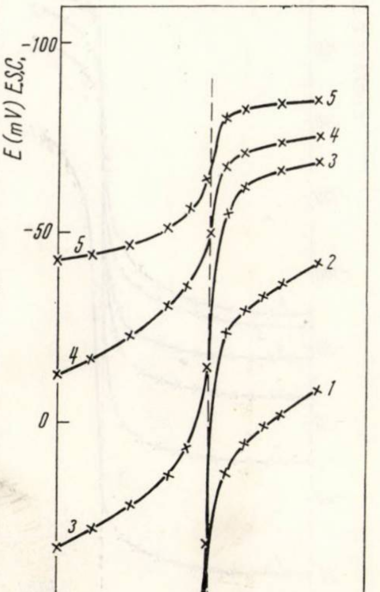

Fig. 4. — Potentiometric titration of Cu(II) M/500 with Na_2EDTA M/50 at pH = 10 ($NH_4OH + NH_4Cl$ buffer). 0.25 ml buffer (curve *1*); 0.5ml buffer (curve *2*); 3 ml buffer (curve *3*); 5 ml buffer (curve *4*); 10 ml buffer (curve *5*).

The influence of temperature. The temperature is a factor which can influence both the titration reactions and the electrode processes In fig. 6 are shown the titration curves obtained by titrating 50 ml of Cu(II) M/500 in the presence of 2ml of 2M NH_4OH at 22° and 55°.

It is noticed that potentials are shifted towards more positive values, without a significant change of the equivalence volume. The smaller potential jump ($\Delta E_{\pm 1\%} = 60$ mV at 55°, compared to $\Delta E_{\pm 1\%} = 90$ mV at 22°) recommends the titration of Cu(II) with Na_2EDTA be performed at room temperature.

Table 2

Potentiometric data titration of Cu(II) M/500 with Na_2EDTA M/50 in NH_4OH and $NH_4OH + NaCl$

TRENNUNG EINIGER AMINOSÄUREN DURCH DÜNNSCHICHTCHROMATOGRAPHIE MIT ORTHOGONALEM TEMPERATURGRADIENT

S. GOCAN und CHRISTINE KYRI

Lehrstuhl für Analytische Chemie der Universität ,,Babeş-Bolyai",
Cluj-Napoca, str. Arany János, nr. 11

Eingegangen am 20. Feb. 1974

Es wird die Möglichkeit der Anwendung des orthogonalen Temperaturgradienten bei der Trennung einiger Aminosäuren durch Dünnschichtchromatographie (in der S-Kammer) gezeigt. Der orthogonale Temperaturgradient begünstigt die Trennung der Komponenten. Man erhält eine viel bessere Auflösung als bei Entwicklung in isothermen Bedingungen.

Auf die Möglichkeit der Anwendung eines orthogonalen Temperaturgradienten in der S-Kammer wies Niederwieser hin.[1]

Um die Vorteile der Dünnschichtchromatographie mit orthogonalem Temperaturgradient zu überprüfen, wählten wir ein System von sechs Aminosäuren: 1. Histidin, 2. Glycin, 3. Glutaminsäure, 4. Alanin, 5. Valin, 6. Leucin.

Die Trennung dieses Gemisches erfolgte auf mikrokristalliner Cellulose (Merck), die Schichtdicke betrug 0,2 mm. Als Fließmittel wurde ein Gemisch[2] von *n*-Butanol-Aceton-Eisessig-Wasser (35–35–10–20, v/v) verwendet. Zur Sichtbarmachung der Aminosäuren wurden die Platten mit einer 0,2% Ninhydrinlösung (0,2% Ninhydrin in 2% Essigsäure in *n*-Butanol) besprüht, anschließend 5 Minuten im Trockenschrank bei 110° getrocknet. Die Aminosäuren erscheinen als blaue Zonen.

Apparatur: Auf die beiden Platten einer S-Kammer wurden zwei Heizplatten angebracht,[1] die einen Temperaturunterschied zwischen den beiden gegenüberliegenden Platten der S-Kammer gewährleisteten, und zwar derart, daß die DC-Platte eine Temperatur t_2 besitzt, die größer ist als die Temperatur t_1 der Gegenplatte. Die Distanz d zwischen DC-Platte und Gegenplatte betrug 3 mm.

Der orthogonale Temperaturgradient (senkrecht auf die Schicht und Fließrichtung) wurde nach folgender Gleichung berechnet:

$$\text{Grad. } t = (t_2 - t_1)/\text{d} \quad (^\circ\text{C/mm})$$

Bevor die Platten in den Fließmitteltrog eingeführt wurden, wartete man in allen Fällen etwa 20 Minuten bis zum Einstellen des orthogonalen Temperaturgradienten. Die weitere Ausführung erfolgte wie bei normaler Dünnschichtchromatographie.

Abb. 3. R_f-Werte als Funktion der mittleren Temperatur t des Intervalls das den Gradienten schuf. (Grad. $t = \Delta t/d = 5/3 = 1{,}66°/\text{mm}$). Entwicklungsdauer :

1 Stunde. Aminosäuren ; 1, Histidin, 2, Glycin, 3, Glutaminsäure, 4, Alanin, 5, Valin und 6, Leucin.

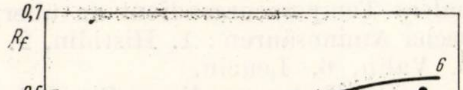

Abb. 4 — Abhängigkeit der R_f-Werte von der Entwicklungsdauer. Grad. t = konstant $= (25-20)/3 = 1{,}66°/\text{mm}$. Aminosäuren :

1, Histidin, 2, Glycin, 3, Glutaminsäure, 4, Alanin, 5, Valin und 6, Leucin.

Ergebnisse : Wir untersuchten in erster Linie die Abhängigkeit der R_f-Werte vom orthogonalen Temperaturgradienten. Die Entwicklungsdauer blieb konstant und zwar betrug sie eine Stunde (Abb. 1), beziehungsweise zwei Stunden (Abb. 2)

Anschließend wurden die Platten bei konstantem orthogonalen Temperaturgradient entwickelt, der aber verschiedenen Bereichen der Temperaturskala angehörte. In Abb. 3 sind die erhaltenen R_f-Werte in Funktion der mittleren Temperatur t des Intervalls, das den Gradienten schuf, dargestellt.

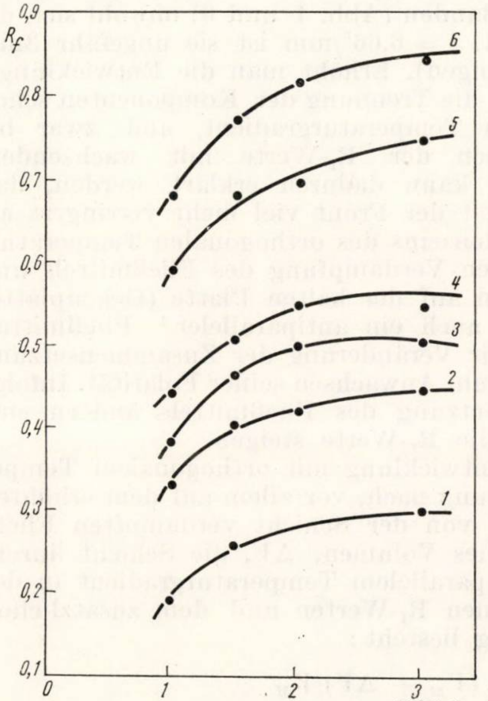

Abb. 5. — Abhängigkeit der R_f-Werte von der Entwicklungsdauer. Grad. t = konstant = (40−35)/3 = 1,66°/mm. Aminosäuren : *1*, Histidin, *2*, Glycin, *3*, Glutaminsäure, *4*, Alanin, *5*, Valin und *6*, Leucin.

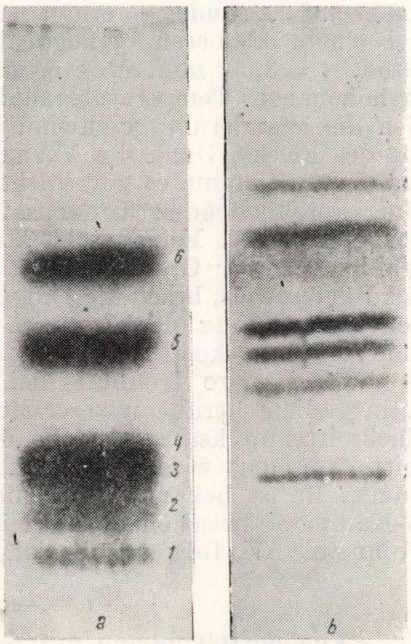

Isotherm 0= Temperaturgradient

t = 20° $\frac{40-35}{3} = 1{,}66°/\text{mm}$

Abb. 6. — Dünnschichtchromatogramme : a) erhalten durch Entwicklung in isothermen Bedingungen. b) erhalten durch Entwicklung im orthogonalen Temperaturgradient. Aminosäuren : *1*, Histidin, *2*, Glycin, *3*, Glutaminsäure, *4*, Alanin, *5*, Valin und *6*, Leucin.

Arbeitet man bei konstantem orthogonalen Temperaturgradient und ändert die Entwicklungsdauer, so erhält man die in Abb. 4 und 5 wiedergegebenen Ergebnisse.

Vergleicht man die in Abb. 6 wiedergegebenen Chromatogramme, bemerkt man die viel besseren Trennergebnisse, die man bei Entwicklung mit orthogonalem Temperaturgradient erhält.

Der positive Einfluß des orthogonalen Temperaturgradienten ist übrigens auch aus den Abbildungen 1—5 ersichtlich.

Diskussion: Arbeitet man in isothermen Bedingungen bei 20° so erhält man eine schwache Trennung der Komponenten 1—4, Glycin und Alanin bleiben ungetrennt, weil die entsprechenden Bande breit sind und sich überlagern (Abb. 1 und 6). Arbeitet man dagegen mit orthogonalem Temperaturgradient so erhält man eine zufriedenstellende Trennung der 6 Aminosäuren bei sehr scharfen Banden (Abb. 1 und 6) obwohl sich die Laufstrecke verringert: (für Grad. $t = 6{,}66°/\mathrm{mm}$ ist sie ungefähr 3mal kleiner als in isothermen Bedingungen). Erhöht man die Entwicklungsdauer auf 2 Stunden so erhält man die Trennung der Komponenten schon bei einem kleineren orthogonalen Temperaturgradient, und zwar bei Grad. $t = 3{,}33°/\mathrm{mm}$. Das Wachsen der R_f-Werte mit wachsendem orthogonalem Temperaturgradient kann dadurch erklärt werden, daß sich die Wanderungsgeschwindigkeit der Front viel mehr verringert als die des Flecks. Dank des Vorhandenseins des orthogonalen Temperaturgradienten kommt es zur selektiven Verdampfung des Fließmittels und einer anschließenden Kondensation auf der kalten Platte (Gegenplatte) der S-Kammer. Es entsteht also auch ein antiparalleler [1] Fließmittelgradient. Dieser Gradient führt zur Veränderung der Zusammensetzung des Fließmittels, beziehungsweise zum Anwachsen seiner Polarität. Infolge der Veränderung der Zusammensetzung des Fließmittels ändern sich die Verteilungskoeffizienten und die R_f-Werte steigen.

Die bessere Trennung bei Entwicklung mit orthogonalem Temperaturgradient beruht, unserer Meinung nach, vor allem auf dem erhöhten Fließmitteldurchsatz. Anstelle des von der Schicht verdampften Fließmittelvolumens wird ein zusätzliches Volumen, ΔV, die Schicht durchsetzen. Es ist bekannt [3], daß bei parallelem Temperaturgradient in der N-Kammer zwischen den erhaltenen R_f-Werten und dem zusätzlichen Volumen, ΔV, folgende Beziehung besteht:

$$R_f = R_{f(\mathrm{iso})}\,(V_M + \Delta V)/V_M$$

V_M = Fließmittelvolumen auf der Schicht und ΔV = von der Schicht verdampftes Fließmittelvolumen.

Es besteht also eine gewisse Analogie zwischen der Wirkung des orthogonalen Temperaturgradienten in einer S-Kammer und der des parallelen Temperaturgradienten in einer N-Kammer.[4–7] Selbst der Verlauf der in beiden Fällen erhaltenen Schaubildern ist ähnlich.[4,6]

Die Trennergebnisse ändern sich, wenn man denselben orthogonalen Temperaturgradient in andere Bereiche der Temperaturskala lagert. So z.B. erhält man schon nach einer Stunde eine sehr gute Trennung aller

[6] C. Liteanu und S. Gocan, *Bull. Soc. chim. France*, **1970**, 4527.

[7] S. Gocan und C. Liteanu, *Rev. Roumaine Chim.*, **17**, 661 (1972).

6 Komponenten wenn der Grad. $t = 1{,}66°/\mathrm{mm}$ zwischen 40—35° gelagert wird (Abb. 3), während man bei demselben Gradient, aber zwischen 25—20° gelagert erst nach 3 Stunden eine zufriedenstellende Trennung erhält (Abb. 4).

Gute Ergebnisse erhält man auch wenn man den Gradienten $(40-20)/3 = 6{,}66°/\mathrm{mm}$ verwendet, (Entwicklungsdauer 1 Stunde; Abb. 1), nur ist die Laufstrecke kürzer als beim Gradienten $(40-35)/3 = 1{,}66°/\mathrm{mm}$, was zu einer schwächeren Auflösung führt.

Das Verlängern der Entwicklungsdauer hat einen positiven Einfluß auf die Trennergebnisse (Abb. 5). Eine zu lange Entwicklungsdauer führt auch hier, ähnlich wie in anderen Entwicklungstechniken, zur Verschlechterung der Auflösung.

Received September 6, 1974

On the basis of the X-ray diffraction patterns, the formation of cobalt and titanium mixed oxides by thermolysis of mixed complexes is proved. Inside the limits of the investigated oxidic compounds, only an ilmenite type structure was found.

By the thermal decomposition of the cobalt and titanium mixed complexes, at temperatures of 300°–400°, mixed oxides are directly obtained, whose oxygen content decreases with rising the temperature.[1,2] Thus, during the thermolysis of cobalt (III) hexammine-titanyl oxalate, the mixed oxides given in table 1 were obtained.

Table 1

Composition of mixed oxides obtained by thermolysis of cobalt (III) hexammine titanyl-oxalate

N° *	Temperature, °C	Composition of oxides
1 a	330	$2/3Co_3O_4.3TiO_2.0.9O_2$
1 b	420	$2/3Co_3O_4.3TiO_2.1/3O_2$
1 c	490	$2/3Co_3O_4.3TiO_2$
1 d	505	$2CoO.3TiO_2.1/4O_2$
1 e	540	$2CoO.3TiO_2.0.2O_2$
1 f	575	$2CoO.3TiO_2.0.1O_2$
1 g	750	$2CoO.3TiO_2.0.04O_2$
1	1000	$2CoO.3TiO_2$

*) The numbers correspond to those given in fig. 1. The composition of the complex from which the oxides were obtained is given in Ref. 1 and 2.

Table 2

Composition of mixed oxides obtained by thermolysis of several mixed complexes, at 1000°

[1] C. GH. MACAROVICI and M. STRĂJESCU, *Rev. Roumaine Chim.*, **13**, 1601 (1968).
[2] M. STRĂJESCU, *Anal. Univ. Timişoara, Seria Sti. Fiz.-Chim.*, **X**, 73 (1972).

The X-ray photographs of the oxides, which are shown in tables 1 and 2, were produced with a T.U.R.M. 60 Dresden apparatus by the Debye-Scherrer powder method. A Cu anti-cathode (λ_{Cu}, $K\alpha_1 = 1.54050$ Å) and a Ni filter were employed at 50 Kw and 10 mA. The diameter of the camera was of 57.5 cm. The exposure time was 3–4 hours.

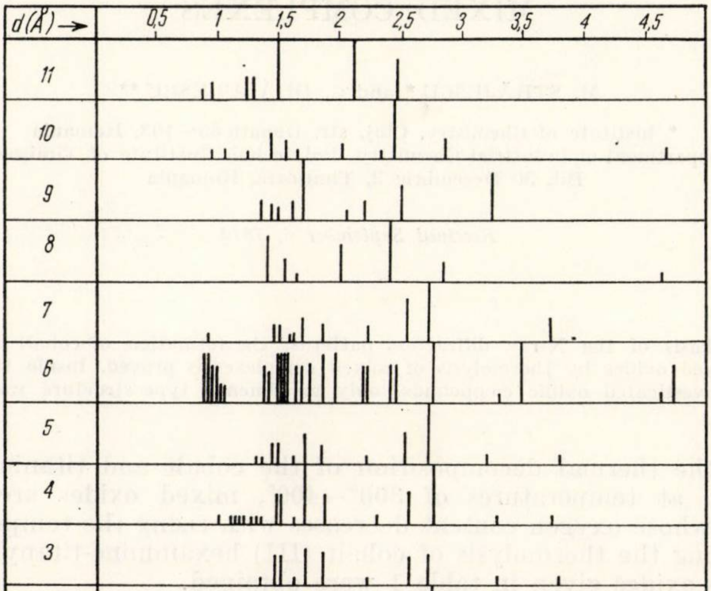

Fig. 1. — X-ray diffraction patterns of mixed oxides of cobalt and titanium. (The composition of the mixed oxides is given in tables 1 and 2. The diffraction patterns *6–11* were reproduced from literature [3,4]: *6* = $CoO.2TiO_2$; *7* = $CoO.TiO_2$; *8* = $2CoO.3TiO_2$; *9* = TiO_2 — rutile; *10* = Co_3O_4 and *11* = CoO).

Figure 1 shows the X-ray powder diffraction patterns. The numbering of the diagrams given in figure 1 is identical with that of the oxides listed in tables 1 and 2. In addition, the d/n values for the simple oxides of cobalt and of titanium, as well as for the cobalt ortho-, meta- and dititanate [3,4] are given.

By comparing the diffraction patterns it has been ascertained for absolutely all cases of mixed oxides which we have obtained that the diffraction lines correspond to those of the metatitanate, $CoTiO_3$, with an ilmenite structure. This structure shows up immediately after decomposition of the initial mixed complex has ended, i.e. above 330° (table 1) and is maintained up to 1000°. By rising the temperature, the diffraction lines become more intense and lines that could not be discerned at lower temperatures, are visible.

The fact that only an ilmenite structure is obtained by the thermal decomposition of the mixed complexes of cobalt and titanium up to 1000°, irrespective of the Ti : Co ratio in the initial complex in the investigated range (Table 2), respectively in the mixed oxides, is in good agreement with the reports of other authors. [5] In the case of the solid state reaction between CoO and TiO_2, at temperatures higher than 1000°, the metatitanate always forms first and, depending on the initial ratio of these two oxides, it remains as such or is converted into cobalt ortho- or dititanate, at temperatures above 1200°.

The formation of the spinel Co_2TiO_4 first [6,7] is categorically contradicted. [8]

The only titanate that has an ilmenite structure is the metatitanate whose CoO : TiO_2 ratio is one. In the oxides obtained by us, this ratio differs from one, being 2 : 3, 3 : 4 and 1 : 2. As there is an excess of TiO_2 in comparison with the composition of metatitanate, we would expect the diffraction lines of rutile to be present in the spectra, too. However, these lines were either not observed or, at best, of the three strong lines of the rutile at 3.24, 2.49 and 1.69 Å, the first is very weak and the last two are shifted and superposed over the $CoTiO_3$ lines. The following would account for this fact.

The titanate with formula $2CoO \cdot 3\,TiO_2$ is not present in the phase diagram of the $CoO-TiO_2$ system.[9,10] Joubert and Durif [11] prepared it by reacting cobalt sulphate with cobalt and lithium titanate. It follows that, in particular conditions, they may also form other types of titanates.

An ordinary isomorphism of $CoTiO_3$ and TiO_2 is excluded [12] because they belong to different spatial groups and even to crystallographic systems, trigonal and tetragonal, respectively. Therefore they cannot form solid solutions.

The absence of the diffraction lines of rutile in the X-ray spectra of the mixed oxides containing an excess of TiO_2 in comparison with the metatitanate, might be explained by assuming the syncrystallization of the excess of titanium dioxide in an identical system with that of $CoTiO_3$.

The uncommon reaction conditions proceed precisely from the way in which the mixed oxides were obtained, i.e. by thermal decomposition of the mixed complexes, which leads to a perfect homogeneous distribution between CoO and TiO_2, at molecular scale. Since $CoTiO_3$ is formed in the system, the problem of a reaction between this compound and the exceeding TiO_2 appears.

Dietzel's theory [13] of the cationic fields intensity asserts that, in order that two oxides form stable combinations, the difference between the cationic fields intensities must exceed a certain minimum value which, expressed in Z/a^2 units is $\Delta(Z/a^2) > 0.3$ (Z = cation charge; a = anion-cation distance). However, we mention that, since Dietzel's empiric rule implies a spherical symmetry of the cationic field, it has a much more limited value for the transition metal ions, which have not such a symmetry, because of the suppresion through coordination of the "d" orbitals degeneration. [14–17]

Since Dietzel's rule is given for a pair of binary oxides, we make an approximation, considering $CoTiO_3$ as a binary oxide. The approximation is possible due to the fact that, in the ilmenite structure of $CoTiO_3$, the two cations are found only in octahedral sites, the Ti–O distances being of 1.92 or 2.06 Å, and the Co–O distances, of 2.08 or 2.16 Å, the mean distances being of 1.99 and 2.12 Å, respectively. [18]

By presuming, instead of the Ti^{4+} and Co^{2+} cations, one cation (M) with a mean charge $(4 + 2)/2 = 3$, that is M^{3+} and by using the average of the mean interatomic distances, i.e. the value 2.055, a Z/a^2 ratio of $3/2.055^2 = 0.71$ was found.

Since in TiO_2,[19] $Z/a^2 = 1.25$, for the fictitious oxidic system $M_2^{3+}O_3-Ti^{4+}O_2$, $\Delta(Z/a^2) = 1.25 - 0.71 = 0.54$. From this value it results that the formation of a stable combination between $CoTiO_3$ and TiO_2 has a considerable probability ($0.54 > 0.3$).

If we admit the reaction as being likely, on the basis of the above mentioned reasons, and considering the fact that cationic radii of Ti^{4+} and Co^{2+} are not too different (0.64 respectively 0.82 Å), it would result that a mixed lattice of ilmenite type is formed. In this lattice, the exceeding titanium cations, likely under the form of Ti^{2+} or Ti^{3+} cations, occupy also the sites of Co^{2+} which is absent from the system in comparison with the stoichiometric ratio of these two metals in the metatitanate. The radius of $Ti^{2+} = 0.76$ Å. The possibility of reducting Ti^{4+} to Ti^{2+} would be offered by the electrons of additional chemically bound oxygen, which evolves out of the system with rising temperature. The absence of the diffraction lines of rutile in the spectra of cobalt and titanium mixed oxides obtained from complexes, might thus be explained.

CONCLUSIONS

By the thermolysis of certain mixed complexes of the cobalt (III) ammine titanyl-oxalate type, up to 1000°, mixed oxides of cobalt and titanium were obtained, whose composition differs from that of known cobalt titanates,[10,11] namely cobalt ortho-, meta-, di- and trititanate. The latter have the following oxidic compositions : $2\,CoO.TiO_2$, $CoO.TiO_2$, $CoO.2TiO_2$ and $2CoO.3TiO_2$.

Even in the case when a mixed oxide with $2CoO.3TiO_2$ composition was obtained, the crystalline structure of the latter was not of a spinel type, of the form $Co_2(Ti_3\,\square)\,O_8$ ($\square$=gap), but of an ilmenite type, similar to that of $CoO \cdot TiO_2$. The same structure was obtained in all cases.

Nevertheless, from the thermal decomposition processes of the mixed complexes of cobalt and titanium, mixed oxides are directly obtained, at temperatures of 300°–600° and by no means physical mixtures of TiO_2 and Co_3O_4 with an appreciable quantity of physically retained oxygen and an ilmenite structure, irrespective of the ratio between these two constituent oxides. This structure which appears simultaneously with the first oxide system at 300°–600°, is consolidated up to 1000°, although the oxygen content of the mixed oxides decreases to values corresponding stoichiometrically to the TiO_2 and CoO of the given oxidic system. The loss of oxygen is monotonous since it does not significantly modify the shape of the thermal analysis curves. [1,2]

The X-ray photographs of the mixed oxides which we obtained were similar to those of the non-equilibrium solid solutions. These are essentially systems with disordered and distorted crystalline structures having many deficiencies and deviations from the stoichiometry of equilibrium systems. These facts, besides the above mentioned ones, are revealed by the X-ray photographs which, especially for the large angles of reflection, show weak and broadened diffraction lines against a dark background. [20]

The size of the particles in the mixed oxides was approximately 1000 Å, a fact certified by the width of the diffraction lines. The same fact ascertains the non-homogeneity of the structural microdeformation in the synthesized mixed oxides.

"Molecular Motions in Liquids" Proceedings of the 24-th Annual Meeting of the Société de Chimie Physique, Paris–Orsay, 2–6 July 1972, edited by Jean Lascombe. D. Reidel Publishing Company, Doddrecht, Holland/Boston – U.S.A.

In the past forty years remarkable progress has been obtained in the development of new concepts, autocorrelations and molecular dynamics as well as in the perfection of some established methods such as dielectric dispersion, infrared and Raman spectroscopy and Rayleigh scattering and the elaboration of new methods of investigation such as inelastic neutron scattering and ultrasonic sound propagation.

The purpose of the "Molecular motions in liquids" Conference in Orsay was, as Jean Lascombe said, to update the results obtained in the study of fluctuation states.

The introductory report to the meeting was Jaques Yvon's paper on phenomena ascribable to classical mechanics and quantum theory, intermolecular forces, impenetrability of molecules, free surfaces, gravity and the role of applied fields, the theory of grand ensembles, chemical potential, metastable states, negative pressures, fluctuations, neutron and light scattering in transparent liquids.

After a survey of the conference programme, the book highlights on other theoretical and experimental papers dealing with: transport phenomena, viscoelastic and ultrasonic relaxation, autocorrelation functions, isotope effects, permittivity and dipole correlations, the influence of FIR absorption on the dielectric behaviour, dielectric relaxation, molecular vibrations in liquids, Raman and infrared spectroscopic studies, hydrogen-bonded systems, nuclear magnetic resonance studies of association and reorientation in liquids, electron spin and nuclear magnetic resonance relaxation studies, self-diffusion, investigation of molecular liquids by neutron spectroscopy, computer "experiments" on simple liquids, study of the relaxation and mechanism by Brillouin spectra, molecular motions in liquids from low-frequency depolarized light scattering, molecular theory of non-linear electro-optical effects in isotropic media, Rayleigh scattering of light from supercooled liquids, Brillouin scattering in the inert-gas liquids, interpretation of far infrared spectra in terms of collision distribution, dielectric absorption of non-polar liquids in the microwave and far infrared region, etc.

The high theoretical and experimental level of the papers presented to the Proceedings of the 24-th Annual Meeting of the Société de Chimie Physique has proved that this field is still subject to active research, owing to the refinement of spectroscopic methods, high speed calculations and the development of applications of the statistical mechanics to the study of the liquid state.

The book gives physical chemists a general view of the state-of-the-art in fluctuation states and stimulates the interest for further work in this field.

CORRIGENDA

The following corrections are to be made in **Nos** 8, 9, **1974** **of this** journal :

In table 9, column 4, top, the following was omitted : b.p. 85—184°.

On page 1361, footnote 1, replace in press (1974) by **19**, 1351 (1974).

On page 1364, line 12, replace diphenyl by diphenylated products.

On page 1371, line 21, replace *3-benzolylpropionic* by *3-benzoyl-propionic*.

On page 1373, footnote *, replace in press by **19**, 1351, 1361 (1974).

The name of Fernand Gallais has appeared among the authors, by mistake.

On pages 1471, 1479 and 1481 the word "rotary" should be replaced by "rotatory"

On page 1472 : — line 3 — read C1 instead of CI ;
— in reference 18 erase, "1970" ;
— in reference 19, replace idem by Compt. rend.

On pages 1473, 1476, 1477 read Δ p instead of Δ_p

On page 1475 — line 1 and 6 ζ (zeta) should be replaced by ξ (csi).
— line 16 and the following 4 lines should be read: bond, the PF_3 derivative having the highest bond order and the PMe_3 derivative the lowest. The total bond order varies approximately from 2 to 1.

On page 1477 — line 16, replace ρ (Ni—P) : by ρ (Ni.P)
— the formula should be written as follows : $\rho(Ni.P) = \Delta\rho + 2\rho(e)_P \pm \delta G \pm \delta\pi$
— and in the first and the second lines after the formula $2\rho(e)$ should be replaced by $2\ \rho(e)_P$

On page 1478 — line 1, δ should be replaced by π
— in table 3, column 8, No. 14, replace 29 by 20 column 6, No. 16 replace 1178 by 1187
— in reference 35, read KUCHITSU instead of KUTCHISU
— in reference 36, read BASSETT instead of BASSET

On page 1479 — line 3 $\varkappa$ (kappa) should be replaced by χ (hi)
— line 16 read "or groups" instead of "of groups"
— line 37 should be read : considered is not affected by the value of the wavelength and seems to be related
— in reference 38, "1961, 252" should be replaced by **252**, 1644 (1961).

CORRIGENDA

The following corrections are to be made in Nos 8 & 9, 1974 of this journal:

In table 6, column 4, for the following was omitted: [illegible] 154°.

On page 1361, footnote 4, replace in press (1974) by 19, 1351 (1974).

On page 1363, line 13, replace diphenyl by diphenylated products.

On page 1371, line 21, replace [illegible] by [illegible].

On page 1372, footnote 7, replace in press by 19, 1351, 1361 (1974).

The name of Fernand [illegible] has appeared among the authors by mistake.

On pages 1371, 1375 and 1381 the word "rotary" should be replaced by "rotatory".

On page 1472 — line 3 — read C1 instead of C4;
— in reference 15 [illegible] "1975";
— reference 18, replace [illegible] by Compt. rend.

On pages 1423, 1470, 1477 read Δ p instead of Δ.

On page 1473. — line 1 and 2 [illegible] should be replaced by [illegible].
— line 10 and the following 4 lines should be read: bond, the PF$_3$ derivative having the highest bond order and the [illegible] derivative the lowest. The total bond orders varies approximately from 2 to 1.

On page 1477 — line 16: replace (Ni—P) by [illegible]
— the formula should be written as follows: [illegible]
— and in the first and the second lines after the formula [illegible] should be replaced by [illegible]

On page 1478 — line 1, 8 should be replaced by π
— in table 3, column 3, No. 14, replace 20 by 30; column 4, No. 14 replace 1158 by 1187
— in reference 36, read [illegible] instead of [illegible]
— in reference 37, read [illegible] instead of [illegible]

On page 1480 — line 5 [illegible] should be replaced by [illegible]
— line 16 read "of groups" instead of "of groups"
— line 27 should be read: [illegible] is not affected by the value of the wavelength, and seems to be related
— in reference 38 "1961, 855" should be replaced by "272, 1953 [illegible]".

NOTE POUR LES AUTEURS

La *Revue Roumaine de* **Chimie** publie des articles en anglais, français, russe, allemand ou espagnol. Les auteurs sont priés d'envoyer des articles, notes, communications et comptes rendus inédits.

Les manuscrits seront dactylographiés à deux intervalles. Les tableaux seront dactylographiés sur des feuilles séparées, de même que la légende des figures. Les diagrammes seront tracés à l'encre de Chine sur papier calque. Les tableaux et les figures seront numérotés par des chiffres arabes, en nombre strictement nécessaire. Prière de ne pas inscrire les mêmes données dans les tableaux et les figures. Les formules chimiques seront incluses dans le texte ; en outre, elles seront transcrites sur des feuilles séparées. Les auteurs sont priés d'indiquer les caractères italiques (en soulignant les lettres au crayon), ainsi que tout autre caractère spécial. L'ordre des références bibliographiques sera celui de leur mention dans le texte ; le nom de l'auteur sera précédé de l'initiale du prénom ; les publications périodiques seront présentées suivant les prescriptions internationales. Les références seront ajoutées à la fin de l'article ; elles paraîtront comme des notes, au bas de la page. Le texte sera précédé d'un résumé comprenant 15 lignes au maximum.

L'entière responsabilité du contenu des articles appartient aux auteurs. On publie des articles dus aux collaborateurs roumains ou étrangers.
